## Keywords:

Long COVID-19  
Cardiopulmonary exercise testing  
fatigue  
dyspnea  
autonomic abnormalities

## ABSTRACT

**Background:** Dyspnea and fatigue are characteristics of long SARS-CoV-2 (COVID)-19. Cardiopulmonary exercise testing (CPET) can be used to better evaluate such patients.

**Research question:** How significantly and by what mechanisms is exercise capacity impaired in patients with long COVID who are coming to a specialized clinic for evaluation?

**Study design and methods:** We performed a cohort study using the Mayo Clinic exercise testing database. Subjects included consecutive long COVID patients without prior history of heart or lung disease sent from the Post-COVID Care Clinic for CPET. They were compared to a historical group of non-COVID patients with undifferentiated dyspnea also without known cardiac or pulmonary disease. Statistical comparisons were performed by *t*-test or Pearson's  $\chi^2$  test controlling for age, sex, and beta blocker use where appropriate.

**Results:** We found 77 patients with long COVID and 766 control patients. Long COVID patients were younger ( $47 \pm 15$  vs  $50 \pm 10$  years,  $P < .01$ ) and more likely female (70% vs 58%,  $P < .01$ ). The most prominent difference on CPETs was lower percent predicted peak  $\text{VO}_2$  ( $73 \pm 18$  vs  $85 \pm 23\%$ ,  $p < .0001$ ). Autonomic abnormalities (resting tachycardia, CNS changes, low systolic blood pressure) were seen during CPET more commonly in long COVID patients (34 vs 23%,  $P < .04$ ), while mild pulmonary abnormalities (mild desaturation, limited breathing reserve, elevated  $\text{V}_E/\text{VCO}_2$ ) during CPET were similar (19% in both groups) with only 1 long COVID patient showing severe impairment.

**Interpretation:** We identified severe exercise limitation among long COVID patients. Young women may be at higher risk for these complications. Though mild pulmonary and autonomic impairment were common in long COVID patients, marked limitations were uncommon. We hope our observations help to untangle the physiologic abnormalities responsible for the symptomatology of long COVID.

After three years, SARS-CoV-2 (COVID-19) is still demonstrating new manifestations both in the acute phase and in the long term. The most common symptoms during the acute infection are fever, cough, shortness of breath, and myalgia, among others<sup>1</sup>. With each new variant there has been little change in these clinical features,<sup>2,3</sup> though there are apparent differences among strains regarding the symptom onset and transmissibility.<sup>3-5</sup>

Symptoms may persist more than 28 days, and new sequelae may appear after the acute infection. This phenomenon has been termed 'post-acute sequelae of SARS-CoV-2 infection' (PASC)<sup>6-8</sup> – more commonly known as "long COVID". A systematic review and meta-analysis published in 2021 reported more than 50 long COVID symptoms, among which fatigue, headache, attention disorders, hair loss, dyspnea, ageusia and anosmia were the most common.<sup>9</sup> Clinical experience from

our own Post COVID Care Clinic corroborates symptom prevalence with fatigue, dyspnea, brain fog, anxiety, unrefreshing sleep, and post exertional malaise being the most reported symptoms.<sup>10</sup>

Cardiopulmonary exercise testing (CPET) is widely used to evaluate the influence of cardiac, respiratory, musculoskeletal, and hematological systems in exercise tolerance.<sup>11–13</sup> Several studies have described the results of CPET in patients with long COVID presenting with various symptoms including dyspnea,<sup>6,14–17</sup> although pulmonary function tests (PFT)<sup>15,16,18</sup> and pulmonary<sup>14,18</sup> and cardiac imaging<sup>14</sup> have also been used. Parameters such as peak  $\text{VO}_2$  were found to be abnormal to varying degrees in patients included in these studies.<sup>6,14–17</sup> Data suggest that peripheral skeletal muscle abnormalities resulting in impaired tissue oxygen extraction is likely the cause of many of these manifestations,<sup>17</sup> rather than pulmonary or cardiac dysfunction. However, similar changes could be present in patients with dyspnea without previous SARS-CoV-2 infection or any cardiopulmonary impairment.<sup>11–13</sup>

This cohort study aims to compare CPET findings of long COVID patients with non-COVID patients with undifferentiated dyspnea on exertion seen at Mayo Clinic. Data gathered from the EMR (electronic medical record) will also serve to describe other symptoms presented as part of long COVID as well as other characteristics to contribute to the data already published by the studies cited above.

### Study design and methods

We carried out a retrospective cohort study to report the cardiorespiratory fitness of patients with long COVID using CPET and compare their results to non-COVID patients with undifferentiated dyspnea on exertion.

### Subjects

Our study group was composed of patients with long COVID presenting to Mayo Clinic's Post COVID Care Clinic between January 2021 and January 2022 for a post-COVID evaluation including CPET. All long COVID patients had PCR (polymerase chain reaction)- or antigen-confirmed SARS-CoV-2 infection during the acute illness. Patients were excluded if they had active cardiac or pulmonary disease pre-COVID. Controls were patients with undifferentiated dyspnea on exertion from a previously created database of CPETs performed between January 2011 and June 2016. Exclusion criterion for this group was a concurrent diagnosis of cardiac or pulmonary disease. After all criteria were applied, 77 long COVID patients were included in the study group and 766 patients in the control group. All study methods were approved by the Mayo Clinic IRB.

### Study procedures

All long COVID patients underwent a standard evaluation in a specialized Post Covid Care Clinic. This included history and physical exam, chest X-ray, and laboratory panel. Echocardiography and pulmonary function tests were not a standard part of the order set but added liberally as clinically appropriate. Symptom-limited exercise testing with respiratory gas exchange analysis (MGC Diagnostics metabolic cart, St. Paul, Minnesota) was performed on a treadmill (GE, Milwaukee, WI) using an accelerated Naughton protocol (2-min workloads, 2 MET increments per workload).<sup>19</sup> Most tests employed a 3-min active recovery at 1.7 MPH/% grade. Electrocardiograms were continuously monitored (GE CASE, Milwaukee, WI), and blood pressure was assessed the last 30 s of each 2-min workload using a stethoscope and aneroid with appropriately sized manually inflated cuff. Patients were encouraged to exercise to fatigue rating of perceived exertion (RPE)  $\geq 17$  on the standard Borg scale.<sup>20</sup> Standard CPET variables, including peak  $\text{VO}_2$  and  $\text{V}_E/\text{VCO}_2$  nadir, were calculated with BreezeSuite software provided MGC Diagnostics using 30 s averages updated every 10 s

(“rolling 30s”). Calibration using gravimetric quality gases was performed before each test. Peak  $\text{VO}_2$  was the highest 30-s averaged  $\text{VO}_2$  during exercise and was expressed in mL/kg/min and as percent of age, sex, and weight predicted based on FRIEND data.<sup>21</sup>  $\text{V}_E/\text{VCO}_2$  nadir was taken as the lowest 30-s average during exercise. Quality of exercise effort was assessed by peak respiratory exchange ratio ( $\text{RER} = \text{VCO}_2/\text{VO}_2$ ). Heart rate (HR) was taken from the continuously monitored ECG (GE CASE 8000, Milwaukee, WI). Rest HR was recorded after 5 min of sitting. Peak HR was based on a 10-s strip taken at peak exercise. HR recovery was defined as the difference between peak HR and HR at 1 min after peak exercise in active recovery. Oxygen saturation ( $\text{O}_2$  sat) was monitored via forehead oximetry using a Nellcor N-595 (Pleasanton, CA). Patients were asked about symptoms at each stage of the test; severity of responses were recorded on a 1 to 10 scale used throughout Mayo Clinic. Details of our CPET protocol have been previously published.<sup>22</sup>

### Study variables

Variables of concern from the CPET included peak  $\text{VO}_2$  and percent predicted peak  $\text{VO}_2$ , resting and peak HR, resting and peak systolic blood pressure (SBP), peak RER, maximum minute volume of expired ventilation ( $\text{V}_E$ ), breathing reserve (BR) – defined as  $100\% \times (1 - \text{maximal } \text{V}_E/40 \times \text{measured or estimated } \text{FEV}_1)$ ,<sup>23</sup> minimum  $\text{O}_2$  saturation, and  $\text{V}_E/\text{VCO}_2$  nadir (lowest value during exercise). Effort on the test was categorized as maximal if peak RER  $\geq 1.15$  was achieved, near-maximal if peak RER was 1.05–1.14, and sub-maximal if peak RER  $< 1.05$ .<sup>24–26</sup>

We also included patient-reported symptoms of general fatigue, dyspnea, chest pain, CNS (central nervous system) changes (which included brain fog, lightheadedness, dizziness, or pre-syncope), and neuromuscular or orthopedic limitations, and identified significant cardiac arrhythmias and ST-T changes during the test.

Other variables included in this study were sex, age, weight, body mass index (BMI), and use of beta blockers. COVID variables included acute illness management (hospitalization, use of oxygen therapy or ventilator, medications), reinfection, vaccination status, specific long COVID symptoms, and a standardized laboratory panel (Hb, ferritin, D-dimer, IL-6, CRP, ESR, ANA, CCP, RF, vitamin D, CK, TSH, AM cortisol). These data were abstracted from the EMR. PFTs and echocardiograms were performed based on clinical suspicion and were not part of the standard workup. All data were double-checked by two researchers (AM and LC). Patient confidentiality was protected by using a numerical identification number. There was no patient contact during the study.

Derived cardiac variables included the following: resting HR  $> 100$  bpm, peak SBP  $< 10$ th percentile for age and sex,<sup>27</sup> heart rate reserve (peak – resting HR), chronotropic incompetence defined as HR reserve  $< 80\%$  of the predicted value for age and sex,<sup>28,29</sup> HR recovery (peak HR – HR at 1-min post-peak exercise), and abnormal HR recovery defined as  $< 13$  bpm during active recovery of  $< 18$  bpm if there was no active recovery. If there was  $\geq 1.0$  mm ST deviation during exercise, regardless of the resting ST segments, the exercise ECG was considered abnormal. Premature ventricular contractions (PVCs) were categorized according to 4 levels: 1) no PVCs; 2) PVCs  $< 5$  per minute; 3) PVCs  $> 5$  per minute or in pairs; 4) ventricular tachycardia (VT). All VT episodes were reviewed for duration: 3–5 beats;  $> 5$  beats but  $< 30$  s;  $\geq 30$  s.

Derived pulmonary responses included: BR  $< 15\%$ , minimum  $\text{O}_2$  saturation  $< 93\%$ , and  $\text{V}_E/\text{VCO}_2$  nadir  $> 2$  standard deviations above the mean for age-sex based norms reported by Sun et al.<sup>30</sup>

### Statistical procedures

To test for differences between long COVID and controls, Pearson's Chi square was used for categorical variables and *t*-tests for continuous variables. When necessary to adjust for covariates including age, sex,

beta blocker, and effort according to peak RER where appropriate, testing was upgraded to logistic regression for categorical variables and ANOVA according to the general linear model was used for continuous variables. SAS was used for all statistical procedures.  $P < .05$  was defined as the level of statistical significance.

**Results**

We identified 77 long COVID patients and 766 controls. Table 1 summarizes information about baseline characteristics of the long COVID group. Mean age was  $47 \pm 15$  years, 55 (71%) were female, and mean BMI was  $30.1 \pm 7.3$  kg/m<sup>2</sup>. During the acute illness, 14 (18%) were hospitalized, and only 2 (2.6%) required a ventilator. Most frequently reported long COVID symptoms were fatigue (92%) and dyspnea (71%) – meaning in general daily activity, not specifically on the CPET.

Elective tests and other laboratory parameters were overall within the normal range.

Table 2 presents comparisons of the long COVID patients and controls. Long COVID patients were slightly younger and more likely female; BMI and use of beta blockers were similar. There were significant differences between the groups in percent predicted peak VO<sub>2</sub>, our principal study variable. Effort on the test as indicated by peak RER was similar in the two groups.

Figure 1 more closely examines the distribution of percent predicted peak VO<sub>2</sub>, which appears to be normally distributed in controls. In long COVID patients, however, the distribution is skewed to the left with significantly higher portions of patients in the percent predicted VO<sub>2</sub> category below 80–89%. Only 5 (6.5%) long COVID patients achieved at least 100% predicted peak VO<sub>2</sub>.

Turning to Table 3, which presents cardiac and pulmonary responses to exercise, long COVID patients achieved a slightly lower peak HR and a borderline lower HR reserve. There was more chronotropic incompetence and low peak SBP in the long COVID patients.

ST-T abnormalities were rare and not different in long COVID versus controls. The 4 long COVID patients with abnormal ST-T wave response

Values are mean ± SD or n (%).  
Abbreviations: BMI = body mass index; FAC = functional aerobic capacity; HR = heart rate; SBP = systolic blood pressure; RER = respiratory exchange ratio; CPET = cardiopulmonary exercise test.  
<sup>a</sup> Adjusted for age and sex.  
<sup>b</sup> Adjusted for beta blocker use.

to exercise all had baseline ST-T abnormalities, so exercise ECG responses were coded as non-diagnostic, as were 22 of the 33 controls with exercise ST-T abnormalities (the remaining 11 interpreted as “positive for ischemia”). PVC frequency was similar in both groups. All episodes of ventricular tachycardia (VT) in both groups were limited to 3–5 best runs.

In terms of pulmonary responses, peak V<sub>E</sub> was lower in long COVID patients versus controls – likely secondary to differences in proportion of females, but breathing reserve was similar, as was minimum O<sub>2</sub> saturation and V<sub>E</sub>/VCO<sub>2</sub> nadir. The frequencies of limited breathing reserve, low O<sub>2</sub> saturation, and high V<sub>E</sub>/VCO<sub>2</sub> nadir were not different between the long COVID patients and controls.

Figure 2 presents the symptom response to exercise. Chest pain was reported in 14% of patients of both groups. General fatigue was more commonly reported as a limiting symptom in controls, and there was a trend ( $P = .09$ ) towards more common reporting of dyspnea. Dizziness/lightheadedness/presyncope and lower extremity neuromuscular complaints were conversely significantly more common in long COVID patients. While high resting HR, chronotropic incompetence, abnormal HR recovery, and low peak SBP were listed under cardiac responses, these could also to some degree represent autonomic abnormalities, reflecting the higher level of dizziness/lightheadedness/presyncope reported in the long COVID patients.

**Discussion**

We have presented detailed CPET results on 77 patients with long COVID at a known time frame after carefully documented acute COVID infection and compared results to a large non-COVID control group of 766 patients evaluated for undifferentiated dyspnea. Our principal finding was a low percent predicted peak VO<sub>2</sub> ( $73 \pm 18\%$ ) in patients with long COVID, even in comparison to the controls complaining of dyspnea ( $85 \pm 23\%$ ). Only 5/77 (6.5%) long COVID patients achieved at least 100% predicted peak VO<sub>2</sub>. Secondary findings were mild pulmonary abnormalities, similar to controls, and mild autonomic impairment including symptoms of dizziness/lightheadedness/presyncope (22%), chronotropic incompetence (44%), or low peak SBP (21%), all more frequently seen than in controls. Cardiac responses to exercise were largely normal with only 4 patients (5.2%) having non-diagnostic exercise ECGs and 11 patients (14%) with frequent PVCs, pairs, or short runs of VT – not different than controls.

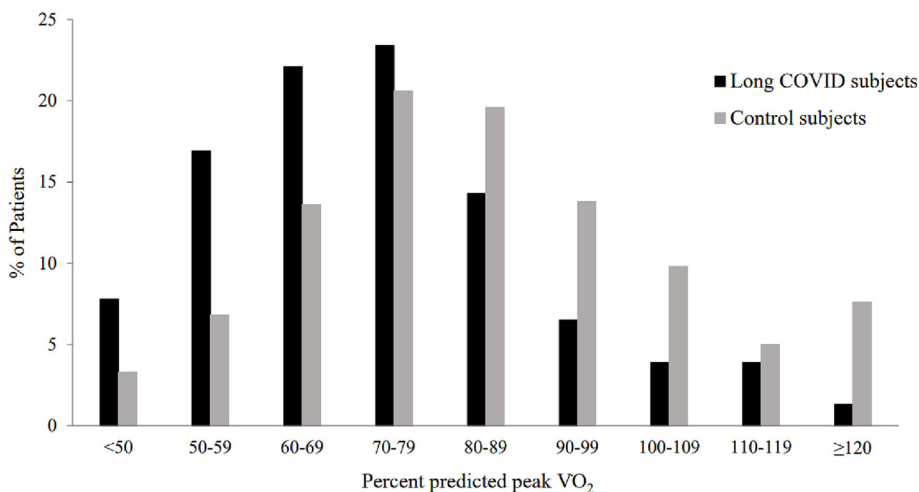

Fig. 1. Comparison of percent predicted peak VO<sub>2</sub> in long COVID patients versus Control subjects.

To date there have been multiple reports of CPET results in patients with prior COVID infection.<sup>6,14-17,31-34</sup> Peak VO<sub>2</sub> ranged from 66% predicted<sup>15</sup> to 91% predicted.<sup>16</sup> Size of the cohorts ranged from only 10 patients<sup>15,17</sup> up to 200 patients<sup>32</sup>. Our study with 77 patients and average peak VO<sub>2</sub> of 73% predicted falls squarely within this range. Peak VO<sub>2</sub> tended to be lower in studies of patients with long COVID syndrome<sup>6,14,15,17,31,34</sup> versus those testing a cohort of post COVID patients at a fixed time point after acute presentation irrespective of persistent symptoms<sup>16,30-32</sup>. Durstenfeld et al. performed a systematic review and meta-analysis of the use of CPET after COVID-19 infection<sup>35</sup>. Their meta-analysis of 9 studies comparing patients either with (464 subjects) or without symptoms (359 subjects) found that the symptomatic subjects' peak VO<sub>2</sub> was 4.9 ml/kg/min lower than asymptomatic subjects.

Table 3 Comparison abnormal exercise test responses in long COVID and dyspnea control subjects.

Abbreviations: HR = heart rate; SBP = systolic blood pressure.

Chronotropic incompetence = HR reserve <80% predicted for age and sex; Abnormal HR recovery = HR Recovery <13 bpm if active recovery or < 18 bpm if no active recovery; Low peak SBP = peak SBP < 10th percentile for age and sex; Submaximal effort = peak respiratory exchange ratio < 1.0; Low O<sub>2</sub> saturation = minimum O<sub>2</sub> saturation < 93%; V<sub>E</sub>/VCO<sub>2</sub> nadir = lowest ratio of V<sub>E</sub> to VCO<sub>2</sub> during exercise; High V<sub>E</sub>/VCO<sub>2</sub> = V<sub>E</sub>/VCO<sub>2</sub> nadir >2 standard deviations from mean for age and sex.

<sup>a</sup> Adjusted for age and sex.

<sup>b</sup> Adjusted for beta blocker use.

<sup>c</sup> Adjusted for effort based on RER.

Singh et al. performed invasive CPET (right heart catheterization with upright cycle ergometer exercise) in 10 recovered COVID-19 subjects without cardiopulmonary disease and compared their responses to matched controls<sup>17</sup>. Percent predicted peak VO<sub>2</sub> averaged 70% for COVID-19 subjects versus 131% for controls. For COVID-19 subjects, cardiac output during exercise was normal, however, tissue oxygen extraction was lower than for controls, indicating a peripheral, rather than central cardiac impairment.

A cardiac etiology for the reduced peak VO<sub>2</sub> in our long COVID group was highly unlikely given the lack of any significant left ventricular dysfunction, ischemia, or arrhythmias based on close review of the resting and exercise ECGs, and available echocardiograms. Echocardiography was ordered liberally (58/77 = 75% of patients) on account of even minor abnormalities on the rest ECG, or clinical suspicion. Left ventricular ejection fraction (LVEF) ranged from 50 to 69% (mean 61 ± 4%). Minor valve abnormalities were listed as follows: mild-moderate tricuspid regurgitation 5/58 = 8.6%; mild-moderate mitral regurgitation 2/58 = 3.4%; moderate pulmonary regurgitation 1/58 = 1.7%; and mild aortic regurgitation 1/58 = 1.7%. On the rest ECG, the only abnormalities seen were T-wave inversion (4/77 = 5.2%), all with normal LVEF, and 1/77 = 1.3% with possible left ventricular hypertrophy (but normal echocardiogram). Almost all exercise ECGs were read as negative for ischemia (73/77 = 95%). Exercise ECG was called non-diagnostic in the 4 patients with baseline ST-T abnormalities. Minor arrhythmias were present on 35 exercise tests (45%), mostly single premature atrial or ventricular complexes.

While there have been many case reports or case series documenting myocarditis during the acute phase of COVID-19<sup>36</sup> persistent myocarditis with reduced LVEF has not been widely reported. Major markers of cardiac function such as LVEF (and most minor markers) were not different in long COVID patients 1-year after hospitalization versus controls.<sup>37</sup> A second study looking at similar echocardiographic and Holter monitor variables only 3 months after hospitalization for long COVID reported mild right ventricular systolic and diastolic dysfunction and cardiac arrhythmias versus matched pre-pandemic controls, but none of these minor findings correlated with patient complaints of fatigue or dyspnea or the course of inpatient hospital care.<sup>38</sup>

Our long COVID patients exhibited a relatively low frequency of minor pulmonary abnormalities identical to the controls. The mild nature of the pulmonary findings was somewhat surprising, given the predilection of COVID for pulmonary tissues. Only one long COVID patient demonstrated severe pulmonary impairment with an O<sub>2</sub> saturation of 83% and V<sub>E</sub>/VCO<sub>2</sub> nadir of 50 during exercise. Other studies have described similarly mild pulmonary abnormalities in CPET in long COVID.<sup>31-33</sup> On the other hand, Grist et al. performed hyperpolarized

Fig. 2. Symptoms during CPET in long COVID patients versus Control subjects.

xenon magnetic resonance imaging on 9 patients with long COVID and found alveolar capillary diffusion limitations in all of them; patients did not undergo CPET, so no exercise data were presented.<sup>39</sup>

Other papers have addressed autonomic abnormalities and symptoms in long COVID. A review of 27 patients with history of confirmed COVID infection referred for autonomic testing at Mayo Clinic (Rochester and Jacksonville) found complaints of lightheadedness (93%), orthostatic headache (22%), syncope (11%), hyperhidrosis (11%), and “burning” (likely neurologic) pain (11%).<sup>40</sup> We found all these symptoms – except actual syncope – reported in our long COVID patients. There have also been other reports of long COVID patients experiencing symptoms suggestive of postural orthostatic tachycardic syndrome, orthostatic cerebral hypoperfusion syndrome, and orthostatic hypotension.<sup>41–42</sup> Central nervous system changes, low peak SBP, and chronotropic incompetence were more common in our long COVID patients than controls. It is not clear – though unlikely – that autonomic impairment after COVID is in any substantive way different than after other viral infections.<sup>43</sup>

A publication by Aranyo et al.<sup>44</sup> provides a more in-depth view of inappropriate sinus tachycardia (IST) in long COVID patients presenting to a specialized clinic. Among 200 study patients, 20% reported IST; one of the main underlying factors was autonomic instability. Also, resting and exercise ECG reports were reviewed looking for any significant arrhythmias, symptomatic drop in BP, angina with ST changes, or left bundle branch block. Only premature ventricular contractions (<5/min) and some T-wave inversions were found. Patients performed a 6 min walk test, but not a CPET.

In our long COVID group, resting sinus tachycardia had lower prevalence (4/77 = 5.2%), though it should be noted that 12/77 patients (16%) were taking beta blockers, thus potentially masking a higher rate of sinus tachycardia. Patients with autonomic abnormalities showed lower predicted peak  $\text{VO}_2$ , both in long COVID ( $68 \pm 16$  vs.  $82 \pm 19\%$  predicted peak  $\text{VO}_2$ ,  $P = .028$ ) and in controls ( $76 \pm 19$  vs.  $94 \pm 22\%$  predicted peak  $\text{VO}_2$ ,  $P < .0001$ ).

Another possible reason for low peak  $\text{VO}_2$  is neuromuscular dysfunction. We found that roughly 1 in 7 (14%) of the long COVID patients reported neuromuscular symptoms specific to the lower extremities during their CPET on the treadmill – compared to only 2.9% of controls. A general reduction in physical activity, compounded by hospitalization, bed rest, and use of corticosteroids, likely explains these findings, though a review of the topic of neuromuscular complications of COVID by Suh and Amato<sup>45</sup> leaves open the possibility that neuromuscular dysfunction may contribute to long COVID.

### Strengths and limitations

Our study included patients with well-documented long COVID, referred clinically for careful assessment of exercise limitations by CPET in a laboratory with high volume and complexity of patients, extensive experience, and expertise. Cardiorespiratory fitness was directly measured as peak  $\text{VO}_2$ .<sup>46</sup> A relevant historical comparison group was available. In terms of limitations, we are not covering the entire spectrum of long COVID. Patients with mild symptoms, limited financial resources, or too sick to comfortably travel were less likely to come to Mayo Clinic for evaluation. Patients with pre-COVID cardiac, pulmonary, or neurologic diseases presenting to other specialty clinics within Mayo were not included in this cohort, though many of them referred for CPET. Our focus was on cardiopulmonary responses to exercise. The findings of relatively frequent autonomic impairment and neuromuscular complaints would be interesting to pursue in a separate, prospectively planned protocol.

### Conclusions

Patients reporting symptoms consistent with long COVID have significantly impaired exercise tolerance with low peak  $\text{VO}_2$  and a variety of symptoms on the exercise test. Their limitations are greater than patients complaining of undifferentiated dyspnea on exertion, but we saw limited evidence of significant underlying cardiac or pulmonary impairment. Autonomic abnormalities were common, however – more frequent than in the controls, and exercise performance and peak  $\text{VO}_2$  were lower in the subset of patients with abnormal autonomic responses. Neuromuscular complaints were reported in 14% of long COVID patients – again, more common than in the controls. We hope that these observations contribute to the understanding of exercise impairment in long COVID, though much is still to be learned.
