ABSTRACT

Background

People with hyperglycaemia concomitant with an acute stroke have greater mortality, stroke severity, and functional impairment when compared with those with normoglycaemia at stroke presentation. This is an update of a Cochrane Review first published in 2011.

Objectives

To determine whether intensively monitoring insulin therapy aimed at maintaining serum glucose within a specific normal range (4 to 7.5 mmol/L) in the first 24 hours of acute ischaemic stroke influences outcome.

Search methods

We searched the Cochrane Stroke Group Trials Register (September 2013), CENTRAL (*The Cochrane Library* 2013, Issue 8), MEDLINE (1950 to September 2013), EMBASE (1980 to September 2013), CINAHL (1982 to September 2013), Science Citation Index (1900 to September 2013), and Web of Science (ISI Web of Knowledge) (1993 to September 2013). We also searched ongoing trials registers and SCOPUS.

Selection criteria

Randomised controlled trials (RCTs) comparing intensively monitored insulin therapy versus usual care in adults with acute ischaemic stroke.

Data collection and analysis

We obtained a total of 1565 titles through the literature search. Two review authors independently selected the included articles and extracted the study characteristics, study quality, and data to estimate the odds ratio (OR) and 95% confidence interval (CI), mean difference (MD) and standardised mean difference (SMD) of outcome measures. We resolved disagreements by discussion.

Main results

We included 11 RCTs involving 1583 participants (791 participants in the intervention group and 792 in the control group). We found that there was no difference between the treatment and control groups in the outcomes of death or dependency (OR 0.99, 95% CI 0.79 to 1.23) or final neurological deficit (SMD -0.09, 95% CI -0.19 to 0.01). The rate of symptomatic hypoglycaemia was higher in the intervention group (OR 14.6, 95% CI 6.6 to 32.2). In the subgroup analyses of diabetes mellitus (DM) versus non-DM, we found no difference for the outcomes of death and disability or neurological deficit. The number needed to treat was not significant for the outcomes of death and final neurological deficit. The number needed to harm was nine for symptomatic hypoglycaemia.

Authors' conclusions

After updating the results of our previous review, we found that the administration of intravenous insulin with the objective of maintaining serum glucose within a specific range in the first hours of acute ischaemic stroke does not provide benefit in terms of functional outcome, death, or improvement in final neurological deficit and significantly increased the number of hypoglycaemic episodes. Specifically, those people whose glucose levels were maintained within a tighter range with intravenous insulin experienced a greater risk of symptomatic and asymptomatic hypoglycaemia than those people in the control group.

PLAIN LANGUAGE SUMMARY

Controlling high blood sugar levels with insulin in people who have had an acute ischaemic stroke

After a stroke, people with high levels of sugar in their blood have increased mortality regardless of their age, how severe the stroke was, or what type of stroke they had. Insulin can reduce blood sugar levels. We do not know what the optimal level of blood sugar should be after a stroke. We searched for trials that compared usual care with intensive insulin treatment (trying to keep blood sugar levels within the normal range of 4 to 7.5 mmol/L) after stroke. We found 11 trials involving 1583 participants. Trying to keep the blood sugar level within a tight range immediately after a stroke did not improve the outcomes of neurological deficit and dependency. It did, however, significantly increase the chance of experiencing very low blood sugar levels (hypoglycaemia), which can be harmful and can cause brain damage and death. On balance, the trials did not show any benefit from intensive control of blood sugar levels after stroke.

BACKGROUND

Description of the condition

Hyperglycaemia (where the blood glucose concentration is greater than 6.1 mmol/L) on admission to hospital is common after acute ischaemic stroke and occurs in up to two-thirds of all patients (Scott 1999). There has been much debate over the years as to whether hyperglycaemia in people with acute stroke is the result of a stress response (Candelise 1985; Jorgensen 1994), poor glycaemic control in people with diabetes, or unrecognised diabetes. Regardless, the majority of clinical trials have concluded that hyperglycaemia predicts increased stroke mortality independently of age, stroke severity, or stroke type (Capes 2001; Gray 1987; Melamed 1976; Weir 1997). However, the uncertainty over whether hyperglycaemia worsens prognosis through the augmentation of acute brain injury (Jorgensen 1994; Kiers 1992; Van Kooten 1993; Weir 1997) or is merely a physiological response to acute stroke (Murros 1992; Murros 1993; O'Neill 1991; Woo 1988) still remains.

Hyperglycaemia has been shown to have a deleterious effect on ischaemic brain tissue in numerous animal studies, and many mechanisms have been proposed to explain this phenomenon (de Courten-Myers 1989; Gisselsson 1999; Lin 1998; Myers 1977; Pulsinelli 1982). One of the most consistent findings is the association between hyperglycaemia and cerebral acidosis (Pulsinelli 1982; Rehncrona 1981). Enhanced acidosis may exaggerate ischaemic neuronal injury by facilitating free radical formation, activating pH-dependent endonucleases, or altering intracellular calcium regulation (Barber 1967; Barry 1993; Combs 1992; Regli 1996; Rehncrona 1981; Siesjo 1985; Siesjo 1996). Moderately and severely elevated blood glucose levels have been shown to enhance cortical intracellular acidosis and significantly worsen mitochondrial function (Anderson 1999; Hoxworth 1999).

It has also been postulated that intracellular acidosis enhances glutamate release. Glutamate plays a central role in neuronal death because it activates post-synaptic glutamate receptors and leads to an excessive influx of calcium, subsequent mitochondrial injury, and cell death (Li 2000; Nedergaard 1996). In addition, the pre-synaptic release of glutamate mediates repeated waves of spreading depression (a decrease of activity in the cortex), which is another mechanism believed to propagate the necrosis of penumbral tissue (Koistinaho 1999; Lo 2003).

Previous studies in humans showed that people with acute ischaemic stroke and hyperglycaemia had worse outcomes when compared with those with normal glycaemic levels. Multiple observational studies have showed that people with hyperglycaemia exhibited greater stroke severity and greater functional impairment than those with normoglycaemia; people with hyperglycaemia were 2.3 times more likely to be dead at 90 days compared with those with normal glucose levels in one study (Stead 2009). To date, most of the work done in humans in the field of hyperglycaemia and stroke has been limited to correlating the presence of hyperglycaemia to ischaemic stroke outcome. The next logical step in this debate is to ascertain whether treating hyperglycaemia following stroke does, in fact, reduce mortality and improve functional outcome.

Description of the intervention

Insulin has a number of effects on glucose metabolism including inhibition of glycogenolysis and gluconeogenesis, increased glucose transport into fat and muscle, increased glycolysis, and stimulation of glycogen synthesis (Ramnanan 2010). All these mechanisms decrease the levels of circulating glucose. Insulin serves to co-ordinate the use of alternative fuels (glucose and free fatty acids) to meet the energy demands of the organism during fasting, exercise, and stress (Farese 1991; Fielding 1998).

How the intervention might work

In acute stroke the initial ischaemia is rarely complete due to collateral blood supply. The ischaemic penumbra is the area of hypoperfused, but still viable, tissue that surrounds a densely ischaemic, hypoxic core. This is the area that is vulnerable to the metabolic imbalances mentioned above. With hyperglycaemia, there is a reduction in penumbral salvage and an increase in brain lactate levels (Parsons 2002). Therefore, it is believed that if the detrimental effects associated with hyperglycaemia are mediated primarily through metabolic mechanisms, tight glycaemic control during acute stroke may reduce the extent of ultimate brain injury (Bruno 2004). Acute hyperglycaemia is associated by neuroimaging with reduced salvage of penumbral tissue and greater final infarct size (Parsons 2002), and hyperglycaemia is associated with reduced benefit from recanalization with thrombolytic therapy (Bruno 2002). Also, experimental studies have showed that administration of insulin during focal and global ischaemia may reduce subsequent brain damage (Auer 1998; Hamilton 1995; Voll 1989; Voll 1991; Wass 1996; Zhu 1994).

Why it is important to do this review

Previous versions of our review (Bellolio 2008; Bellolio 2011) showed that the use of insulin to maintain glycaemia in a tight range had no improvement in functional outcome, death, or final neurological deficit and significantly increased the number of hypoglycaemic episodes.

The purpose of this review is to update the previous review with new information to ascertain whether the use of insulin to control hyperglycaemia within a tight range in the acute phase of ischaemic stroke influences outcome.

OBJECTIVES

To determine whether intensively monitoring insulin therapy aimed at maintaining serum glucose within a specific normal range (4 to 7.5 mmol/L) in the first 24 hours of acute ischaemic stroke influences outcome.

METHODS

Criteria for considering studies for this review

Types of studies

All randomised controlled trials (RCTs) comparing insulin with placebo, low dose insulin versus high dose insulin, or close monitoring of glucose versus loose monitoring in people with acute ischaemic stroke with blood glucose levels greater than 6.1 mmol/L were eligible for inclusion.

Types of participants

Trials that included adults, older than 18 years of age, presenting within 24 hours of acute ischaemic stroke with serum glucose levels greater than 6.1 mmol/L were eligible for inclusion. We included people of either gender both with and without diabetes.

Definite ischaemic stroke implies people in whom computed tomography (CT) or magnetic resonance imaging (MRI) was performed before randomisation. Presumed ischaemic stroke refers to people who did not have a CT or MRI so haemorrhage could not be excluded.

Types of interventions

We included trials that evaluated intervention with insulin, or tight glycaemic control, to maintain a glycaemic level between 4 and 7.5 mmol/L (72 to 135 mg/dL). The intervention had to start within 24 hours of symptom onset. The control interventions were placebo, no treatment, or loose control with insulin.

Types of outcome measures

Primary outcomes

Death or dependency at the end of the scheduled follow-up. Dependency is defined as being severely dependent on others in activities of daily living, or being significantly disabled; this corresponds to a Barthel Index score 60 or less, or a modified Rankin Scale grade 3 to 6 (Uyttenboogaart 2007).

Secondary outcomes

1. Measures of neurological deficit after intervention for hyperglycaemia, including the National Institutes of Health Stroke Scale (NIHSS) and the European Stroke Scale (ESS).
2. Number of deaths in each group at the end of the scheduled follow-up.
3. Hypoglycaemia, defined as glucose concentration less than 3 mmol/L. Symptomatic hypoglycaemia was defined as confusion, visual disturbances, seizures, sweating, or hunger in a person with a glucose level lower than 3 mmol/L. The numbers of hypoglycaemic events (symptomatic and asymptomatic) in each group were compared.

Search methods for identification of studies

See the 'Specialized register' section in the [Cochrane Stroke Group](#) module. We did not apply any language restrictions and arranged translation of relevant articles published in languages other than English.

Electronic searches

We searched the Cochrane Stroke Group Trials Register (last searched September 2013). We also searched MEDLINE (1950 to September 2013) (Appendix 1), the Cochrane Central Register of Controlled Trials (CENTRAL) (*The Cochrane Library* 2013, Issue 8) (Appendix 2), EMBASE (1980 to September 2013) (Appendix 3), Science Citation Index (1900 to September 2013) (Appendix 4), Web of Science (1993 to September 2013) (Appendix 5), and CINAHL (1982 to September 2013) (Appendix 6). The Cochrane Stroke Group Trials Search Co-ordinator developed the MEDLINE search strategy, which was adapted for the other databases by a reference librarian who also ran the searches.

In an effort to identify further published, unpublished, and ongoing trials we searched:

1. Stroke Trials Directory (www.strokecenter.org/trials/),
2. ClinicalTrials.gov (<http://clinicaltrials.gov/>),
3. Current Controlled Trials (www.controlled-trials.com/),
4. SCOPUS (www.scopus.com/).

Searching other resources

We checked the reference lists of the selected articles to identify additional trials.

Data collection and analysis

Selection of studies

Two review authors (MFB and RMG) independently screened the titles and abstracts of the records identified from the electronic searches and excluded obviously irrelevant studies. We obtained the full texts of the remaining papers and the same review authors selected studies for inclusion based on the predefined criteria. The review authors were not blinded to the journal, institution, or study authors.

Data extraction and management

Using a standardised data extraction form and working in duplicate, two review authors (MFB and RMG) abstracted the following descriptive data from every study: description of randomisation, concealment of participants, blinding, intention to treat and lost to follow-up as part of the quality assessment. The same two review authors also collected information on: definitive or presumed acute ischaemic stroke (based on the use of CT or MRI before or after randomisation), number of participants, gender, age, proportion of people with diabetes, setting (stroke unit, critical care unit, or non-critical care unit), characteristics of treatment and control interventions (insulin dose, frequency, route, and duration), co-interventions, and frequency of the glucose level checks.

We abstracted the specific stroke outcomes from every study. We collected end-of-study deaths, Barthel score, Rankin Scale, National Institutes of Health Stroke Scale (NIHSS), European Stroke Scale (ESS), and the number of hypoglycaemic events (symptomatic and asymptomatic). Outcomes were collected at the end of follow-up. Follow-up was defined for each study as ≤ 30 or ≤ 90 days. We contacted all the authors of the included studies, if data were missing or unclear, to obtain full details.

The same two review authors resolved any discrepancies between the two sets of data through discussion. One author (MFB) entered the data into the Review Manager software, RevMan 5.2 (RevMan 2012) and performed the analyses.

Assessment of risk of bias in included studies

Two review authors (MFB and RMG) independently assessed risk of bias for each study using the criteria outlined in the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2011). We resolved any disagreements by discussion. We assessed the risk of bias according to the following domains.

1. Random sequence generation.
2. Allocation concealment.
3. Blinding of participants and personnel.

4. Blinding of outcome assessment.
5. Incomplete outcome data.

We graded the risk of bias for each domain as high, low, or unclear and provided information from the study report together with a justification for our judgment in the 'Risk of bias' tables.

Measures of treatment effect

The treatment was insulin and the measurements of treatment effect were glucose levels and functional scales including death, Barthel score, Rankin Scale, NIHSS, ESS, and the number of hypoglycaemic events (symptomatic and asymptomatic).

Unit of analysis issues

The glucose level is a continuous variable and was provided in mg/dL or mmol/L; all the values were converted to the same unit (mmol/L) prior to any analysis.

When the scales used different units of measure, that is Barthel and ESS to evaluate functional outcome, we used standardised mean differences (SMDs) as recommended by the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2011).

Dealing with missing data

We contacted all the authors of the included studies, if data were missing or unclear, to obtain full details regarding study design, outcomes, and attrition rates. When the data were not available, we included the study in the qualitative analysis. For missing measures of precision, that is missing standard deviations, we estimated these with the available information, like interquartile range or standard error, according to the *Cochrane Handbook for Systematic Reviews of Interventions* (Higgins 2011).

Assessment of heterogeneity

We assessed clinical heterogeneity by determining whether the characteristics of the participants, interventions, outcome measures, and timing of outcome measurement were similar across studies. We assessed statistical heterogeneity using the I^2 statistic.

Assessment of reporting biases

When the data were not available we contacted the study authors for more information. If data were still missing we classified the study as unclear. For the assessment of publication bias, we evaluated funnel plots if at least 10 studies examined the same outcome.

Data synthesis

We used RevMan 5.2 (RevMan 2012) for all the meta-analyses.

We analysed the primary outcome of death or dependency at the end of the scheduled follow-up as a binary outcome.

For the secondary outcome of neurological deficit after intervention, the NIHSS and the ESS are ordinal scales with a minimum increment of one point and we used these as continuous variables for the purposes of the analyses. The NIHSS ranges from 0 to 42 points, with 0 points being no measurable neurological deficit. The ESS ranges from 0 to 100 points, with 0

points being bedridden. We analysed hypoglycaemia as a binary outcome with a cut-off value of less than 3 mmol/L and defined symptomatic hypoglycaemia as confusion, visual disturbances, seizures, sweating, or hunger in a person with a glucose level lower than 3 mmol/L.

For continuous outcomes we determined the pooled mean difference (MD) between the treatment and control interventions and the associated 95% confidence interval (CI) using a fixed-effect model. For continuous outcomes using different scales (for example for assessment of the final deficit with the NIHSS and ESS) we determined the pooled SMD between the treatment and control interventions and the associated 95% CI using a fixed-effect model. For binary outcomes we determined the odds ratio (OR) between the treatment and control interventions and the associated 95% CI using a fixed-effect model.

When any of the values in the outcome was zero, a 0.5 continuity correction factor was applied automatically by the RevMan software (0.5 added to all cells).

Subgroup analysis and investigation of heterogeneity

We determined subgroup analyses a priori. We compared:

1. diabetic versus non-diabetic cohorts for the outcomes of death and dependency, and final neurological deficit. Most of the studies did not report results separated by diabetic status so we did the analysis comparing the cohorts with more than 50% diabetic versus less than 50% diabetic;
2. outcomes measured at less than 30 days versus 90 days.

To explore these hypotheses, we estimated the difference in treatment effects between subgroups or treatment-subgroup interactions (Altman 2003).

We quantified heterogeneity and inconsistency in the studies using the I^2 statistic, which describes the proportion of variance across studies not due to chance.

Sensitivity analysis

We determined sensitivity analyses a priori. We excluded:

1. studies with presumed diagnosis of ischaemic stroke (studies that did not perform CT or MRI before the randomisation, therefore haemorrhagic strokes were not excluded);
2. studies where the controls received insulin (loose control studies);
3. studies with inadequate allocation concealment;
4. the largest study.

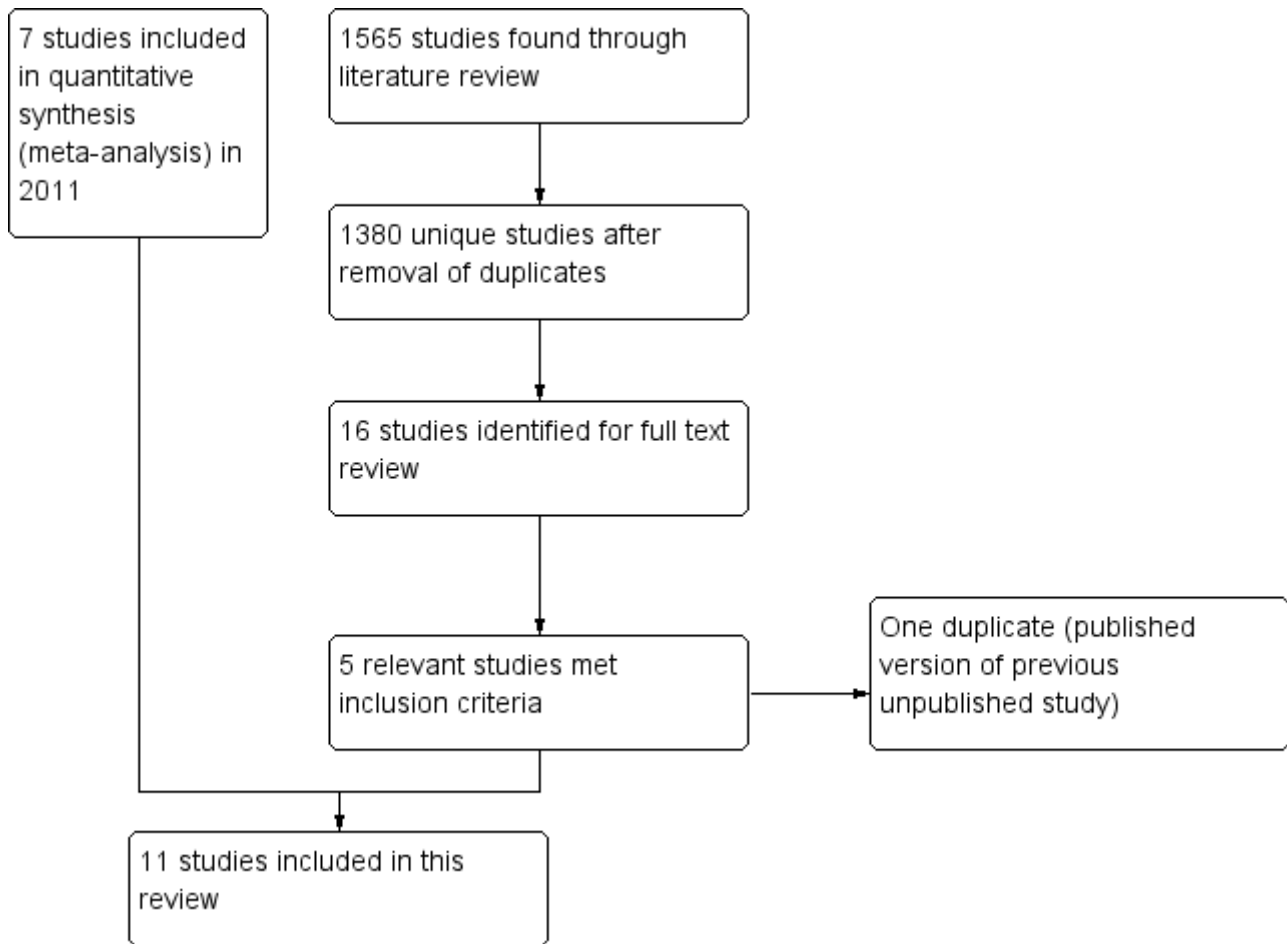

RESULTS

Description of studies

Results of the search

We obtained a total of 1565 articles and, after removing duplicates, we manually screened 1380 records. We retrieved a total of 16 trials for more detailed evaluation. We included four new trials and one study was the published version of a previously included study (Staszewski 2011). See Figure 1 for details.

Figure 1. Study flow diagram.

Included studies

We included a total of 11 trials involving 1583 participants (791 participants in the intervention group and 792 in the control group). Three ongoing studies at the time of our previous review were completed and have been included in this review (Azevedo 2009; INSULINFARCT 2012; McCormick 2010).

Enrolled participants were typically older people (mean age 74 years) with equal gender distribution. Baseline characteristics were similar in the intervention and control groups, with higher baseline glycaemic levels measured at admission in the cohorts with a higher proportion of people with diabetes mellitus.

In GIST-UK 2007, 16% of the cohort had a disease different from ischaemic stroke but with a measurable neurological impairment (for example intracranial haemorrhage).

In nine studies participants had a definitive diagnosis of acute ischaemic stroke prior to randomisation. All 11 studies reported intervention with an intravenous insulin infusion. Vynychuk 2005 reported the results separately for participants with and without diabetes mellitus.

For the functional outcome, four studies used the Barthel score and six studies used the modified Rankin Scale. Walters 2006 did not report functional outcome scales.

One study in the previous version of this review (Staszewski 2007) is now included as a published study (Staszewski 2011).

For the neurological deficit assessment, six studies reported the NIHSS and one reported the ESS at the end of the follow-up. The NIHSS is a 42-point score; a higher score indicates a worse functional outcome and higher level of disability. The ESS score ranges from 0 to 100 points, 0 being bedridden and a higher score showing a better functional outcome. Ten studies reported hypoglycaemia and eight reported deaths; Vynychuk 2005 did not report these outcomes.

Azevedo 2009 was available in abstract format only and we contacted the author to obtain more information. We also contacted the author of an ongoing study (NCT00373269) and the study is currently inactive. We contacted other authors for the previous version of this review.

Excluded studies

Excluded studies were those that did not meet the inclusion criteria. Some studies were not included because: (1) they were not randomised trials, (2) they had a mixed critical care population with less than 5% of the participants having ischaemic stroke (Green 2010), or (3) stroke was an outcome of the study but the study was not done on stroke participants (CIMT Trial; Miyashita 2008; VADT).

Risk of bias in included studies

All studies were randomised with a parallel design. [GRASP 2009](#) was stratified by glucose concentration, and [Vriesendorp 2009](#) was stratified by dysphagia and diabetes mellitus (DM). All studies except [Vriesendorp 2009](#) had adequate generation of randomisation. There was a high risk of bias in allocation concealment in five of the 11 studies, and most of the assessors of outcomes were not blinded.

Four studies had a high risk of bias secondary to inadequate allocation: in [Staszewski 2011](#) the list was read by the investigator

entering the participant into the trial; [Vriesendorp 2009](#) used consecutive envelopes; and [Azevedo 2009](#) and [Kreisel 2009](#) did not report this information. In none of the studies were physicians blinded to the intervention. Participants were blinded to the intervention in [Azevedo 2009](#) and [THIS 2008](#), and in four studies the outcome assessment was blinded ([GIST-UK 2007](#); [GRASP 2009](#); [Staszewski 2011](#); [THIS 2008](#)).

[GRASP 2009](#) and [Walters 2006](#) were pilot studies, and [GIST-UK 2007](#) was stopped early due to the slow enrolment rate. See the summary risk of bias in [Table 1](#) and [Figure 2](#).

Figure 2. Risk of bias summary: review authors' judgements about each risk of bias item for each included study.

	Random sequence generation (selection bias)	Allocation concealment (selection bias)	Blinding of participants and personnel (performance bias)	Blinding of outcome assessment (detection bias)	Incomplete outcome data (attrition bias)
Azevedo 2009	+	?	-	-	?
GIST-UK 2007	+	+	-	+	-
GRASP 2009	+	+	-	+	+
INSULINFARCT 2012	+	+	-	-	+
Kreisel 2009	+	?	-	-	+
McCormick 2010	+	?	-	-	?
Staszewski 2011	+	-	-	+	+
THIS 2008	+	+	-	+	+
Vynychuk 2005	+	+	-	-	-
Vriesendorp 2009	-	-	-	-	-
Walters 2006	+	+	-	-	+

Allocation

Six studies had adequate allocation, two studies had a high risk of bias because either the list was read by the investigator (Staszewski 2011) or consecutive envelopes were used (Vriesendorp 2009), and two studies did not provide this information (Kreisel 2009; McCormick 2010).

Blinding

All the studies had a high risk of bias with regard to blinding. Most of the studies were not blinded to the treatment arm and had different treatments and co-interventions for the intervention and control groups. In no studies were the physicians blinded to the intervention. Two studies (Azevedo 2009; THIS 2008) had participants blinded to the intervention. Four studies had outcome assessors blinded to the allocation group (GIST-UK 2007; GRASP 2009; Staszewski 2011; THIS 2008).

Incomplete outcome data

Most of the studies had an adequate attrition rate and the loss to follow-up was between 0% (Staszewski 2011; THIS 2008; Vynychuk 2005; Walters 2006) to 15.2% (Vriesendorp 2009). The loss to follow-up was 7.4% in GIST-UK 2007, 7.5% in Kreisel 2009, 1.4% in GRASP 2009, unknown in Vynychuk 2005 but estimated to be 2.3%, estimated to be 15.2% in Vriesendorp 2009, and 2.2% in INSULINFARCT 2012. Loss to follow-up was not reported in Azevedo 2009 or McCormick 2010. All the studies used intention-to-treat (ITT) analyses. One study reported results per protocol and used ITT (INSULINFARCT 2012). GIST-UK 2007 was terminated early because of the low enrolment rate.

Selective reporting

It is possible that there was reporting bias. However, we did not detect significant selective reporting among the included studies. Most of the studies had a functional outcome reported as well as death and hypoglycaemia as outcomes.

Other potential sources of bias

Azevedo 2009 was available in abstract format only thereby increasing the risk of bias and risk to methodological quality. Full text articles were available for the other 10 studies.

Effects of interventions

The mean glycaemic level during treatment was significantly lower in the intervention group than in the control group, with an MD of -0.63 (95% CI -0.80 to -0.46, Analysis 4.1). The average glucose level in the intervention group was 6.7 mmol/L, and 7.3 mmol/L in the loose control group.

Dependency or death

Modified Rankin grades and Barthel scores were used. Meta-analysis of the nine comparisons (1516 participants) found no significant difference between the treatment and control groups, with an OR of 0.99 (95% CI 0.79 to 1.23, Analysis 1.1).

Death

Meta-analysis of the nine comparisons (1422 participants) found no significant difference between the treatment and control groups, with an OR of 1.09 (95% CI 0.85 to 1.41, Analysis 1.2).

Final neurological deficit

NIHSS and ESS were used. Meta-analysis of the eight comparisons (1432 participants) found no significant difference between the treatment and control groups, with a pooled SMD of -0.09 (95% CI -0.19 to 0.01, Analysis 2.1).

When using the dichotomised outcome of dependency on others for functional activities, the comparison of the nine studies had an OR of 1.03 (95% CI 0.81 to 1.32, Analysis 2.2).

Hypoglycaemia

Meta-analysis of the 10 comparisons (1455 participants) found a significant difference in the incidence of hypoglycaemia between the treatment and control groups, with an OR of 14.6 (95% CI 6.6 to 32.2) for symptomatic hypoglycaemia and an OR of 18.4 (95% CI 9.1 to 37.3) in participants with or without symptoms of hypoglycaemia (Analysis 3.1 and Analysis 3.2).

Subgroup analyses

Diabetes mellitus versus no diabetes mellitus (DM)

For the outcome of dependence or death we compared those studies with 50% or more of the cohort having DM versus the studies with less than 50% of the cohort with DM. Vynychuk 2005 reported these cohorts separately. The studies included in the DM group were THIS 2008 (100% DM in the intervention group and 73.3% in the control group), Walters 2006 (53.9% in the intervention and 50% in the control group), and GRASP 2009 (50% in the intervention and 64% in the control group). The studies included in the no DM cohort were GIST-UK 2007 (17% in the intervention and 16% in the control), Staszewski 2011 (0% DM), Kreisel 2009 (30% DM in the intervention and 35% in the control group), McCormick 2010 (28% in the intervention and 40% in the control group), INSULINFARCT 2012 (8% in the intervention and 17% in the control group), and Vriesendorp 2009 (35% in the intervention and 40% in the control group).

The meta-analysis found no significant difference between the treatment and control groups for the outcome of dependency or death when stratified by DM status, with an OR of 0.66 (95% CI 0.35 to 1.24) for DM and an OR of 1.02 (95% CI 0.81 to 1.30) for participants without DM (Analysis 1.3).

For the outcome of final neurological deficit, the SMD for participants with DM was -0.06 (95% CI -0.43 to 0.31) and for participants without DM it was -0.08 (95% CI -0.19 to 0.03, Analysis 2.3).

Follow-up

For the outcome of dependency or death, we compared the studies with the outcome measured earlier than 30 days versus 90 days. The studies with 30 days of follow-up were: Azevedo 2009, Kreisel 2009, McCormick 2010, Staszewski 2011, Vynychuk 2005, Vriesendorp 2009, and Walters 2006. However, Staszewski 2011 and Walters 2006 did not report this outcome. The studies with 90 days of follow-up were GIST-UK 2007, GRASP 2009, INSULINFARCT 2012, and THIS 2008. Meta-analysis of the comparisons found no significant difference between the treatment and control groups when stratified by follow-up, with an OR of 0.74 (95% CI 0.43 to 1.25) for 30 days and an OR of 1.05 (95% CI 0.82 to 1.34) for 90 days (Analysis 1.4).

For the outcome of final neurological deficit, we found a statistically significant difference between 30 days and 90 days of follow-up, in favour of the intensive glucose control group, with a SMD of -0.47 (95% CI -0.72 to -0.23) for 30 days and 0.00 (95% CI -0.12 to 0.11) for 90 days of follow-up ([Analysis 2.4](#)).

Sensitivity analyses

1. Excluding the studies with a presumed diagnosis of ischaemic stroke ([GIST-UK 2007](#); [Vriesendorp 2009](#)): the OR for death or dependency (primary outcome) was 0.82 (95% CI 0.58 to 1.17).
2. Excluding studies where the controls received insulin: in all the studies except [Walters 2006](#) the control group received insulin. The range of glycaemia was different in the different studies. The study by [Vynychuk 2005](#) did not report the intervention in the control group.
3. Excluding studies with inadequate allocation concealment ([Azevedo 2009](#); [Kreisel 2009](#); [McCormick 2010](#); [Staszewski 2011](#); [Vriesendorp 2009](#)). The outcome of dependency or death had an OR of 1.0 (95% CI 0.79 to 1.26).
4. Excluding the largest study: this was the [GIST-UK 2007](#) study because the results were the same as above with an OR of 0.82 (95% CI 0.58 to 1.17).

DISCUSSION

Our updated systematic review and meta-analyses found similar results to those published two years ago and suggest that the administration of intravenous insulin in an attempt to maintain serum glucose within a specific normal range in the first hours of acute ischaemic stroke does not provide benefit in terms of functional outcome or deaths at 30 days or 90 days, or improvement in final neurological deficit.

While there was no difference in net benefit noted between the treatment and control groups, there was a significant difference between the groups with regard to the adverse event of hypoglycaemia. Specifically, those participants who were maintained within a more tight range of glycaemia with intravenous insulin experienced a greater risk of symptomatic and asymptomatic hypoglycaemia than those in the control group.

When examining the endpoint of dependency or death, subgroup analyses showed that there was no difference between participants with DM and those without, and there was no difference when looking at the outcome at 30 days or 90 days.

For the endpoint of final neurological deficit, we found no difference in the mean NIHSS or ESS scores between the intervention and control groups. In the subgroup analyses there was no statistically significant difference between the DM and non-DM cohorts. This means that the treatment did not appear to be more effective in one or the other group of participants.

For the subgroup analyses of neurological deficit at 30 days versus 90 days, the effect of the intervention was favourable in those studies that reported the outcome at 30 days but not at 90 days; this result is difficult to interpret because the natural history of ischaemic stroke is that the outcomes improve and stabilize by three months, which is likely to be why this time point is more common and reliable in studies of ischaemic stroke. Another possible explanation for this result is better quality of the studies that reported the outcomes at 90 days; as these studies were

bigger and accounted for 81% of the total number of participants included in the review; two of the three studies were blinded to the allocation group when evaluating the neurological and functional outcomes. In comparison, for the 30-day outcome only one of the five studies was blinded for the neurological and functional outcome assessments.

When plotting the results in a two by two table we found that the number needed to treat (NNT) or to harm (NNH) for the outcome of death was 91, meaning that one in every 91 patients could be harmed by the treatment, with an absolute risk increase of 1.10% in the treatment group (95% CI -3.3 to 5.5%). Because the confidence interval includes positive and negative numbers, the NNT or NNH was not significant between the treatment and control groups for this outcome.

The NNT for the outcome of dependency or death was 419, meaning that one in every 419 patients could benefit from the treatment, with an absolute risk reduction of 0.24% in the treatment group (95% CI -4.5% to 5.0%). Because the confidence interval includes positive and negative numbers, the NNT was not significant between the treatment and control groups for this outcome.

The NNH for the outcome of symptomatic hypoglycaemia was nine, meaning that one in every nine patients will have a symptomatic hypoglycaemic event with an absolute risk increase of 11.5% in the treatment group (95% CI 9.1 to 13.9%). This is statistically significant. The 95% CI for the NNT ranges from 7.2 to 11.0.

Remaining questions include how tight the control must be to obtain the most benefit without increasing the risk for severe hypoglycaemia, and whether an acuity level exists in which this benefit is not clearly visualized ([Bochicchio 2008](#)). The extent to which intensive insulin therapy and tight control of blood glucose improve the outcome after ischaemic neurological insults remains unclear. The benefit of such treatment regimes may be negated by the hypoglycaemic episodes, which may aggravate neurological injury ([Prakash 2008](#)). Although it seems sensible to control hyperglycaemia in people with neurological injury the treatment must account for potential hypoglycaemic episodes, which can be detrimental. Therefore, it seems prudent that we accept slightly less tight blood glucose control than in critically ill people without neurological injury.

Summary of main results

Our review suggests that the administration of intravenous insulin in an attempt to maintain serum glucose within a specific normal range in the first hours of acute ischaemic stroke does not provide benefit in terms of functional outcome, disability, improvement in final neurological deficit, or death at 30 or 90 days, and confers a greater risk of symptomatic and asymptomatic hypoglycaemia.

Overall completeness and applicability of evidence

The studies identified in this review are sufficient to address the objectives of the review, and the population that is included allows for good generalization of the results and external validity. The studies include more than 1000 participants from different countries overall. These results discourage the maintenance of a tight glycaemic control.

Quality of the evidence

We included 11 trials involving 1583 participants (791 intervention and 792 controls). There was an intermediate risk of bias overall. The allocation concealment was adequate in most of the studies, but most of the studies were not blinded. The heterogeneity across the studies was adequate.

Potential biases in the review process

The results of this systematic review and meta-analysis should be interpreted with caution for several reasons. First, only 11 studies were available for inclusion in the analyses. Second, the studies were performed in a stroke unit and not in the general ward. Specialised units for the management of people with stroke have been shown to improve the outcomes of those people presenting with haemorrhagic and ischaemic strokes, and should be the preferred setting ([Langhorne 1993](#)).

For the meta-analyses we decided to use the fixed-effect method instead of the random-effects method because of a suspected acceptable level of heterogeneity across the studies ([Cook 1995](#)). The random-effects method assumes that the different studies are estimating different, yet related, treatment effects ([DerSimonian 1986](#)). The random and inverse variance methods will give similar results when there is no heterogeneity among the studies. Where there is heterogeneity, confidence intervals for the average treatment effect will be wider if the random-effects model rather than a fixed-effect model is used, and corresponding claims of statistical significance of the treatment effect will be more conservative. It is also possible that the central estimate will change if there are relationships between the observed treatment effects and sample sizes. The fixed-effect model is based on the mathematical assumption that a single common effect underlies every study in the meta-analysis; this assumes that there is low heterogeneity among the studies.

When evaluating heterogeneity the readers must be cautious in interpreting the I^2 statistic because of the moderate number of studies included and the small number of participants in each study. Therefore, tests that do not reject the null hypothesis do not necessarily indicate absence of heterogeneity ([Montori 2003](#)). However, we decided that it was sensible to pool the results. Heterogeneity comes from clinical differences. For instance, the biggest study ([GIST-UK 2007](#)) included 16% of participants without an ischaemic stroke, contributing to some degree to heterogeneity. Another source of heterogeneity is differences in the treatment effects secondary to a different methodological approach ([Montori 2003](#)); for instance, few studies were blinded to the allocation group when assessing the outcome. To explore heterogeneity we performed subgroup analyses. One particular problem with the [GIST-UK 2007](#), the biggest included study, is that there might be confounding that is secondary to lower blood pressure levels in the intervention group. This study found that the overall mean plasma glucose level and mean systolic blood pressure were significantly lower in the glucose-insulin-potassium group (MD in glucose 0.57 mmol/L, $P < 0.001$; MD in blood pressure 9.0 mm Hg, $P < 0.0001$).

For the secondary outcome of final neurological deficit, we used ordinal scales (NIHSS and ESS) as continuous outcomes, and we made the assumption that they followed a normal distribution for the purposes of the meta-analyses, but we acknowledge that in clinical practice most of the functional scales have a skewed

distribution in favour of better scores. We are aware that the methods for meta-analysis of continuous data assume that the outcomes have a normal distribution in each treatment arm in each study. This assumption may not always be met, although this is less important in large studies.

For the final neurological deficit, we used the SMD approach instead of the MD because the scales were different (NIHSS and ESS). In this case, the standard deviation was used to standardise the MDs to a single scale as well as in the computation of study weights. It is assumed that a variation between standard deviations reflects only differences in measurement scales and not differences in the reliability of the outcome measures or variability among trial populations. These limitations of the methods should be borne in mind where an unexpected variation of standard deviations across studies is observed.

Sensitivity analyses test the robustness of the results relative to features of the primary studies and to key assumptions and decisions ([Cook 1995](#)), and they test for bias due to the retrospective nature of systematic reviews. Sensitivity analyses in meta-analysis allow more appropriate and reliable conclusions when problems such as unavailable estimates are present ([Riley 2004](#)). We were able to perform only a minor percentage of the previously proposed sensitivity analyses due to the fact that, for the primary outcome, some studies did not report enough data.

Reviewing research for systematic reviews implies a retrospective nature and therefore is subject to random and systematic error ([Montori 2003](#)). In order to decrease this error, we wrote a protocol before the search was made and two review authors worked independently in the extraction of the information, with substantial agreement in the decisions on which studies should be included.

Publication bias could affect our review despite our extensive search procedure. More than 10 studies (ideally more than 30 studies) should be included in order to provide a funnel plot ([Lau 2006](#)). We did not contact pharmaceutical companies manufacturing insulin. Our meta-analysis included only RCTs and we found only one unpublished study in the previous version of the review that was subsequently published in 2011. We contacted the authors for clarification in regards to study information when appropriate.

Agreements and disagreements with other studies or reviews

Clinical trials that investigated the role of intensive glycaemic control on critically ill people have produced controversial results. Studies in favour of tight glucose control include [Van den Berghe 2001](#), which showed that insulin therapy decreases mortality in people with DM and those undergoing surgery. Another study reported beneficial outcomes with strict blood glucose control after cardiac surgery ([Ingels 2006](#)). A study by Lazar et al found that tight glycaemic control in people with DM undergoing coronary artery bypass graft (CABG) improved perioperative outcomes, enhanced survival, and decreased the incidence of ischaemic events and wound complications ([Lazar 2004](#)). A study by Vriesendorp et al, on people undergoing surgery for oesophageal cancer, reported an association between postoperative glucose levels and an increased length of hospital stay, but not an increase in infectious complications ([Vriesendorp 2004](#)).

Our results are in keeping with other more recent trials of tight glycaemic control. In a study of 400 people after cardiac surgery, there was an increased incidence of death and stroke in the intensive insulin treatment group (Gandhi 2007). In a later study, Van den Berghe et al studied 1200 people and showed that there was no change in mortality among people in medical intensive care units (ICU) (Van den Berghe 2006). Brunkhorst et al studied 537 people with sepsis and found no significant difference between the intensive and conventional therapy groups in the rate of death or mean score for organ failure (Brunkhorst 2008). The CREATE-ECLA 2005 study compared glucose-insulin-potassium infusion with usual care in 20,000 people presenting with ST-segment elevation myocardial infarction and found a lack of benefit on mortality, cardiac arrest, and cardiogenic shock. The multicentre Normoglycaemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study had a mixed ICU population with 6104 people. This study provided evidence that intensive insulin treatment was associated with increased mortality and increased hypoglycaemia without significant differences in critical care unit or hospital length of stay, number of days of mechanical ventilation, or need for renal replacement therapy. In a meta-analysis of 29 RCTs involving 8432 participants (Wiener 2008) there was no difference in hospital mortality between tight and usual glucose control (21.6% versus 23.3%).

AUTHORS' CONCLUSIONS

Implications for practice

Evidence from this systematic review indicates that, compared with control intervention, the administration of insulin with the aim of

maintaining glucose within a specific range immediately after acute ischaemic stroke does not reduce dependency, neurological deficit, or mortality at 30 days or 90 days. These findings did not change in the subgroup analysis of those with diabetes mellitus compared with those without diabetes mellitus. There was, however, a significant increase in episodes of hypoglycaemia in the treatment group. This review provides no evidence to support the use of intensive insulin therapy for tight glucose control after acute stroke. The number needed to treat is not significant for the outcome of death or the composite outcome of dependency and death, and the number needed to harm is nine for symptomatic hypoglycaemia.

Implications for research

In animal studies and human studies of acute stroke, hyperglycaemia has been shown to have a deleterious effect on the critical area of ischaemic penumbra. This review and other similar studies of glucose control have been unable to provide reliable evidence that tight glycaemic control improves functional outcome or reduces mortality in people with acute ischaemic stroke. At this time, the benefits of maintaining tight glucose control do not outweigh the potential risks of hypoglycaemia to the already vulnerable ischaemic penumbra in ischaemic stroke patients.

CHARACTERISTICS OF STUDIES
Characteristics of included studies [ordered by study ID]

Azevedo 2009

Methods	Randomised, parallel design
Participants	34 consecutive acute ischaemic strokes; 14 randomised to intensive insulin therapy and 20 control carbohydrate
Interventions	Continuous intravenous insulin infusion Control: carbohydrate restrictive strategy, intravenous infusion glucose-free and enteral nutrition 33.3% carbohydrates, regular insulin SQ Goal < 150 mg/dL
Outcomes	Follow-up until discharge Outcomes: glucose level, NIHSS, death, hypoglycaemia
Notes	Abstract format only Author contacted and provided extra information

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Computer-generated random-number table and sealed envelopes
Allocation concealment (selection bias)	Unclear risk	Not reported
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Not reported

GIST-UK 2007

Methods	Randomised, parallel design
---------	-----------------------------

Insulin for glycaemic control in acute ischaemic stroke (Review)

Copyright © 2014 The Cochrane Collaboration. Published by John Wiley & Sons, Ltd.

GIST-UK 2007 (Continued)

Participants	933 participants: 464 in the intervention group and 469 in the control group
Interventions	Glucose-insulin-potassium (10% dextrose, 20 mmol KCl, 16 units insulin); continuous intravenous infusion for 24 hours to maintain capillary glycaemia 4 to 7 mmol/L, plasma glucose 4.6 to 8 mmol/L, measured every 8 hours
Outcomes	At 90 days ESS and Rankin Scale
Notes	71/464 (15.3%) non-ischaemic strokes in the intervention group, 78/469 (16.6%) non-ischaemic strokes in the control group; stopped early

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Low risk	Adequate
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Blinded
Incomplete outcome data (attrition bias) All outcomes	High risk	7.4% lost to follow-up and early termination

GRASP 2009

Methods	Randomised, parallel design, stratified by glucose concentration
Participants	74 participants (3 arms): 24 participants in the intervention group (tight control), 50 participants in the control group
Interventions	Intravenous insulin infusion in normal saline (plus glucose 5% and 20 mEq/L potassium infusion) and subcutaneous insulin with each meal; continuous intravenous insulin infusion individually adjusted; target 70 to 110 mg/dL, or 3.9 to 6.1 mmol/L in the tight control group, with capillary glucose check every 1 to 4 hours for 5 days or discharge
Outcomes	At 90 days NIHSS and Rankin
Notes	

Risk of bias

Bias	Authors' judgement	Support for judgement
------	--------------------	-----------------------

Insulin for glycaemic control in acute ischaemic stroke (Review)

GRASP 2009 (Continued)

Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Low risk	Adequate
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Blinded
Incomplete outcome data (attrition bias) All outcomes	Low risk	1.4% lost to follow-up

INSULINFARCT 2012

Methods	Randomised, parallel design, not blinded
Participants	180 enrolled: 90 each arm, ITT and 85 each arm per protocol analysis
Interventions	Intravenous continuous infusion of Actrapid insulin with 1 hourly glucose check and dose adjustment; aim to get glucose < 7; continued for 24 hours Control subcutaneous insulin, glucose check every 4 hours x 24 hours; stop point of 8 mmol/L at which no insulin given
Outcomes	At 90 days Glucose level, NIHSS, Rankin, death, hypoglycaemia, infarct volume by MRI
Notes	

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Low risk	Adequate
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded

INSULINFARCT 2012 (Continued)

Incomplete outcome data (attrition bias) All outcomes	Low risk	Adequate
---	----------	----------

Kreisel 2009

Methods	Randomised, parallel design
Participants	40 participants: 20 in each arm
Interventions	Continuous intravenous insulin infusion individually adjusted; target 80 to 110 mg/dL, or 4.44 to 6.1 mmol/L with capillary glucose check every 1 to 4 hours for 5 days
Outcomes	120 days Rankin Scale
Notes	Main objective of the study was feasibility of insulin for control of glycaemia and hypoglycaemic events

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Unclear risk	Not enough information
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded
Incomplete outcome data (attrition bias) All outcomes	Low risk	10% lost to follow-up (4 of 40 lost to clinical follow-up, 1 of 40 (2.5%) lost to survival follow-up)

McCormick 2010

Methods	Randomised, parallel design, placebo controlled
Participants	40 participants: 25 intervention, 15 control
Interventions	Glucose-insulin-potassium Continuous intravenous infusion 100ml/hour x 24 hours (10 participants), 48 hours (5 participants) or 72 hours (10 participants); dose adjusted to keep capillary blood glucose between 4 to 7 mmol/L; glucose checked 1 hourly until euglycaemia achieved and subsequently 2 hourly

McCormick 2010 (Continued)

Outcomes	Hypoglycaemia, Rankin Scale, death
Notes	3 different durations of treatment

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Unclear risk	Not enough information
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded
Incomplete outcome data (attrition bias) All outcomes	Unclear risk	Not reported

Staszewski 2011

Methods	Randomised, parallel design
Participants	50 participants: 26 intervention and 24 controls
Interventions	Continuous intravenous insulin infusion adjusted to maintain euglycaemia (4.5 to 7 mmol/L); capillary glucose every 1 hour initially (every 4 hours once the participant was stable) for 24 hours
Outcomes	At 30 days Glucose level, NIHSS, Rankin, death, hypoglycaemia
Notes	Same study used in 2007 with unpublished results. Now has been published

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	High risk	Inadequate (random list was read by investigator)
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded

Insulin for glycaemic control in acute ischaemic stroke (Review)

Staszewski 2011 (Continued)

Blinding of outcome assessment (detection bias) All outcomes	Low risk	Blinded
Incomplete outcome data (attrition bias) All outcomes	Low risk	None lost to follow-up

THIS 2008

Methods	Randomised, parallel design
Participants	46 participants: 31 in the intervention group, 15 in the control group
Interventions	Continuous intravenous insulin infusion individually adjusted; target 5 to 7.2 mmol/L; capillary glucose every 1 hour for 72 hours
Outcomes	At 90 days NIHSS and Barthel
Notes	Almost all had diabetes mellitus (100% of intervention and 73% of control participants)

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Low risk	Adequate
Blinding of participants and personnel (performance bias) All outcomes	High risk	Participants were blinded, clinicians and data collectors were not blinded
Blinding of outcome assessment (detection bias) All outcomes	Low risk	Blinded
Incomplete outcome data (attrition bias) All outcomes	Low risk	None lost to follow-up

Vynchuk 2005

Methods	Randomised, parallel design
Participants	128 participants: 61 intervention, 67 control
Interventions	Continuous intravenous infusion 100 ml/hour per 4 hours with insulin doses adjusted by glucose level, until desired glucose level reached (< 7 mmol/L); measured every 4 hours

Insulin for glycaemic control in acute ischaemic stroke (Review)

Vinychuk 2005 (Continued)

Outcomes	At 30 days NIHSS and Barthel
Notes	Diabetes mellitus and non-diabetes mellitus cohorts reported separately

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Low risk	Adequate
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded
Incomplete outcome data (attrition bias) All outcomes	High risk	Reported none lost to follow-up; however, estimated to be at least 2.3% based on the percentages of the figures at follow-up

Vriesendorp 2009

Methods	Randomised, parallel design
Participants	33 participants: 13 basal insulin, 10 meal-related insulin, 10 controls
Interventions	Stopped oral glucose lowering drugs Basal group: intravenous infusion insulin adjusted every hour until < 6.1 mmol/l and bolus after meals Meal group: SQ long acting as basal and SQ rapid acting as meal related insulin, measured before and 2 hours after meals, and twice at night to detect hypoglycaemia Target: 4.4 to 6.1 mmol/l
Outcomes	At 5 days NIHSS and hypoglycaemia
Notes	

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	High risk	Consecutive envelopes
Allocation concealment (selection bias)	High risk	Consecutive envelopes stratified for dysphagia and diabetes mellitus

Vriesendorp 2009 (Continued)

Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded
Incomplete outcome data (attrition bias) All outcomes	High risk	15% without outcome documented at 5 days

Walters 2006

Methods	Randomised, parallel design
Participants	25 participants: 13 in the intervention group, 12 in the control group
Interventions	Continuous intravenous insulin infusion for 48 hours; target 5 to 7.9 mmol/L; monitored every 2 hours
Outcomes	30 days
Notes	Pilot study looking at feasibility

Risk of bias

Bias	Authors' judgement	Support for judgement
Random sequence generation (selection bias)	Low risk	Adequate
Allocation concealment (selection bias)	Low risk	Adequate
Blinding of participants and personnel (performance bias) All outcomes	High risk	Not blinded
Blinding of outcome assessment (detection bias) All outcomes	High risk	Not blinded
Incomplete outcome data (attrition bias) All outcomes	Low risk	None lost to follow-up

ESS: European Stroke Scale

ITT: intention-to-treat

MRI: magnetic resonance imaging

NIHSS: National Institutes of Health Stroke Scale

Characteristics of excluded studies *[ordered by study ID]*

Study	Reason for exclusion
CIMT Trial	Not stroke participants; stroke is an outcome
De Azevedo 1997	Intervention is diet; both groups received the same regimen of insulin
GIST 1999	Overlapping cohort with GIST-UK 2007
GLUCOVAS	Not randomised clinical trial design, these are cohorts with intervention
Green 2010	Only 3.7% of the cohort is ischaemic stroke
Miyashita 2008	Not stroke participants; stroke is an outcome
VADT	Not stroke participants; stroke is an outcome

Characteristics of ongoing studies *[ordered by study ID]*
[NCT00373269](#)

Trial name or title	Effect of insulin on infarct size and neurologic outcome after acute stroke
Methods	RCT
Participants	Adults with acute stroke
Interventions	Insulin
Outcomes	Primary outcome is change in infarct volume measured on diffusion-perfusion MRI
Starting date	January 2004 to January 2010
Contact information	Nina T Gentile, MD
Notes	clinicaltrials.gov NCT00373269

[SHINE](#)

Trial name or title	Stroke Hyperglycemia Insulin Network Effort (SHINE)
Methods	RCT
Participants	Acute ischaemic stroke < 12 hours from onset
Interventions	Intravenous insulin to maintain target glucose concentration of 80 to 130 mg/dL
Outcomes	Modified Rankin Scale score at 3 months Hypoglycaemia
Starting date	April 2012

[Insulin for glycaemic control in acute ischaemic stroke \(Review\)](#)

SHINE (Continued)

Contact information Karen C Johnston, MD

Notes ClinicalTrials.gov NCT01369069

MRI: magnetic resonance imaging
RCT: randomised controlled trial

DATA AND ANALYSES

Comparison 1. Dependency or death

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Dependency or death at the end of the follow-up	9	1516	Odds Ratio (M-H, Fixed, 95% CI)	0.99 [0.79, 1.23]
2 Death	9	1422	Odds Ratio (M-H, Fixed, 95% CI)	1.09 [0.85, 1.41]
3 Diabetes mellitus versus no diabetes mellitus	8	1482	Odds Ratio (M-H, Fixed, 95% CI)	0.97 [0.77, 1.21]
3.1 Diabetes mellitus	3	194	Odds Ratio (M-H, Fixed, 95% CI)	0.66 [0.35, 1.24]
3.2 No diabetes mellitus	6	1288	Odds Ratio (M-H, Fixed, 95% CI)	1.02 [0.81, 1.30]
4 Less than 30 days versus 90 days of follow-up	9	1516	Odds Ratio (M-H, Fixed, 95% CI)	0.99 [0.79, 1.23]
4.1 30 days	5	289	Odds Ratio (M-H, Fixed, 95% CI)	0.74 [0.43, 1.25]
4.2 90 days	4	1227	Odds Ratio (M-H, Fixed, 95% CI)	1.05 [0.82, 1.34]

Analysis 1.1. Comparison 1 Dependency or death, Outcome 1 Dependency or death at the end of the follow-up.

Analysis 1.2. Comparison 1 Dependency or death, Outcome 2 Death.

Analysis 1.3. Comparison 1 Dependency or death, Outcome 3 Diabetes mellitus versus no diabetes mellitus.

Analysis 1.4. Comparison 1 Dependency or death, Outcome 4 Less than 30 days versus 90 days of follow-up.

Comparison 2. Functional neurological outcome

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 NIHSS or ESS at the end of the follow-up	8	1432	Std. Mean Difference (IV, Fixed, 95% CI)	-0.09 [-0.19, 0.01]

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
2 Independent in daily activities	9	1224	Odds Ratio (M-H, Fixed, 95% CI)	1.03 [0.81, 1.32]
3 Diabetes mellitus versus no diabetes mellitus	8	1432	Std. Mean Difference (IV, Fixed, 95% CI)	-0.07 [-0.18, 0.03]
3.1 Diabetes mellitus	3	146	Std. Mean Difference (IV, Fixed, 95% CI)	-0.06 [-0.43, 0.31]
3.2 No diabetes mellitus	6	1286	Std. Mean Difference (IV, Fixed, 95% CI)	-0.08 [-0.19, 0.03]
4 Less than 30 days versus 90 days of follow-up	8	1432	Std. Mean Difference (IV, Fixed, 95% CI)	-0.09 [-0.19, 0.01]
4.1 30 days	5	273	Std. Mean Difference (IV, Fixed, 95% CI)	-0.47 [-0.72, -0.23]
4.2 90 days	3	1159	Std. Mean Difference (IV, Fixed, 95% CI)	-0.00 [-0.12, 0.11]

Analysis 2.1. Comparison 2 Functional neurological outcome, Outcome 1 NIHSS or ESS at the end of the follow-up.

Analysis 2.2. Comparison 2 Functional neurological outcome, Outcome 2 Independent in daily activities.

Analysis 2.3. Comparison 2 Functional neurological outcome, Outcome 3 Diabetes mellitus versus no diabetes mellitus.

Analysis 2.4. Comparison 2 Functional neurological outcome, Outcome 4 Less than 30 days versus 90 days of follow-up.

Comparison 3. Hypoglycaemia

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Symptomatic hypoglycaemia	10	1455	Odds Ratio (M-H, Fixed, 95% CI)	14.60 [6.62, 32.21]
2 Hypoglycaemia (with or without symptoms)	10	1455	Odds Ratio (M-H, Fixed, 95% CI)	18.41 [9.09, 37.27]

Analysis 3.1. Comparison 3 Hypoglycaemia, Outcome 1 Symptomatic hypoglycaemia.

Analysis 3.2. Comparison 3 Hypoglycaemia, Outcome 2 Hypoglycaemia (with or without symptoms).

Comparison 4. Mean glucose level

Outcome or subgroup title	No. of studies	No. of participants	Statistical method	Effect size
1 Mean glucose level	8	1398	Mean Difference (IV, Fixed, 95% CI)	-0.63 [-0.80, -0.46]

Analysis 4.1. Comparison 4 Mean glucose level, Outcome 1 Mean glucose level.

ADDITIONAL TABLES

Table 1. Risk of bias summary

Study	Generation of randomisation	Allocation concealment	Blinding: participants and physicians	Blinding: outcome to allocation group	Lost to follow-up (%)
Vinychuk 2005	Low risk	Low risk	High risk	High risk	0
GIST-UK 2007	Low risk	Low risk	High risk	Low risk	7.4
Staszewski 2011	Low risk	High risk	High risk	Low risk	0
THIS 2008	Low risk	Low risk	High risk	Low risk	0
Walters 2006	Low risk	Low risk	High risk	High risk	0
GRASP 2009	Low risk	Low risk	High risk	Low risk	1.4
Kreisel 2009	Low risk	Unclear risk	High risk	High risk	10
McCormick 2010	Low risk	Unclear risk	Unclear risk	High risk	Not reported
INSULINFARCT 2012	Low risk	Low risk	High risk	High risk	2.2
Vriesendorp 2009	High risk	High risk	High risk	High risk	15.2
Azevedo 2009	Low risk	Unclear risk	High risk	High risk	Not reported

APPENDICES

Appendix 1. MEDLINE search strategy

We used the following search strategy for MEDLINE (Ovid).

1. cerebrovascular disorders/ or basal ganglia cerebrovascular disease/ or exp brain ischemia/ or carotid artery diseases/ or carotid artery thrombosis/ or intracranial arterial diseases/ or cerebral arterial diseases/ or exp "intracranial embolism and thrombosis"/ or exp stroke/
2. (isch?emi\$ adj6 (stroke\$ or apoplex\$ or cerebral vasc\$ or cerebrovasc\$ or cva or attack\$)).tw.
3. ((brain or cerebr\$ or cerebell\$ or vertebrobasil\$ or hemispher\$ or intracran\$ or intracerebral or infratentorial or supratentorial or middle cerebr\$ or mca\$ or anterior circulation) adj5 (isch?emi\$ or infarct\$ or thrombo\$ or emboli\$ or occlus\$ or hypoxi\$)).tw.
4. 1 or 2 or 3

WHAT'S NEW

Date	Event	Description
30 October 2013	New search has been performed	We updated the literature searches to September 2013. We included four new studies. There are now 11 studies involving 1583 participants included in the review. The conclusions have not changed.
30 October 2013	New citation required but conclusions have not changed	Updated review. Conclusions not changed.

HISTORY

Protocol first published: Issue 3, 2005

Review first published: Issue 9, 2011

Date	Event	Description
17 March 2008	Amended	Converted to new review format.
5 February 2008	New citation required and major changes	The protocol has been extensively revised and updated and replaces the previously published version. There has been a change of authors.

CONTRIBUTIONS OF AUTHORS

MF Bellolio wrote the background section, collected the data, did the analyses and wrote the results and conclusion of the full review and the updated review.

RM Gilmore wrote the background section, collected the data, wrote the results and conclusion of the full review, and abstracted data and quality measurements for the updated review.

LG Stead devised the initial review and wrote the original protocol.

MFB and RMG updated this version of the review.

The authors approve and take full responsibility for the contents of this systematic review.

DECLARATIONS OF INTEREST

None of the authors has any conflicts of interest to disclose.

SOURCES OF SUPPORT

Internal sources

- Mayo Clinic, USA.
Protected time for research to the principal investigator
