ABSTRACT: Inorganic−organic metal halide perovskite solar cells (PSCs) show power conversion efficiency values approaching those of state-of-the-art silicon solar cells. In a quest to find suitable charge transport materials in PSCs, hematite (α-Fe$_2$O$_3$) has emerged as a potential electron transport layer (ETL) in n−i−p planar PSCs due to its low cost, UV light stability, and nontoxicity. Yet, the performance of α-Fe$_2$O$_3$-based PSCs is far lower than that of state-of-the-art PSCs owing to the poor quality of the α-Fe$_2$O$_3$ ETL. In this work, solvent-assisted crystallization of α-Fe$_2$O$_3$ ETLs was carried out to examine the impact of solvents on the optoelectronic properties of α-Fe$_2$O$_3$ thin films. Among the various solvents used in this study (deionized water, ethanol, iso-propanol, and iso-butanol), optimized ethanol-based α-Fe$_2$O$_3$ ETLs lead to champion device performance with a power conversion efficiency of 13% with a reduced hysteresis index of 0.04 in an n−i−p-configured PSC. The PSC also exhibited superior long-term inert and ambient stabilities compared to a reference device made using a SnO$_2$ ETL. Through a series of experiments spanning structural, morphological, and optoelectronic properties of the various α-Fe$_2$O$_3$ thin films and their devices, we provide insights into the reasons for the improved photovoltaic performance. It is noted that the formation of a pinhole-free compact morphology of ETLs facilitates crack-free surface coverage of the perovskite film atop an α-Fe$_2$O$_3$ ETL, reduces interfacial recombination, and enhances charge transfer efficiency. This work opens up the route toward novel ETLs for the development of efficient and photo-stable PSCs.
1. INTRODUCTION

Hybrid inorganic−organic metal halide perovskite solar cells (PSCs) have emerged as a promising thin film photovoltaic (PV) technology due to their low cost of fabrication, high power conversion efficiencies (PCEs), and low-temperature processing.[1,2] The unprecedented increase in device efficiencies from 3.8% in 2009 to a certified value of 25.7% in 2022 has instigated a revolution in PV technology.[3,4] Such a high performance stems from the unique optoelectronic properties of perovskites such as a high absorption coefficient, long carrier lifetime, high mobility, and tunable band gap[5−7] together with an extensive optimization of charge transport layers (CTLs), namely, the electron transport layer (ETL) and hole transport layer (HTL),[8,9] and their interfaces with the perovskite layer. Controlling the properties of these CTLs is crucial as they control the physico-chemical properties of their interfaces with the perovskite and also control the extraction/transport of photogenerated charges to their respective electrodes.[10] To achieve high device performance, the CTLs must exhibit low charge transfer resistance, minimal optical absorption, appropriate energy band level alignment with the absorber layer, and high mobility for efficient charge transport.[11−14]

In the state-of-the-art n−i−p PSCs, metal oxide (MO$_X$) semiconductor TiO$_2$-, ZnO-, SnO$_2$-, Nb$_2$O$_5$-, CeO$_x$-, Cr$_2$O$_3$-, Fe$_2$O$_3$-, and WO$_3$-based ETLs remain a preferred choice.[15−22] TiO$_2$ and SnO$_2$ are the most frequently applied ETLs, and solar cells based on these have demonstrated PCEs approaching 25%.[23−25] The TiO$_2$ ETL is known for its defect-rich surface and also leads to degradation in PSCs upon exposure to UV illumination hampering the device operational stability.[26,27] The TiO$_2$ ETL also requires a high annealing temperature exceeding 500 °C, which hinders its application in mass production. SnO$_2$ ETLs can be processed at low temperatures and offer a high mobility, wide band gap, and superior stability than the TiO$_2$ counterpart. Benefiting from these properties, SnO$_2$ ETLs have also demonstrated PCE

exceeding 25% performance in PSCs. Tin, however, suffers from limited supply issues which are reaching a critical level, and therefore, alternative non-toxic and abundant materials for ETLs should be explored.[28] Likewise, ZnO is another n-type semiconductor metal oxide with high mobility, high transparency, and a wide band gap.[29] Yet, the ZnO/perovskite interface induces chemical instability of the perovskite film owing to the presence of hydroxyl (−OH) groups.[30]

Recently, hematite (α-Fe_2O_3), a thermodynamically stable oxide of iron with n-type semiconducting properties, has attained global interest due to its low UV photocatalytic activity favorable in enhancing the UV stability of PSCs.[31] α-Fe_2O_3 is a low-cost, abundant, and non-toxic material with an optical band gap of 2−2.3 eV.[32−34] Due to its lower-lying conduction band minimum (CBM) than that of TiO_2, α-Fe_2O_3 can expedite the electron extraction from the perovskite layer.[35] However, a low mobility and poor conductivity of α-Fe_2O_3 in its pristine form limit its performance as the ETL in PSCs. Hu et al. employed α-Fe_2O_3 as the ETL in $MAPbI_3$ PSCs and exhibited a PCE of 11% with improved stability as compared to a TiO_2 ETL-based PSC. They reported a higher built-in potential across the perovskite layer in the α-Fe_2O_3 PSCs, which leads to enhanced charge extraction and lower charge accumulation at the interface.[36,37] Similarly, Hou et al. employed a hematite−fullerene bilayer in a planar PSC and exhibited an enhanced PCE of 14%.[38] Zhu et al. designed a non-equilibrium doping strategy to prepare Ti−Fe_2O_3 ETLs and exhibited a PCE of 17.8% with superior charge transport owing to high electron mobility and low trap density.[39] Guo et al. applied interface engineering for bifunctional modification of the α-Fe_2O_3/perovskite interface by using PbI_2 resulting in significant improvement in energy level alignment and suppressed $J−V$ hysteresis.[20] Yet, all these reports lack a detailed understanding of the morphology, crystallization, and optoelectronic properties of the pristine α-Fe_2O_3 ETL with their potential in PSCs and demand further investigation.

In this work, we report a systematic investigation of the solvent-assisted crystallization of hematite thin films using deionized water (DIW), ethanol, iso-propanol, and iso-butanol. The choice of the solvent used for crystallization impacts the film morphology, film thickness, and film quality.[40] The triple-cation PSCs were fabricated in an n−i−p architecture to gain thorough insights into the impact of solvents on the PV performance of the α-Fe_2O_3 ETL-based devices. The PSCs with the optimized solvent and appropriate concentration demonstrated a PCE of 13.01%, which is till date the highest ever reported PCE obtained using a pristine α-Fe_2O_3 ETL. The optimal device also exhibited excellent long-term stability in the inert and ambient atmospheres as compared to a reference device based on a SnO_2 ETL. The proposed strategy for optimizing the ETLs can be an important step forward for the other emerging ETLs for efficient and stable PSCs.

2. EXPERIMENTAL SECTION

2.1. Materials. Formamidinium iodide (FAI, 99.99%), methylammonium bromide (MABr, 99.99%) (Greatcell), lead(II)iodide (PbI_2, 99.99%) (TCI), tin(IV)oxide (SnO_2, 15% H_2O colloidal dispersion) (Alfa Aesar), cesium iodide (CsI, 99.9%), bis(trifluoromethane sulfonyl)imide (Li-TFSI, 99.99%), iron(III)nitrate nonahydrate [$Fe(NO_3)_3$·$9H_2O$, 99.9%], lead bromide ($PbBr_2$, 99.9%) (Sigma-Aldrich), indium tin oxide (ITO) substrates (ITO, 15 Ω/sq), and spiro-OMeTAD (>99%) (Lumtec) were used as procured.

Dimethylformamide (DMF, 99.8%), 4-*tert*-butyl pyridine (tBP), chlorobenzene (CB, 99.8%), ethanol, isopropanol, dimethyl sulfoxide (DMSO, 99.9%), isobutanol, and acetonitrile (ACN, 99.9%) were purchased from Aldrich.

2.2. Preparation of ETL Dispersions. The ETL dispersions were prepared by dissolving $Fe(NO_3)_3$·$9H_2O$ in DIW, ethanol, isopropanol, and isobutanol in different mole ratios followed by stirring for 10 min as shown in Figure S1. The solutions were used to make ETLs under ambient conditions without filtering.

2.3. Preparation of Triple-Cation Perovskite and Spiro-OMeTAD Precursors. The triple-cation perovskite precursor was synthesized by dissolving 1.1 M PbI_2 and 0.2 M $PbBr_2$ in a mixed solvent of DMF/DMSO (4:1) followed by heating at 90 °C for 45 min. 1 M FAI and 0.2 M MABr were added to the above-mentioned solution. Finally, 53 μL of CsI (1.5 M CsI in DMSO) was mixed in the combined solution to attain the composition $Cs_{0.05}(FA_{0.83}MA_{0.17})_{0.95}Pb(I_{0.83}Br_{0.17})_3$ of the triple-cation perovskite and/or for convenience as CsFAMA.[41] To prepare spiro-OMeTAD (spiro) precursor solution, 73 mg of spiro was dissolved in CB (1 mL) followed by the addition of 17.5 μL of Li-TFSI (52 mg in 100 μL of ACN) and 28.8 μL of tBP as dopants to enhance conductivity.[42]

2.4. Device Fabrication. ITO-coated glass substrates were etched using zinc powder and HCl (2 M). The etched substrates were cleaned sequentially with soap, distilled water, acetone, and isopropyl alcohol for 20 min. The substrates were then dried using N_2. The dried substrates were plasma-treated using O_2 for 7 min followed by UV−ozone treatment for 20 min. The ETLs were prepared by spin-coating the $Fe(NO_3)_3$·$9H_2O$ dispersions (75 μL) in different solvents (DIW, ethanol, iso-propanol, and iso-butanol) and with molar concentrations (0.1, 0.2, 0.5, and 1 M) at 4000 rpm (1000 rpm s^{-1}) for 45 s followed by thermal annealing at 300 °C for 60 min with a ramp rate of 10°/min. The ETL-deposited substrates were transferred to a N_2-filled glovebox to deposit the perovskite and HTL. The perovskite precursor (45 μL) was spin-coated on the ITO/α-Fe_2O_3 substrate at 1000 rpm (1000 rpm s^{-1}) for 10 s and then 6000 rpm (4000 rpm s^{-1}) for 25 s followed by antisolvent CB (250 μL) dripping for 10 s before the end of the second step, followed by annealing at 120 °C for 10 min. The HTLs were prepared by spin-coating 30 μL of the spiro precursor onto the perovskite layer at 4000 rpm (1000 rpm s^{-1}) for 40 s. The HTL-deposited films were stored in a desiccator for 12 h before electrode evaporation. Finally, WO_3 (3 nm) and Ag (100 nm) were thermally evaporated under a vacuum of 8 × 10^{-6} mbar. The active area of the PSCs was defined by a shadow mask to be 0.133 cm^2.

2.5. Characterization. X-ray diffraction (XRD) patterns were recorded to examine the crystalline structure of prepared samples using an X-ray diffractometer (Bruker D8 AD-VANCE). The morphology of the thin films was investigated by field-emission scanning electron microscopy (FE-SEM, Zeiss Gemini). The topography of the perovskite thin films was further analyzed by atomic force microscopy (Park NX 10). The optical characteristics were investigated by measuring transmission and absorption spectra via a UV−vis−NIR spectrophotometer (Cary 5000). The steady-state photo-luminescence (PL) and time-resolved PL (TRPL) measurements were performed to study the charge transport mechanism using a fluorescence spectrometer (PicoQuant FluoTime 300) equipped with a 404 nm laser source. The
Figure 1. (a) XRD spectra of α-Fe$_2$O$_3$ thin films with different solvents used for crystallization and (b) transmission spectra of the same.

Figure 2. Top and cross-sectional views of CsFAMA perovskite thin films deposited atop ITO/α-Fe$_2$O$_3$ ETLs: (a,b) W-α-Fe$_2$O$_3$, (c,d) E-α-Fe$_2$O$_3$, (e,f) iP-α-Fe$_2$O$_3$, and (g,h) iB-α-Fe$_2$O$_3$. (i) XRD spectrum of CsFAMA perovskite thin films deposited on top of the different α-Fe$_2$O$_3$ ETLs.

PSCs were measured inside the glovebox for photocurrent–voltage (J–V) measurements using a Keithley 2410 source meter equipped with a solar simulator under a simulated AM 1.5 G spectrum (100 mW cm^{-2}). The external quantum efficiency measurements (EQE) were performed by using a xenon light source equipped with a grating monochromator (LOT-Oriel Omni 300). The carrier mobility and trap densities were measured using space charge limited current (SCLC) measurements.

3. RESULTS AND DISCUSSION

Formation of a high-quality ETL strongly depends on the solvent used for the hydrolysis and the annealing process, among other important parameters.[40] For our work, we have selected four types of solvents, i.e., DIW (evaporation point 100 °C), ethanol (78 °C), iso-propanol (82 °C), and iso-butanol (108 °C), for the crystallization of α-Fe$_2$O$_3$ ETLs. These various α-Fe$_2$O$_3$ ETLs are labeled as W-α-Fe$_2$O$_3$, E-α-

Fe$_2$O$_3$, iP-α-Fe$_2$O$_3$, and iB-α-Fe$_2$O$_3$, respectively. The α-Fe$_2$O$_3$ ETLs were prepared by spin-coating an iron nitrate non-ahydrate [Fe(NO$_3$)$_3$·9H$_2$O] precursor dispersed in different solvents (Figure S1) at 4000 rpm for 45 s followed by thermal annealing at 300 °C for 60 min in air.

Figure 1a shows the XRD patterns of the different α-Fe$_2$O$_3$ ETLs deposited on ITO. The diffraction peaks at 33.1, 35.8, 41, and 49.1° can be assigned to (104), (110), (113), and (024) crystallographic planes of rhombohedral hematite, respectively (JCPDS: 01-1053).[43] The XRD diffractograms suggest identical crystallinities for the ETLs prepared from different solvents. Transmittance spectra of the various α-Fe$_2$O$_3$ ETLs (Figure 1b. See absorbance data in Figure S2) deposited over the ITO surface show variation in the transmittance for different solvents used, which is the result of different film morphologies and different thicknesses. The lowest transmittance for the iP-α-Fe$_2$O$_3$ ETL in the entire wavelength range is due to a higher film thickness of the ETL,
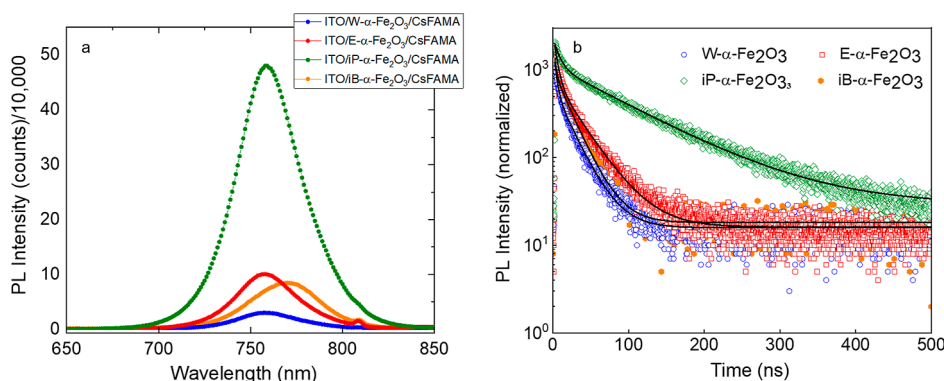

Figure 3. (a) Steady-state PL spectra of CsFAMA films on the ITO/α-Fe$_2$O$_3$ ETL with different solvents and (b) TRPL transients of the same. The PL is recorded using a pulsed laser with an excitation wavelength of 404 nm and a repetition rate of 2 MHz.

which can have detrimental impact on the light management in the final device stack.[44] The onset of the transmittance, suggest that the different solvents used for crystallization can also lead to different stoichiometry or defect density leading to a different optical band gap of the α-Fe$_2$O$_3$ films.

The surface morphology of different α-Fe$_2$O$_3$ ETLs deposited on glass/ITO substrates was analyzed by SEM and was compared with the morphology of a bare ITO (Figure S3). The various α-Fe$_2$O$_3$ ETLs adapt the ITO surface morphology owing to the formation of an ultra-thin layer. Clearly, the choice of the solvent plays an important role in determining the morphology of the ETL. While all the ETLs show a good coverage over the ITO substrate, the E-α-Fe$_2$O$_3$ and iP-α-Fe$_2$O$_3$ ETLs show the least ITO patches. This difference in the morphology can originate from different film thicknesses due to the different solvents used. A higher film thickness for E-α-Fe$_2$O$_3$ and iP-α-Fe$_2$O$_3$ ETLs is evident from the transmission spectra, which also improves the surface coverage of these ETLs. Figure 2 exhibits the top and cross-sectional views of the triple-cation perovskite (CsFAMA) deposited on the various α-Fe$_2$O$_3$ ETLs. All ETLs demonstrate a crack-free, uniform, and densely packed morphology. The cross-sectional SEM images of perovskite films suggest fused perovskite grain boundaries, which are favorable for efficient charge transport and low non-radiative recombination.[45] The crystallinity of the CsFAMA perovskite deposited onto the W-α-Fe$_2$O$_3$, E-α-Fe$_2$O$_3$, iP--α-Fe$_2$O$_3$, and iB-α-Fe$_2$O$_3$ ETLs and bare ITO is depicted in Figure 2i. All perovskite films show preferential crystal orientation for the (001) and (002) planes. No peak associated with the hexagonal δ-phase was observed for the perovskite films onto α-Fe$_2$O$_3$ ETLs confirming the formation of a desirable tetragonal photoactive α-phase (black).[46] Notably, a diffraction peak at 2θ position of 12.6° was observed for W-α-Fe$_2$O$_3$ and iB-α-Fe$_2$O$_3$ ETLs, which suggests a PbI$_2$ residue probably due to incomplete conversion of the perovskite phase or due to degradation of the perovskite film over these ETLs.

In order to probe the charge extraction rates from the perovskite layer to the various ETLs, we recorded steady-state PL and TRPL spectra of CsFAMA perovskite layers deposited atop W-α-Fe$_2$O$_3$, E-α-Fe$_2$O$_3$, iP-α-Fe$_2$O$_3$, and iB-α-Fe$_2$O$_3$ ETLs (Figure 3). Initially, the CsFAMA deposited on the bare ITO glass substrate exhibited an emission peak centered at 761 nm with a τ_{ave} of 238 ns (Figure S4 and Table S1). The CsFAMA deposited on the W-α-Fe$_2$O$_3$, E-α-Fe$_2$O$_3$, and iP-α-Fe$_2$O$_3$ ETLs shows suppressed PL emission intensity, which is

attributed to quenching of charge carriers. A comparison of the PL spectra suggests nearly 5 times higher PL intensity for the iP-α-Fe$_2$O$_3$ ETL <u>than that for other</u> ETLs, which is indicative of inefficient charge transfer. The quenched PL intensity for W-α-Fe$_2$O$_3$, E-α-Fe$_2$O$_3$, and iB-α-Fe$_2$O$_3$ ETL samples indicates a more efficient charge carrier extraction and transport from the perovskite layer to the aforementioned ETLs. One should, however, note that the PL spectra contain information about two processes, i.e., charge extraction and interfacial recombination, and lower (or higher) PL spectra can have a contribution from both factors. From a PL spectrum on a quenching surface alone, such as the one used in this study, a distinction between the two processes cannot be made. Comparing the PL spectra with TRPL transients, to some extent, provides a more accurate overview of the interfacial processes.

To further examine the charge transport kinetics, the TRPL decay transients were fitted using a bi-exponential function consisting of τ_1 and τ_2 (related to fast and slow decay components, respectively) and A (decay amplitude)

$$f(t) = A_1 \exp\left(\frac{-t}{\tau_1}\right) + A_2 \exp\left(\frac{-t}{\tau_2}\right) \tag{1}$$

and average lifetime was calculated according to eq 2 and results are summarized in Table S2.

$$\tau_{ave} = \frac{\sum A_i \tau_i^2}{\sum A_i \tau_i} \tag{2}$$

The fast decay component is attributed to charge carrier extraction by the ETL and non-radiative recombination (within the bulk or at the perovskite surface/interface), while the slow decay component is related to radiative recombination of the charge carriers in the bulk of the perovskite films.[41] Fitting the TRPL transients yielded a τ_1 of 3.40, 4.82, 7.58, and 2.22 ns for W-α-Fe$_2$O$_3$, E-α-Fe$_2$O$_3$, iP-α-Fe$_2$O$_3$, and iB-α-Fe$_2$O$_3$ ETLs with an amplitude of 69.2, 70.7, 52.9, and 62.72%, respectively. The higher amplitudes and slow τ_1 for DIW and ethanol solvent-based ETLs suggest faster electron extraction, which may be due to a lower trap density in the perovskite films deposited atop these ETLs. Notably, the iB-α-Fe$_2$O$_3$ ETL sample showed the smallest τ_1, suggesting the least efficient charge extraction from the perovskite among all the four ETLs. This is affirmed from the red-shifted PL emission peak that also suggests a higher defect density in the iB-α-Fe$_2$O$_3$/perovskite and also the lowest PCE in devices, as will be
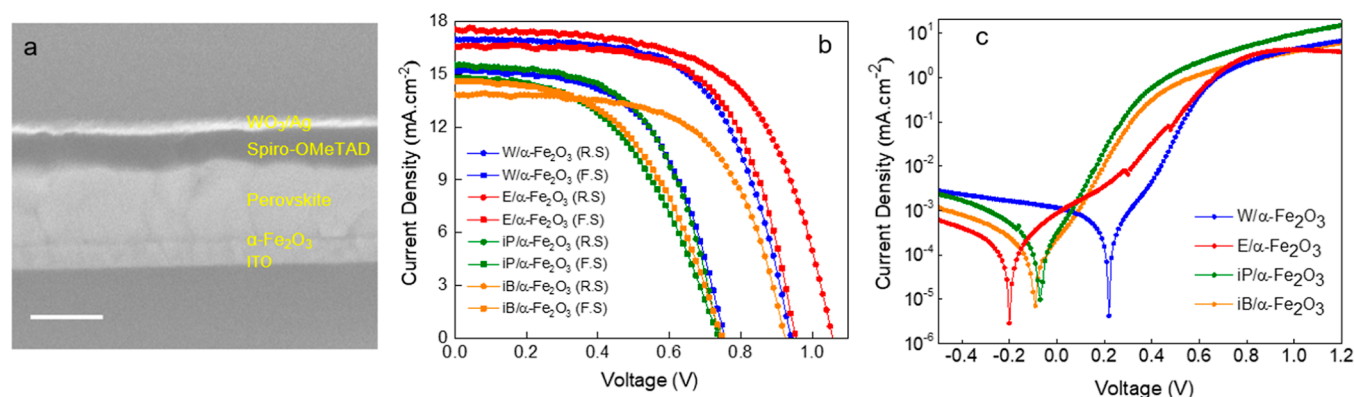

Figure 4. (a) Cross-sectional view of a complete PSC. Scale bar 400 nm. (b) $J-V$ curves of the PSCs using four different α-Fe$_2$O$_3$ ETLs in forward and reverse scan directions. (c) Dark $J-V$ curves of the same.

discussed later on. It is important to note that a reduced lifetime on a quenching film could originate from either a better charge transfer efficiency or a higher defect density at the interface. TRPL transients alone cannot decouple the two possible mechanisms, and one has to also compare the device performances to suggest a more plausible scenario. The average lifetime for the W-α-Fe$_2$O$_3$, E-α-Fe$_2$O$_3$, and iB-α-Fe$_2$O$_3$ ETLs is lower than that for the iP-α-Fe$_2$O$_3$ ETL. A comparison of the PL lifetimes of the various ETLs with their PL intensities suggests that the iP-α-Fe$_2$O$_3$ ETL leads to the least efficient charge extraction than the other three ETLs.

In order to validate the charge transfer behavior of these various ETLs, we fabricated PSCs in regular planar (n−i−p) configuration with the structure (ITO/α-Fe$_2$O$_3$/CsFAMA/spiro-OMeTAD/WO$_3$/Ag) as shown in Figure 4a. The cross-sectional view shows a crack-free dense perovskite film of thickness around 400 nm deposited atop the α-Fe$_2$O$_3$ ETL.

The PV performance of PSCs was measured under 1 sun illumination AM 1.5G irradiation at a scan rate of 0.01 V s^{-1}. The corresponding PV parameters, i.e., the open-circuit voltage (V_{OC}), short current density (J_{SC}), and fill factor (FF), together with the PCE in the forward scan (J_{SC} to V_{OC}) and reverse scan (V_{OC} to J_{SC}) are summarized in Figure 4b and Table 1. The

exhibited the highest PCE of 10.07% (J_{SC} of 15.67 mA cm^{-2}, V_{OC} of 1.06 V, and FF of 60.8%) and also showed the lowest HI of 0.10 (Table 1). The superior performance in the E-α-Fe$_2$O$_3$-based PSC stems mostly from an improved V_{OC} (130 mV higher than that of the W-α-Fe$_2$O$_3$, which showed the second highest PCE) and FF, both suggesting reduced interfacial recombination for this type of ETL. This is also confirmed from the reduced hysteresis—a phenomenon that strongly depends on the recombination and interfacial charge accumulation of the E-α-Fe$_2$O$_3$-based PSCs (HI of 0.1) than all other ETLs.[44,48]

All these observations suggest that the E-α-Fe$_2$O$_3$ ETL forms a favorable interface with the perovskite layer. The results are also consistent with PL and TRPL measurements that show a superior charge extraction using the E-α-Fe$_2$O$_3$ ETL. A higher HI in the other ETLs is indicative of higher interfacial recombination, thus rendering them not favorable for high-efficiency PSCs. The control device with the SnO$_2$ ETL exhibited a PCE of 16.6%. Although the PCE of the α-Fe$_2$O$_3$ ETL is lower than that of the SnO$_2$ counterpart, the fact that the low-cost hematite shows a comparable performance in PSC shows potential as alternative ETL. We also investigated the PV performance of the PSC based on α-Fe$_2$O$_3$ ETLs using different solvents (DIW, iso-propanol, and iso-butanol) in varying concentrations. The corresponding $J-V$ curves are shown in Figure S6, and the parameters are listed in Table S3. A comparison of this data together with Tables 1 and 2 suggests ethanol to be a preferred solvent for the crystallization of hematite thin films, which results in the highest PV performance parameters. The E-α-Fe$_2$O$_3$ ETL-based films manifested a high-quality and pin-hole-free compact ETL. This is probably due to the better solubility of the α-Fe$_2$O$_3$

Table 1. Photovoltaic Parameters of PSCs Using α-Fe$_2$O$_3$ Made from Different Solvents

precursor in ethanol, which originates from the presence of the hydroxyl group and a polar C−O bond making its interaction with other materials easier.

The dark JV curves of these devices provide further insights into the origin of varying PV performance due to the different ETLs (Figure 4c). The E-α-Fe$_2$O$_3$ ETL shows the lowest reverse current among all the ETLs which indicates its efficient hole blocking behavior. This possibly originates from the improved morphology of the E-α-Fe$_2$O$_3$ ETL. The iP-α-Fe$_2$O$_3$ and iB-α-Fe$_2$O$_3$ ETL-based devices demonstrated a higher reverse current density suggesting that higher leakage currents in these devices limit the PV performance.

We chose the E-α-Fe$_2$O$_3$ ETL for further investigation and optimization. We first optimized the molar concentrations of E-α-Fe$_2$O$_3$ in a wide range of 0.1, 0.2, 0.5, and 1 M to vary the film thickness. The transmission spectra for the various E-α-Fe$_2$O$_3$ ETLs deposited on ITO show a decrease in the transmittance with increasing molar concentrations suggesting the formation of a thicker ETL (Figure S7). The absorption spectra exhibited identical absorption in wavelengths ranging from 550 to 800 nm (Figure S8). The top and cross-sectional SEM images of ITO/E-α-Fe$_2$O$_3$ ETLs with concentrations (of 0.2, 0.5, and 1 M) confirm a uniform and continuous surface coverage with no visible pinholes (Figure S9). The thickness of E-α-Fe$_2$O$_3$ ETLs with concentrations of 0.2, 0.5, and 1 M is found to be 42, 68, and 127 nm, respectively. One should note the trade-off between the film morphology and transmittance as the film thickness varies. While a thinner layer improves the transmittance of the ultrathin ETLs, it often yields films with pinholes due to incomplete surface coverage. A thick ETL although facilitates the formation of a pinhole-free film but at the cost of reduced transmittance, which limits the light absorption efficiency of the perovskite layer and the attainable

J_{SC} thereby. Ideally, a thin compact ETL with negligible transmittance is preferred.

We investigated the PV performance of these various ETLs in PSCs (Figure 5a), and the corresponding PV parameters are summarized in Table 2. The 0.2 M E-α-Fe$_2$O$_3$ ETL-based device exhibited the highest PCE of 13% (J_{SC} of 19.2 mA cm^{-2}, V_{OC} of 1.05 V, and FF of 64.48%) with an HI of 0.04. An optimized ETL thickness is necessary. While thinner ETLs increasing charge collection also lead to higher recombination, we observe a reduced charge collection for thick films, again leading to higher recombination, which impacts the J_{SC} and FF. As can be seen in Table 2, in the case of a thinner ETL (0.1 M concentration), we observed an HI of 0.1 and a lower J_{SC} than that of the 0.2 M counterpart, which is indicative of higher recombination as the ETL thickness decreased. The superior performance of the 0.2 M concentration was reproducible over several devices fabricated in different batches, as shown in Figure S10.

We further recorded dark JV measurements of the PSCs (Figure S11), which also exhibited suppressed charge recombination for the optimized 0.2 M E-α-Fe$_2$O$_3$ ETL-based PSC and the highest injection current. Notably, the optimized 0.2 M E-α-Fe$_2$O$_3$ ETL-based PSCs showed slightly lower performance than a control device made using the SnO$_2$ ETL (PCE of 16.60%) suggesting room for further improvement. Nevertheless, these results show that with an optimized morphology and thickness, low-cost hematite has high potential as a future electron transport material.

For a reliable reporting of PCE, we measured stabilized PCE using maximum power point tracking (Figure 5b). The stabilized PCEs are 9.34, 12.4, 5.9, and 3.5% for 0.1, 0.2, 0.5, and 1 M E-α-Fe$_2$O$_3$ ETLs, respectively. To validate the J_{SC} in our PSCs, we measured EQE. Figure 5c demonstrates the
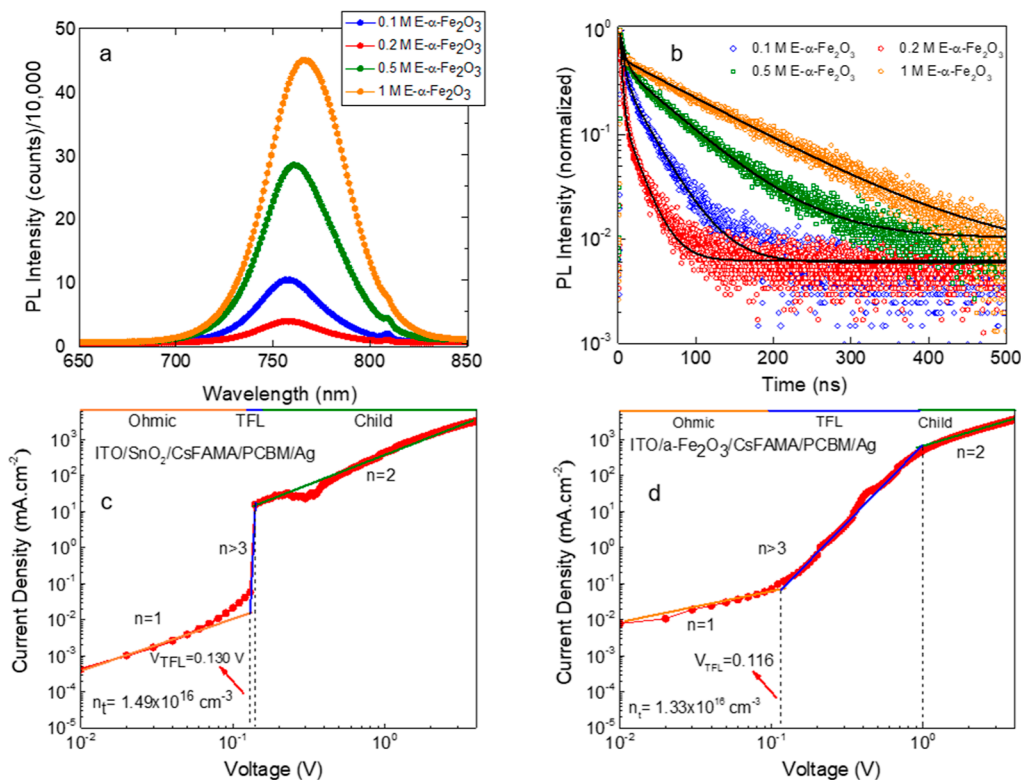

Figure 6. (a) Steady-state PL spectra and (b) time-resolved PL transients of CsFAMA films deposited on ITO/E-α-Fe$_2$O$_3$ ETLs with different molar concentrations in ethanol. (c) SCLC curve of a reference ETL made using SnO$_2$ vs (d) SCLC curve of the champion ETL.

spectra for the perovskite devices with E-α-Fe$_2$O$_3$ ETLs. The highest EQE for the 0.2 M concentration affirms optimized charge collection using this ETL. The integrated J_{SC} calculated from the EQE spectra matches well with that obtained from J–V measurements confirming the reliability of the measurements performed. In order to investigate the stability of the α-Fe$_2$O$_3$ ETL-based PSCs, we measured device stability of the champion and control devices in an inert (N$_2$) and in an ambient atmosphere for 30 days (Figure 5d). The 0.2 M E-α-Fe$_2$O$_3$ ETL-based device demonstrated comparable stability to the SnO$_2$ reference counterpart in an inert atmosphere and retained 86% of its initial PCE after 30 days of storage. For the devices stored under ambient conditions, superior stability is noted for the 0.2 M E-α-Fe$_2$O$_3$ ETL-based PSC, which retained 62% of the initial PCE (higher than the reference PSC showing only 45% of the initial PCE).

In order to investigate the mechanism behind the improved PV performance of the 0.2 M E-α-Fe$_2$O$_3$ ETL-based PSCs, we performed PL and TRPL measurements. Figure 6a shows the PL spectra for the CsFAMA perovskite deposited on the various E-α-Fe$_2$O$_3$ ETLs with different molar concentrations. The films were deposited on ITO glass and excited from the glass side (ETL/perovskite interface) to better compare the properties at this interface. The 0.2 M E-α-Fe$_2$O$_3$ ETL shows around 3, 8, and 12 times quenched PL intensity than 0.1, 0.5, and 1 M counterparts, respectively, and also a blue-shifted PL emission peak. The emission peaks for the perovskite films deposited atop 0.1, 0.2, 0.5, and 1 M 0.2 M E-α-Fe$_2$O$_3$ ETLs are centered at 756, 757, 760, and 766 nm, respectively, suggesting a lower defect density in the perovskite films on 0.1 and 0.2 M ETLs. The TRPL measurements also affirm a faster charge extraction in the 0.2 M sample. In order to extract the carrier extraction time, the TRPL transients were fitted using a

biexponential function (Figure 6b), and the corresponding parameters are listed in Table S4. The 0.2 M E-α-Fe$_2$O$_3$ ETL showed the fastest τ_1 of 2.55 s with an amplitude of 90.87%, which together with the JV data shown in Figure 5 and Table 2 (the highest J_{SC} and EQE for 0.2 M films) suggests an enhanced charge transfer efficiency at the ETL/perovskite interface using this ETL. The average lifetime also showed a strong dependence on the ETL concentration, and the shortest $\tau_{average}$ of 10 ns was noted for the optimal 0.2 M ETL, which is manifolds faster than that of its counterparts.

To confirm the reduced defect density (n_t) in the optimal ETL, we performed the SCLC measurements in reference (ITO/SnO$_2$/CsFAMA/PCBM/Ag) and target ETL-based devices [ITO/E-α-Fe$_2$O$_3$ (0.2 M)/CsFAMA/PCBM/Ag], Figure 6c,d. The SCLC curve consists of three distinct regions (Ohmic, trap-filled, and trap-free) based on the value of the exponential (n).[49,50] The conductivities (σ) of crystals can be assessed in the Ohmic region at a low bias ($I \propto V$). The charge carrier mobilities can be evaluated in the trap-free region at a high bias ($n = 2$, cyan line) by Mott–Gurney's law ($\mu = \frac{8J_D L^3}{9\varepsilon\varepsilon_o V^2}$).[51] The third region where the current rapidly increases is called the trap-filling region ($n > 3$, pink line), which is used to measure the trap densities as $n_t = \frac{2V_{TFL}\varepsilon\varepsilon_o}{eL^2}$ where V_{TFL} is trap-filled limit voltage, L is the thickness of the absorber layer, ε is the dielectric constant ($\varepsilon = 65$ for the perovskite), ε_0 is the vacuum permittivity (8.8542×10^{-14} F/cm), and e is the charge (1.602×10^{-19} C).[17] The trap densities were calculated to be 1.33×10^{16} cm^{-3} and 1.49×10^{16} cm^{-3} for the target and reference devices, respectively. A lesser trap density for the target device suggests fewer defect states as compared to the reference device. Similarly, the electron mobility was measured

by fabricating the electron-only devices with configuration (ITO/E-α-Fe$_2$O$_3$/WO$_3$/Ag) using the concentrations 0.1 and 0.2 M as shown in Figure S15. The values for mobility are found to be 3.7×10^{-4} cm^2 V s^{-1} and 5.2×10^{-4} cm^2 V s^{-1} for 0.1 and 0.2 M E-α-Fe$_2$O$_3$ ETLs, respectively. The mobility values are consistent with the previous literature[52] suggesting that the films made in this work are of high quality.

4. CONCLUSIONS

In summary, the solvent-assisted crystallization of α-Fe$_2$O$_3$ thin films with various solvents (DIW, ethanol, iso-propanol, and iso-butanol) has been investigated thoroughly. Our experiments revealed that the choice of the solvent significantly impacts the morphology and defect density of the α-Fe$_2$O$_3$ ETLs. The ethanol-based ETLs show a pinhole-free compact film formation, which results in improved charge extraction and superior PV performance than those of the ETL prepared using other solvents. The improved performance also stems from a superior hole-blocking capability of the E-α-Fe$_2$O$_3$ ETL, as evident from the dark current−voltage curve comparison. The optimized E-α-Fe$_2$O$_3$ ETL demonstrated a pinhole-free compact morphology facilitating the formation of a high-quality crack-free perovskite film atop. When compared to a SnO$_2$ reference, the E-α-Fe$_2$O$_3$ ETL also showed a lower trap density, high electron transfer efficiency, and electron mobility—all these contributing to a PCE of 13% with a low HI of 0.04. The target device also exhibited long-term stability in an inert and ambient environment as well, thus showing the potential of α-Fe$_2$O$_3$ ETLs for the development of efficient and stable PSCs.
