Cognitive impairment, Neurotoxicity  
Chemotherapy drugs, CICI

## ABSTRACT

Cancer is the second leading cause of death worldwide despite efforts in early diagnosis of the disease and advances in treatment. The use of drugs that exert toxic effects on tumor cells or chemotherapy is one of the most widely used treatments against cancer. However, its low toxic selectivity affects both healthy cells and cancer cells. It has been reported that chemotherapeutic drugs may generate neurotoxicity that induces deleterious effects of chemotherapy in the central nervous system. In this sense, patients report decreased cognitive abilities, such as memory, learning, and some executive functions after chemotherapy. This chemotherapy-induced cognitive impairment (CICI) develops during treatment and persists even after chemotherapy. Here we present a review of the literature on the main neurobiological mechanisms involved in CICI using a Boolean formula following the steps of the PRISMA guidelines that were used to perform statements searches in various databases. The main mechanisms described in the literature to explain CICI include direct and indirect mechanisms that induce neurotoxicity by chemotherapeutic agents. Therefore, this review provides a general understanding of the neurobiological mechanisms of CICI and the possible therapeutic targets to prevent it.

## 1. Introduction

Cancer is one of the leading causes of death worldwide [47]. In 2020, the World Health Organization reported 19,292,789 new cancer cases, with breast cancer being the most prevalent type [87]. Hallmarks of these polygenic diseases are replicative immortality, angiogenesis induction, resisting cell death, sustaining proliferative signaling, evading growth suppressors, activating invasion and metastasis, cellular energetics dysregulation, genome instability, and mutation, eluding immune destruction, and tumor-promoting inflammation [40]. Due to cancer's etiology complexity, each patient requires different types of treatment or a combination of them, chemotherapy and radiotherapy are among the main treatments, given their effectiveness in increasing patient survival with different types of cancer [86].

Several chemotherapeutic drugs are used in cancer treatment, classified by the mechanism of action. Alkylating agents (cyclophosphamide, cisplatin, carboplatin) and nitrosoureas are DNA crosslinkers [22]. Anti-metabolites such as fluorouracil and methotrexate inhibit DNA synthesis, and plant alkaloids (vincristine, paclitaxel, docetaxel) induce apoptosis through DNA damage [38]. Anti-tumor antibiotics inhibits topoisomerase II [21], or inhibits the synthesis and repair

mechanisms of DNA [17]. Nevertheless, an essential issue of chemotherapy drugs is their effects on healthy and cancer cells, inducing multiple side effects.

Epidemiological studies in the United States record that as of 2019, there were 16.9 million cancer survivors [7]. It has been reported that one side effect of chemotherapy for the treatment of peripheral tumors and central nervous system tumors is known as “chemobrain,” “chemo fog,” or cancer-related cognitive impairments. Chemobrain includes impairment of learning, memory, attention, and executive function impairment [49,74]. Other studies have described that the prevalence of cognitive impairment after chemotherapy is estimated to be 15 %– 75 %, and up to 17 %– 35 % suffer long-term effects [61,63].

Common symptoms reported by patients suffering from CICI include the inability to solve problems, lack of concentration, difficulty finding the right words when speaking, memory loss, learning disabilities, impaired executive functions, and processing speed [61,69]; other neurobehavioral changes affecting the patient's quality of life after chemotherapy are anxiety and depression [57]. Even when it has been reported that just having a cancer diagnosis can affect cognitive function, evidence supports that chemotherapy further alters proper cognitive functioning [48].

Epidemiological studies can be expected to report an increasing number of new cancer cases in the coming years and consequently the number of reports of patients with cognitive impairment will increase. Currently, research is focused on understanding the neurobiological mechanisms underlying CICI and the search for therapeutic targets [64, 77]. Although some mechanisms underlying CICI have been described, knowledge about the effects of different chemotherapeutics on cognition is constantly growing. This review aims to present a comprehensible update on the leading neurobiological mechanisms involved in chemobrain.

## 2. Methodology

PRISMA guidelines [58] were used to perform a scoping review to identify the literature update the leading neurobiological mechanisms involved in chemotherapy-induced cognitive impairment (CICI). First, several databases were selected from the electronic sources provided by the Pontificia Universidad Javeriana (Academic Search Complete, Google Scholar, Nature, ProQuest, ScienceDirect, Scopus, SpringerLink, Taylor & Francis, and Web of Science). Then, the Boolean search was performed with the following formula: chemobrain AND mechanism AND biochemical AND cellular. Inclusion criteria were defined as follows: original articles or reviews in English, peer-reviewed, published in the period 2012–2021, with clinical, in vivo, and in vitro study models. Additional articles were identified from the reference lists of previously selected articles and chosen for further review; in this case, the publication date was not considered.

**Fig. 1.** Preferred Reporting Items for Systematic Reviews (PRISMA) flowchart for articles and reviews search process. 408 documents were identified with the Boolean search in the following databases: Academic Search Complete = 39, Google Scholar = 157, Nature = 2, ProQuest = 50, ScienceDirect = 22, Scopus = 122, SpringerLink = 12, Taylor & Francis = 3 and Web of Science = 1. Additional documents from the reference lists = 11. Finally, 283 records were screened and finally 51 articles were selected for full-text review. Created with BioRender.com.

PRISMA flowchart depicts the articles and reviews’ selection process (Fig. 1). All previously obtained articles were reviewed, and duplicates were excluded. Other exclusion criteria were as follows: articles that corresponded to abstracts or conference reports, articles on neurodegenerative diseases, computational approaches, neurobehavioral changes, or articles in which the chemotherapy regimen was not specified. Subsequently, the selected articles were read and analyzed, and the information was summarized in Table 1. Finally, the results section briefly describes each neurobiological mechanism in the table.

## 3. Results

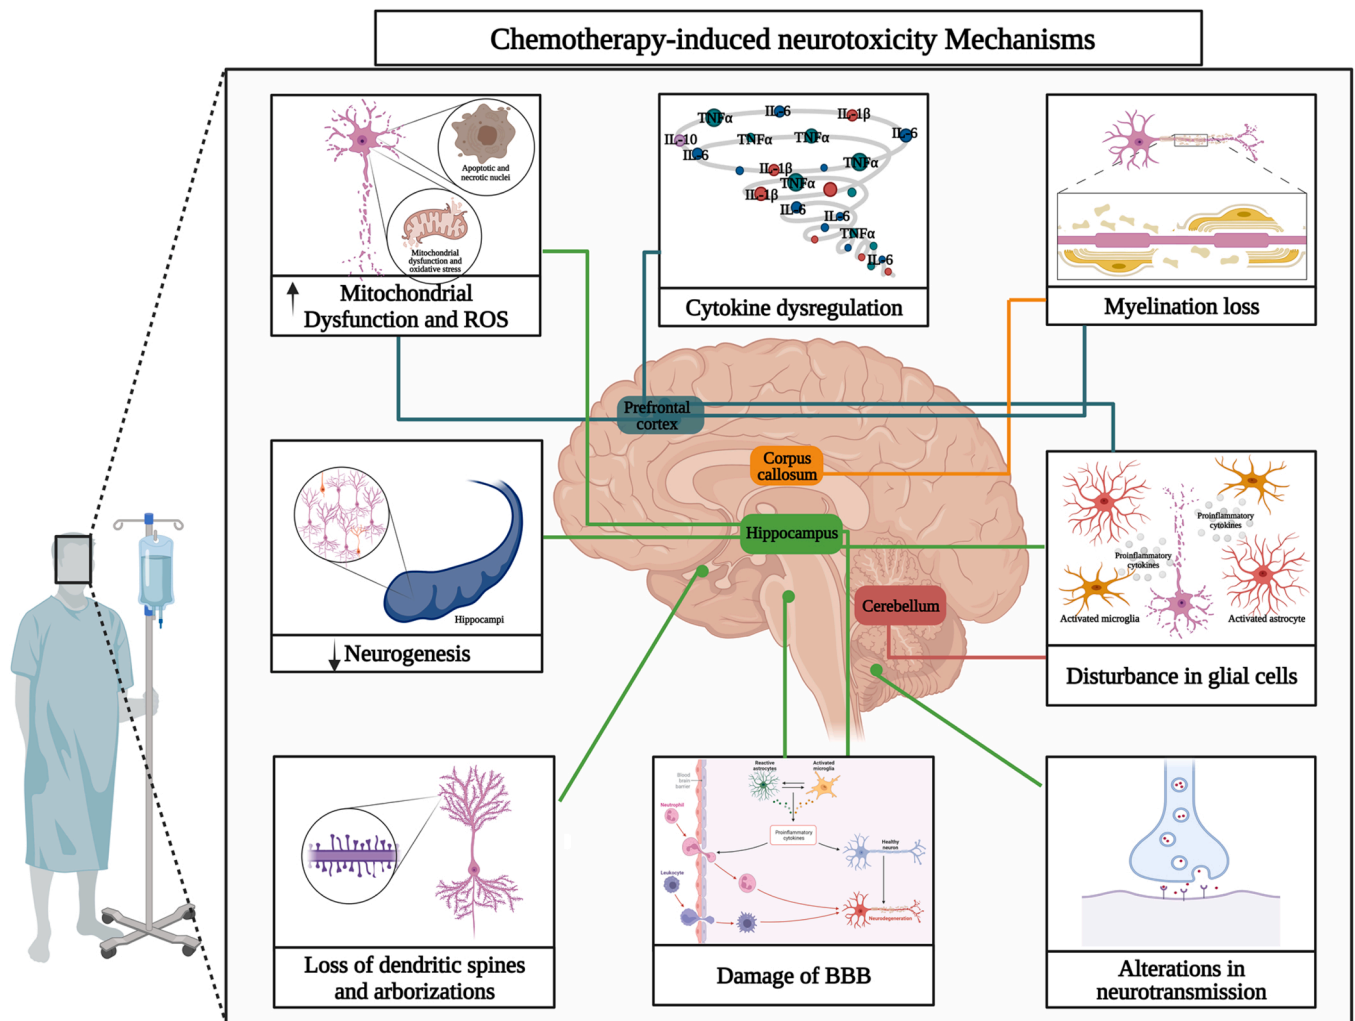

This section will be briefly described the main neurobiological mechanisms underlying CRCI found in the literature search (Table 1), including neurotoxicity, decreased neurogenesis, loss of dendritic spines and dendritic complexity, altered neurotransmission, disruption of glial cells, loss of myelination and cytokine dysregulation leading to neuroinflammation (Fig. 2).

### 3.1. Mechanisms of neurotoxicity

Neurotoxicity is related to damage, dysfunction, and neurodegeneration of the neurons in the Central Nervous System (CNS) or the peripheral nervous system (PNS) [66]. The functionality of the CNS depends on the interaction between neurons and glial cells (astrocytes, oligodendrocytes, and microglia). Exogenous agents such as chemotherapeutic drugs have been reported to be toxic to the nervous system

**Table 1**  
Neurobiological mechanisms involved in the development of Cancer-related cognitive impairment.

Type of chemotherapy drug	Mechanism of action	Chemotherapy agent	Neurobiological mechanisms						
			Neurotoxicity	Diminish neurogenesis	Loss of dendritic spines and arborizations	Alterations in neurotransmission	Disturbance in glial cells	Myelination loss	Cytokine dysregulation
Alkylating agents	DNA crosslinker[22]	Cyclophosphamide	[75][43][54]	[26] Reviewed in[43]	[32]		[26]	[44]	
		Cisplatin	[28][22][25]	[77][10] Reviewed in[43]	[67][10]	[12]	[77]	[45][12]	
Nitrosoureas Anti-metabolites	DNA crosslinker[22] Inhibits DNA synthesis[22]	Carboplatin	[66]	Reviewed in[43]		[49]			
		Carmustine	[59]		[14][43]	[37]	[39]	[39]	[37]
Plant alkaloids	DNA damage inducing apoptosis [38]	Fluorouracil	[14]	[85]	[2]		[34][35]	[34][35]	
		Methotrexate	[22][66][59]						
Anti-tumor antibiotics	Inhibits topoisomerase II[21], or inhibits the synthesis and repair of DNA[17]	Vincristine	[59][43][60]						
		Paclitaxel	[42][56][66]	[42]				[56]	
Combination	-	Docetaxel	[30][66][78]				[30]		
		Doxorubicin	[22][73][82]	[26]	[83][32]	[4][11][79]	[20]	[5][78][82]	
Combination	-	Mitoxantrone	[6]						
		BEP (bleomycin, etoposide, cisplatin)						[8]	
		CMF (cyclophosphamide, methotrexate, and 5-fluorouracil)		[18]	[9]			[19]	[19]
Combination	-	DAC (Docetaxel, Doxorubicin, Cyclophosphamide)			[74]			[74]	
		AC (Doxorubicin, and cyclophosphamide)	[13]					[13]	

**Fig. 2.** Chemotherapy-induced Neurotoxicity Mechanisms. The blue lines indicate mechanisms occurring in the prefrontal cortex, the green lines indicate mechanisms occurring in the hippocampus, the orange line indicates processes occurring in the corpus callosum and the red line indicates processes occurring in the cerebellum. and other organs such as bone marrow and lungs, so chemotherapeutics doses are limited [66].

Chemotherapy-induced neurotoxicity may affect neurons through mechanisms that decrease functionality directly or indirectly. Neurotoxicity is a crucial mechanism underlying CICI as it directly impairs the homeostasis and viability of neurons in essential brain areas involved in cognitive processes. Some neurotoxic effects rely on increased oxidative stress, mitochondrial dysfunction, and apoptosis. Consequently, the loss of neuronal plasticity induces a decrease in neurogenesis, decreased dendritic arborization, loss of spines and demyelination, and alterations related to neurotransmission that may cause neurodegeneration. In addition, damage indirectly caused by the effect of glial cells (macroglia or microglia), such as neuroinflammation and damage to the BBB, are highlighted. This section will review the direct and indirect mechanisms of chemotherapy-induced neurotoxicity.

### 3.1.1. Chemotherapeutics induce direct mechanisms of neurotoxicity

**3.1.1.1. Mitochondrial dysfunction and oxidative stress.** Neurotoxicity induced by chemotherapeutic agents has also been linked to mitochondrial dysfunction, oxidative stress, and consequent DNA damage. Platinum derivatives such as oxaliplatin and cisplatin may enter neuronal cells and binding to mitochondrial DNA (mDNA), forming mDNA adducts that cannot be repaired in mitochondria due to the

absence of DNA repair systems. These platinum-mDNA adducts disrupt physiological mDNA replication and transcription, which can lead to abnormal protein synthesis and impairment of the function of the mitochondrial electron transport chain, in turn, to decreased cellular metabolism, increased production of ROS (reactive oxygen species), and oxidative stress [88]. In addition, it has also been reported that cisplatin induces mitochondrial dysfunction as evidenced by decreased respiratory capacity and morphological alterations, events related to the poor performance of treated animals in new object/place recognition (NOPRT) tests [25]. Likewise, the cisplatin analog, carboplatin, produces mitochondrial damage and oxidative stress ([24] reviewed in [66]). A study in C57/BL6J mice treated with cisplatin (34.5 mg/kg cumulative dose) impaired performance on the novel object and place recognition task, as well as on the social discrimination task, suggesting that treatment with cisplatin-induced cognitive deficits that are associated with structural abnormalities in the brain relative to induced morphological abnormalities in the brain on the level of white matter organization, neuronal arborization, and dendritic spine density [89]. In this same model of cisplatin-induced cognitive impairment, all have been observed peripheral neuropathy was observed with neuroprotection from metformin treatment, which was associated with protection against mitochondrial damage and decreased neuroinflammation [89]. Another study showed elevated oxidative stress (nitrotyrosine, 4-hydroxynonenal) and DNA damage (pH2AX,

pATM) in cortical neurons from chemotherapy patients. The study identifies markers of oxidative stress and DNA damage in autopsy tissue sections of the frontal lobe of cancer patients treated with chemotherapy (n = 15), cancer patients not treated with chemotherapy (n = 10), and patients with no history of cancer (n = 10). Of the known chemotherapy regimens, the most frequently administered drugs were cisplatin (42.9 %), carboplatin (28.6 %), cyclophosphamide (28.6 %), doxorubicin (28.6 %), pemetrexed (28.6 %), paclitaxel (28.6 %), cytarabine (21.4 %), etoposide (21.4 %), vincristine (21.4 %) and docetaxel (14.3 %), gemcitabine (14.3 %), ifosfamide (14.3 %), azacitidine (7.1 %), decitabine (7.1 %), fluorouracil (7.1 %), irinotecan (7.1 %), eribulin (7.1 %), busulfan (7.1 %), fludarabine (7.1 %), daunorubicin (7.1 %) and oxaliplatin (7.1 %). Patients received a median of 3 chemotherapeutic agents (range 2–8) and were treated with a median of 5.5 cycles of chemotherapeutic regimens (range 1–17). This work shows for the first time that cancer patients treated with chemotherapy have elevated markers of oxidative stress and DNA damage in cortical neurons compared with cancer patients not treated with chemotherapy and patients without a cancer history. Importantly, these observations highlight the relevance of human neuronal oxidative stress and DNA damage in studying the mechanisms that may contribute to CRCI [80].

Chemotherapeutic agent doxorubicin (DOX) has been implicated in cognitive decline, mostly via cytokine-induced neuroinflammatory and oxidative and mitochondrial damage to brain tissues. Cognitive dysfunction was induced in female Wistar rats by administering ten cycles of DOX (2.5 mg/kg, intra-peritoneal, once in 5 days), as we observed significant impairment of episodic memory in object recognition task (ORT). Also, DOX human neuroblastoma (IMR32) cells in vitro study resulted in increased cellular death, apoptosis, and intracellular ROS generation, with inhibition of neurite growth in differentiated IMR32 cells [68]. On the other hands, DOX-induced neurotoxicity Wistar male rat model led to neurobehavioral alterations and neurochemical deficits in the Hippocampus region. This study depicted the persistent increase in proinflammatory cytokines (IL-1 $\beta$ , TNF- $\alpha$ ) that led to increased oxidative stress, lipid peroxidation, depletion in GSH level, and changes in vivo antioxidant defense SOD and CAT activity. This study depicted the persistent increase in proinflammatory cytokines (IL-1 $\beta$ , TNF- $\alpha$ ) that led to increased oxidative stress, lipid peroxidation, depletion in GSH level, and changes in vivo antioxidant defense SOD and CAT activity. The authors showed that the animals with DOX significantly impaired mitochondrial redox activity, decreasing the mitochondrial respiratory chain complex I, II, and IV. In addition, the results have shown increased oxidative stress markers such as MDA level, reduction in GSH level, and reduction activities of SOD and CAT in the hippocampus of animals DOX treated group [33].

Another study with Male C57BL/6 mice DOX-induced chemobrain model intraperitoneal injections of 2.5 mg/kg DOX every two days for a total of seven injections over a 2-week period. The results showed elevated pro-inflammatory levels (TNF- $\alpha$ , IL-1 $\beta$ , and IL-6) and a marked increase in Iba1 and GFAP immunoreactivity in the brains of DOX-treated animals. In addition, systemic DOX administration triggered oxidative damage as indicated by a significant elevation in the levels of MDA, protein carbonyl, and 8-OHdG, depletion of reduced GSH, and reduction of SOD activity. DOX impaired brain mitochondrial function, as evidenced by the decreased mitochondrial respiratory complex activities, the ATP deficiency, and the increased ROS in DOX-treated mice. The results also demonstrated that decreased synaptic density and dendritic spine loss were paralleled with mitochondrial dysfunction after DOX exposure [83]. The above results suggest that chemobrain is a potential side effect of doxorubicin administration and the key role of cytokine-induced, oxidative/nitrosative stress in the development of cognitive dysfunction. Doxorubicin-induced neurotoxicity was also associated with acute alterations in synaptic plasticity, apoptosis, and lipid peroxidation, suggesting an increase of oxidative stress in a hippocampal cell line (H19–7/IGF-IR) [3].

### 3.1.1.2. Loss of neuronal plasticity mechanisms

**3.1.1.2.1. Reduced neuronal survival.** It has been described in a murine model that intraperitoneal injections of cyclophosphamide (CPA) cause histopathological damage in the cerebral cortex, characterized by necrotic and apoptotic nuclei [75]. Similarly, intraperitoneal injections of paclitaxel in a murine model increased apoptosis in hippocampal neurons by increasing proinflammatory cytokines [56]. Furthermore, reduced neuronal survival has also been reported using cisplatin in an in vitro model of cortical neurons [28]. In this case, astrocyte-mediated mitochondrial transfer induced recovery of cisplatin-treated neurons. In this case, astrocyte-mediated mitochondrial transfer induced recovery of cisplatin-treated neurons. On the other hand, it was reported that acute cisplatin treatment causes an increase in apoptotic cells in the CA1, CA3, and subgranular zone (SGZ) of the dentate gyrus in the hippocampus of male rats [10]. Also, it has been reported that DOX induced histopathological damage showing nuclear pyknosis in mice hippocampal neurons, particularly in the subiculum, fascia dentata, and hilus, along with darker cytoplasm and abnormal morphology [73]. Interestingly, an in vitro assay differentiated SH-SY5Y human neuronal cell model, mitoxantrone was more toxic than DOX, with decreased viability and the observation of apoptotic nuclei. Further assays revealed that cytotoxicity was mediated by depolarization of the mitochondrial membrane potential after 48 h of exposure to chemotherapeutics [6]. Other studies have shown that another chemotherapeutic drug, vincristine, destroys hippocampal tissue when administered unilaterally or bilaterally to mice [60].

**3.1.1.2.2. Diminishing neurogenesis.** Neurogenesis is a complex process in which a wide range of cellular and molecular events generate fully mature postmitotic neurons. In the adult mammal brain, neurogenesis has been documented in different regions, including the olfactory bulb, neocortex, striatum, and hippocampus [76]. Notably, particular emphasis has been given to hippocampal neurogenesis due to its relationship with higher cognitive functions, especially with learning and memory [52]. In this vein, it has been reported in a murine model that intraperitoneal injections of cyclophosphamide and doxorubicin caused a 47 % and 53 % decrease in the number of immature doublecortin (DCX)-labeled neurons, respectively when compared to saline treated controls; also, ectopic migration of these immature neurons was observed [26]. A decrease in neurons labeled simultaneously with NeuN (a marker for mature neurons) and BrdU (a marker for proliferative cells) was also observed after treatment with these chemotherapeutics, suggesting that hippocampal neurogenesis was significantly impaired [26,43]. Similarly, the use of the CMF (cyclophosphamide, methotrexate, and fluorouracil) regimen in an in vivo model also resulted in a decrease of proliferative cells in the hippocampus, specifically in the dentate gyrus [18].

Brain-Derived Neurotrophic Factor (BDNF) plays a critical role in the growth, development, plasticity, differentiation, and survival of new neurons, and reduction in its expression leads to memory deficits. It has been reported that the systemic administration of fluorouracil induces a decrease of DCX and BDNF-positive cells in the hippocampus ([62] reviewed in [14]), therefore suggesting a disruption in hippocampal neurogenesis (Reviewed in [43]). Moreover, the systemic administration of fluorouracil reduced the expression of the BDNF levels in rat hippocampus, affecting learning and memory ([62] reviewed in [14]).

Other study reported that cisplatin treatment resulted in the depletion of neural stem cells (NSCs) cultured in vitro; however, NSCs were more resilient than differentiated hippocampal neurons [10]. Notably, antioxidant treatments can prevent the deleterious effect of cisplatin and carmustine on hippocampal neurogenesis, suggesting that oxidative stress is an important mechanism in this context (Reviewed in [43]; Reviewed in [77]).

Comparable with these results, it was reported that intravenous injection of methotrexate in rats significantly reduced DCX expression in the hippocampus. This effect was accompanied by a decrease in BDNF and Nuclear factor erythroid-related factor (Nrf2) levels in both the

hippocampus and prefrontal cortex, both factors critical in the regulation of neurogenesis and subsequent differentiation of NSCs [50,85]. The decline in NSCs viability has also been observed in paclitaxel-treated cells in culture [42].

As evidenced above, several chemotherapeutics decrease the expression of neurotrophic factors allowing impaired neurogenesis in critical areas for learning and memory. It is suggested that impaired NSCs production, migration, and differentiation is a possible neurobiological mechanism underlying chemotherapeutic-induced cognitive impairment.

**3.1.1.2.3. Loss of dendritic arborizations and spines.** Neuronal connectivity and function are highly related to the number of dendritic spines and dendritic tree complexity [10]. Dendritic spines are specialized protrusions in the excitatory synapses [23]. These tiny structures have been reported as critical in synaptic plasticity because their morphology and density are essential for memory and learning processes [23]. Four types of dendritic spines have been proposed based on their morphology: mushroom spines, thin spines, stubby spines, and cup-shaped spines, while mushroom spines are considered the most stable thin spines are considered the least stable [23]. The potential importance of dendritic spines in memory and learning has been described from long-term potentiation (LTP). In this process, the spines with the highest activity will be maintained over time [51]. Similarly, it has also been documented that the complexity of the dendritic tree has an essential role in memory formation and consolidation [2].

Several chemotherapeutics can cause a reduction in the density of dendritic spines and dendritic branches. Intravenous injection of cyclophosphamide or doxorubicin in ovariectomized mice reduced the density of stubby dendritic spines in the dentate gyrus [32]. Similarly, intraperitoneal injection of doxorubicin in mice decreases the density of dendritic spines and synaptic density in neurons of the CA1 region of the hippocampus [83]. Also, in vivo and in vitro models, it was documented that treatment with cisplatin caused a reduction in the density of dendritic spines and dendritic branches in apical and basal dendrites in pyramidal neurons of the CA1 and CA3 regions of the hippocampus [10]. The synaptic damage induced by cisplatin was not reversible, even after five days post-treatment [10].

Similar results show that the intrathecal application of methotrexate using a juvenile murine model considerably affects the dendritic architecture and reduces the density of mushroom dendritic spines in CA1, CA3, and dentate gyrus of the hippocampus [2]. Consistent with these results, it was reported in another murine model that the intraperitoneal application of docetaxel, doxorubicin, and cyclophosphamide (DAC) significantly eliminated dendritic spines of medial prefrontal cortex neurons [74].

More complex effects were reported in CMF-treated animals that exhibited a significant increase in the number of stubby spines and a decrease in the number of mushroom-shaped spines in the DG, while in CA1 and CA3 regions of the hippocampus, there was a significant increase in the density of dendritic spines [9]. However, decreases in the number of branch points, dendritic ends, dendritic length, and dendritic complexity were observed in CMF-treated animals. In addition, it has been described in an aged murine model that the use of intraperitoneal injections of fluorouracil caused a decrease in the density of mushroom dendritic spines in the DG while the density of thin and stubby dendritic spines increased. Accordingly, apical dendrites of pyramidal neurons of the CA1 region showed a decreased density of mushroom spines but an increased density of stubby spines. However, a decrease in thin spines was documented in the basal dendrites of pyramidal neurons in CA3 [37]. Also, it has been that fluorouracil negatively affected dendritic complexity in DG neurons [37].

These results indicate that chemotherapeutic treatment affects dendritic spine dynamics and that there is also a tendency to decrease dendritic complexity in pyramidal neurons of the hippocampus. One of the most marked trends was the decreased number of mushroom dendritic spines and the increase in thin and stubby spines. Given that

mushroom spines are the most stable and the thin spines the least stable, changes in the density ratio of these spines could explain, in part, the development of chemobrain.

**3.1.1.2.4. Alterations in neurotransmission.** Neuronal communication occurs via an electrochemical gradient; the action potential travels through the neuron cell body and generates neurotransmitter release to the synaptic cleft [29]. It has been seen that the most important brain regions in cognition, such as the prefrontal cortex and the hippocampus, are densely innervated with serotonergic, cholinergic, and dopaminergic afferents. Therefore, neurotransmitters such as serotonin, acetylcholine, and dopamine (DA) are essential modulators of memory and learning [36] [55]. Also, glutamate plays a vital role in cognition, specifically in spatial memory, given that hippocampal neurons are glutamatergic [41].

It has been described an increased brain acetylcholine levels in a Rat Model of Cisplatin-Induced Cerebral Inflammation and Oxidative Damage while generating a decrease in the relative expression levels and activity of acetylcholinesterase [12]. In contrast, in another in vivo model, it has been reported that the use of doxorubicin produces a reduction in the levels of acetylcholine in both hippocampus and prefrontal cortex [4]. Researchers found that DOX treatment impaired learning and memory [4]. Also, decreased dopamine release in the striatum was documented after intravenous application of fluorouracil in a murine model; these findings were correlated with the decrease in attention shown by these animals [46]. Similar results were obtained after treating animals with carboplatin; DA and serotonin release were negatively affected while DA uptake was decreased in the striatum; these changes that correlate to the impairment in spatial learning exhibited by the carboplatin-treated animals [49]. Additionally, it has been found that intraperitoneal application of doxorubicin generates a decrease of DA and its extra-neuronal metabolite 3-methoxytyramine (3-MT) in both the frontal cortex and hippocampus of treated animals compared to the control [11]. In parallel, another research group documented that doxorubicin produced a slower glutamate uptake in the frontal cortex, while the dentate gyrus produced a slower clearance of glutamate and, consequently, an overflow of glutamate in this region [79]. All this together affected the swimming speed of the doxorubicin-treated group; however, this effect lasted only 24 h after administration [79].

As mentioned before, chemotherapeutic agents can affect the homeostasis of different neurotransmitters suggesting that the release or capture of neurotransmitters can be negatively compromised and thus contribute to the deterioration of cognitive processes associated with memory and learning, common symptoms presented by patients with CRCI.

**3.1.1.2.5. Demyelinating processes in brain.** In the CNS, myelination is a complex and lifelong process in which oligodendrocytes wrap segments of the axons of specific neurons. These segments become isolated and enable the saltatory action potential, which is an evolutionary mechanism that allows faster conduction and processing of information. ([1]; de [31]). Two types of myelination have been described. The first is intrinsic myelination, which occurs independently of neuronal activity. The second is adaptive myelination, which is regulated and shaped by neuronal activity and is associated with neuroplasticity, which is critical for learning [16]. The deleterious effect of chemotherapeutics on myelination has been reported in a murine model; methotrexate exposure has been documented to decrease the cortical expression of BDNF, which, together with TrkB, is required for adaptive myelination [34]. Interestingly, BDNF expression is normalized after microglia depletion, although the underlying mechanisms are unknown [34,35]. Also, toxic effects on CNS progenitor cells and non-dividing oligodendrocytes have been reported with the use of fluorouracil both in vivo and in vitro [39]. Administration of fluorouracil generates delayed damage in myelin and axons, which can be observed up to 56 days after the completion of the treatment, resulting in a myelopathy that did not correlate with chronic inflammation or vascular damage caused by the chemotherapeutic [39].

Similarly, it has been documented that the use of a CMF regimen generates a decrease in myelin essential protein (MBP) and O4 (a pro-oligodendrocyte marker), as well as a decrease in both the area covered by myelin and reduced thickness of the sheath in the corpus callosum of female rats [19]. This study, however, correlates neuroinflammation with loss of myelination and subsequent cognitive impairment [19]. In addition, oligodendrocyte survival results were dose-dependent after treating cells in culture with cisplatin ([27] reviewed in [77]). The same research group reported similar results in *vivo* and *in vitro* models in which decreased oligodendrocyte survival was evidenced by treatment with fluorouracil [39].

These results indicate that chemotherapeutics can also negatively affect the myelination process. This damage appears to be persistent despite the cessation of chemotherapeutics. It would partially explain why some patients report chemobrain symptoms persist years after completing cycles of chemotherapy.

### 3.1.2. Chemotherapeutics induce indirect mechanisms of neurotoxicity

**3.1.2.1. Activation of glial cells.** As mentioned before, glial cells are important for CNS functioning. Particularly, astrocytes have been reported as the physical and metabolic support of neurons [53]. However, it has been described that astrocytes are involved in many other processes. In particular, astrocytes have been shown to play a crucial role in cognitive processing by contributing to synaptic transmission and structural plasticity, where bidirectional communication between neurons and astrocytes is established [72]. Accordingly, it has also been reported that astrocytes and microglia play an essential role in the formation and pruning of synapses. Also, it has been reported that the central role of microglia is to phagocytize apoptotic neuronal bodies and some synapses [81]. In recent years, it has been reported that microglia modulates the formation of new neurons in the hippocampus, regulates dendritic and axonal growth, and stimulates the formation, modulation, and relocation of synapses, processes necessary for memory formation [71].

Glial activation is a feature of the immunocompetent cells, such as microglia and astrocytes, in response to injury or toxic agents. Effects of microglial activation after the intraperitoneal administration of cyclophosphamide have been observed in the hippocampus of male rats that show an increase in ED1-positive cells (a marker of microglial activation) in response to treatment; also, this effect seems to be related to impaired performance on novel place recognition (NORT) and contextual fear conditioning tests [26]. In concurrence, in a male murine model, it has been shown that intermittent intraperitoneal application of docetaxel generates an increase in GFAP-positive astrocytes, indicating astrocyte activation. This activation was seen 48 h after docetaxel administration and extended, at lower levels, up to 9 days after application. Furthermore, it was noted that docetaxel-treated animals performed worse in the novel object recognition test [30]. Likewise, in a juvenile murine model, it has been shown that peritoneal application of methotrexate induces microglial activation, which in turn affects oligodendrocyte maturation dynamics and increases astrocyte reactivity. The authors also reported that the reduction of microglia restored tri-glial stability and cognitive function, assessed by the novel object recognition task [34,35]. Other authors have also shown that administration of DOX-induced astrocytic activation in the frontal cortex, striatum, hippocampus, hypothalamus, and cerebellum. Finally, the authors suggested that these results partially explained the cognitive impairment evidenced by a more unsatisfactory outcome in new object recognition tests [20].

These results reflect the enormous impact of chemotherapeutics on glial populations. Notably, the activation of astrocytes and microglia was evidenced. This is relevant since these processes cause tissue damage due to the release of proinflammatory cytokines that, in turn, generate neuroinflammation and, ultimately, neurodegeneration [65].

**3.1.2.2. Neuroinflammation by cytokine dysregulation.** Cytokines play a fundamental role in the development and physiology of the CNS. However, the CNS is especially vulnerable to dysregulated cytokine and some changes in the microenvironment due to diseases or external factors. Chemotherapy frequently leads to chronic inflammation that can induce damage to tissue and cell infiltration in the CNS. The mentioned phenomena intertwine, generating a vicious cycle of inflammatory and tissue damage, eventually leading to neurodegeneration [15].

It has been documented that cyclophosphamide in a murine model generates alterations among cytokines. Within the proinflammatory cytokines, interleukin-1 $\beta$  (IL-1 $\beta$ ), tumor necrosis factor  $\alpha$  (TNF $\alpha$ ), and interleukin-6 (IL-6) were found to be significantly elevated in the hippocampus and cortex. In contrast, the anti-inflammatory cytokine IL-10 was significantly decreased. In sum, this imbalance induces a neuro-inflammatory environment contributing to cognitive impairment, evidenced by increased immobility time in the forced swim test (FST) and decreased performance in the latency retention transfer test observed in treated animals. These tests evaluate the extent of behaviors associated with depression and memory acquisition and retention [44].

In agreement, it has been reported that the application of cisplatin generates IL-1 $\beta$ , and TNF $\alpha$ , elevation in the hippocampus of a murine model. Along with these results, it was also described that treated animals performed worse in the NORT and motor coordination tests [45]. Similarly, other authors reported in another murine model that the application of cisplatin caused a significant increase in the level of TNF $\alpha$  and IL-6 in the cerebral cortex of the treated group [12]. Likewise, it has been reported that intraperitoneal application of fluorouracil in an aged murine model increased the levels of IL-1 $\beta$ , IL-2, IL-3, IL-4, IL-5, and IL-17 in the hippocampus after one month of treatment, which was related to detrimental effects on mature hippocampal neurons [37].

Furthermore, other researchers have described that chronic intraperitoneal application of paclitaxel in a male murine model elevates levels of the proinflammatory cytokines TNF $\alpha$  and IL-1 $\beta$  in the hippocampus, and these results were related to the subsequent decrease in spatial memory of treated animals by increasing escape latency times in the Morris Water Maze (MWM) test [56]. Notably, treatment with the bleomycin, etoposide, and cisplatin (BEP) regimen in patients with testicular cancer (TC) also significantly increased TNF $\alpha$  levels compared to the group with TC but did not receive BEP treatment. In this study, elevated TNF $\alpha$  levels were associated with poorer cognitive performance [8].

Moreover, the administration of DOX generates a dramatic increase in the levels of the proinflammatory cytokines TNF $\alpha$  and IL-17, while the anti-inflammatory cytokine IL-10 declines in the hippocampus of treated animals. Treated animals also showed reduced short-term memory as measured by the spontaneous alternation test (SAP) [82]. Consistent with this, in another murine model in which DOX was applied intraperitoneally, an overexpression of TNF $\alpha$  levels was evidenced in the brain [78]. Similarly, in a female OVX murine model, it was reported that the application of the regimen doxorubicin and cyclophosphamide (AC) produced in the hippocampus a significant elevation of the cytokines IL-2, IL-3, IL-4, IL-6, IL-10, IL-1 $\alpha$ , IL-17, and TNF $\alpha$  [13].

In addition, it has been reported that using the CMF regimen in an aged female murine model generated increased levels of the proinflammatory cytokines TNF $\alpha$  and IL-1 $\beta$  but reduced levels of the anti-inflammatory cytokine IL-10 in the corpus callosum. Intriguingly, after one month of cessation of treatment with the CMF regimen, the treated animals exhibited worse performance in memory and discrimination tests [19]. Similar results were obtained with the DAC regimen in which levels of the proinflammatory cytokines TNF $\alpha$  and IL-6 were significantly increased, but levels of the anti-inflammatory cytokine IL-4 and IL-10 were decreased in the whole brain, especially in the prefrontal cortex and hippocampus of a female murine model [74].

**3.1.2.3. Damage to the blood-brain barrier.** Chemotherapeutics

promotes an imbalance between proinflammatory and anti-inflammatory cytokines. Pro-inflammatory cytokines, which are over-produced in cancer or in response to chemotherapy, can reduce the integrity of the blood–brain barrier (BBB) and can lead to infiltration of neutrophils and leukocytes. Remarkable, it was documented that regardless of the chemotherapeutic used, the cytokine frequently found to be elevated as TNF $\alpha$ . This finding is important since it has been described in the literature that the expression of this cytokine is related to increased oxidative stress and mitochondrial dysfunction, which decreased in a TNF $\alpha$  null model [70]. Additionally, it has also been described that the elevation of reactive oxygen species (ROS) and, consequently, of proinflammatory cytokines generate physical damage to the BBB, which subsequently contributes to the entry of small concentrations of chemotherapeutics that generally cannot pass the BBB, as is the case of DOX. In addition, pro-inflammatory molecules such as TNF- $\alpha$  can cross BBB and stimulate microglial cells to produce further inflammatory cytokines, which promote brain damage [70]. On the other hand, a few chemotherapeutic agents can cross the BBB. For example, Methotrexate crosses the blood-brain barrier at high doses; standard doses are generally not associated with neurotoxicity. Nitrosoureas (e.g., carmustine, lomustine) can cross the blood-brain barrier and have been used to treat primary brain tumors (e.g., gliomas) and melanoma, and lymphomas have metastasized to the brain. Cytosine arabinoside is an antimetabolite that crosses the blood-brain barrier. Ifosfamide, an alkylating prodrug, and some of its metabolites, bio-activated by the liver, can penetrate the blood-brain barrier. Unlike cyclophosphamide, ifosfamide is associated with CNS toxicity in 10–30 % of treated patients. Some reported CNS effects include confusion, drowsiness, hallucinations, seizures, and extrapyramidal symptoms [84].

Finally, the described mechanisms show the different effects of chemotherapeutic agents that directly or indirectly affect the communication or function of essential brain regions involved in cognition, such as the prefrontal cortex, hippocampus and striatum [36]. For this reason, further research should continue to explore the short- and long-term effects of chemotherapeutics, as this will also help in the development of therapeutic strategies.

### 3.2. Future directions

Although different investigations have linked the link between the adverse effects of chemotherapy and cognitive dysfunction, the causes and mechanisms of neurotoxicity are still not well understood. This review examined relevant articles published on this topic to gather knowledge about the mechanisms associated with chemotherapy-induced cognitive impairment. For example, the mechanisms of action of several chemotherapeutic agents have been reported to be related to increased oxidative stress and mitochondrial dysfunction, which causes neuronal damage and therefore affects neurogenesis, neuroplasticity, and cognitive function. In addition, evidence shows that oxidative stress can disrupt the integrity of the blood-brain barrier, allowing neurotoxic substances to enter the brain parenchyma. Therefore, the systemic administration of antioxidant molecules or protectors of mitochondrial activity may be promising in preventing cognitive deterioration. Likewise, plant-derived natural products could potentially prevent or reduce chemotherapy-initiated neurotoxicity. Then, there is a need to explore a possible therapeutic approach to minimize the neurotoxicity induced by systemic chemotherapeutic agents.

On the other hand, CRCI can be caused by an increase in the levels of proinflammatory cytokines, which leads to an increase in inflammation, with effects in the reduction of metabolism in critical regions for learning and memory processes, such as the hippocampus, which can lead to memory impairment. Additionally, it has been reported that the induced inflammatory environment decreases the integrity of the BBB and makes it permeable to neurotoxins. Alternatively, peripheral leukocytes and neutrophils can induce microglia and macroglia activation

with increased proinflammatory cytokine production. In this scenario, naturally occurring molecules with anti-inflammatory activity together with combination chemotherapy could be a novel therapeutic approach to prevent the progression of neurotoxicity in patients treated for cancer.

On the other hand, the mechanisms that imply the reduction of neurogenesis, the deregulation of plasticity, and, therefore, neuronal dysfunction still need to be clarified and investigated in future studies since they could shed light on pharmacological targets that allow the development of therapeutic strategies preventative against chemo brain.

Since most of the original articles presented here report results obtained in healthy mouse models, it is essential to validate these results in cancer models, rarely contemplated, to dissect chemotherapy-induced cognitive impairment from the effects induced by the disease itself. In addition, during the review, it became apparent that some murine models used only males or only females or only ovariectomized females. In these cases, valuable information about the effect of chemotherapy in the groups not under consideration could be lost. Therefore, it would be enlightening if more controls could be considered within the experimental design to have a global vision of the results obtained.

## 4. Conclusion

Cancer-Related Cognitive Impairment is a complex phenomenon mediated by altered neurobiological mechanisms that lead to neurotoxicity, decreasing functionality directly or indirectly. The main neurotoxic effects rely on increased oxidative stress and mitochondrial dysfunction that finally can lead to the loss of neuronal plasticity, inducing decreased dendritic arborization, loss of spines, demyelination, and alterations related to neurotransmission that may cause neurodegeneration. Other mechanisms of damage indirectly caused by the effect of glial cells (macroglia or microglia), such as neuroinflammation and damage to the BBB, are highlighted in the pathophysiology.
