Abstract

The prevailing model of steroid hormone nuclear receptor function assumes ligand-induced homodimer formation followed by binding to DNA hormone response elements (HREs). This model has been challenged by evidence showing that the glucocorticoid receptor (GR) forms tetramers upon ligand and DNA binding, which then drive receptor-mediated gene transactivation and transrepression. GR and the closely-related mineralocorticoid receptors (MR) interact to transduce corticosteroid hormone signaling, but whether they share the same quaternary arrangement is unknown. Here, we used a fluorescence imaging technique, Number & Brightness, to study oligomerization in a cell system allowing real-time analysis of receptor-DNA interactions. Agonist-bound MR forms tetramers in the nucleoplasm and higher order oligomers upon binding to HREs. Antagonists form intermediate-size quaternary arrangements, suggesting that large oligomers are essential for function. Divergence between MR and GR quaternary structure is driven by different functionality of known and new multimerization interfaces, which does not preclude formation of heteromers. Thus, influencing oligomerization may be important to selectively modulate corticosteroid signaling.

1 | INTRODUCTION

The mineralocorticoid and glucocorticoid receptors (MR and GR, respectively) are members of the steroid hormone receptor subfamily of nuclear receptors (NR3C). Steroid receptors share a common modular protein architecture (Green & Chambon, 1987) that includes a highly-divergent N-terminal domain (NTD), a highly conserved DNA-binding domain and a moderately conserved ligand-binding domain (DBD and LBD) (Grossmann et al., 2022). The NTD of both MR and GR is intrinsically disordered but both contain divergent ligand-independent transcription activation function 1 domains (AF-1), that provide an interaction surface for a diversity of transcriptional co-regulators (Fuse et al., 2000; Grossmann et al., 2022; Lavery & McEwan, 2005; Tallec et al., 2003). The highly conserved DBD between MR and GR imparts essentially indistinguishable DNA binding specificity (Hudson et al., 2014). The LBD similarity between both receptors confers promiscuous ligand activation for MR, binding both mineralocorticoids such as aldosterone or glucocorticoids such as cortisol or corticosterone with similar high affinity (Arriza et al., 1987; Bledsoe et al., 2002; Fagart et al., 2005; Li et al., 2005). MR and GR evolved from a gene duplication event predating the appearance of aldosterone (Baker & Katsu, 2019). MR was then co-opted as a receptor system for a new class of steroid hormones, mineralocorticoids, which regulate mineral and water homeostasis (Rossier et al., 2015). However, MR retained its high-affinity glucocorticoid binding and thus participates in mediating biological responses to both types of hormones (Gomez-Sanchez & Gomez-Sanchez, 2014; Grossmann et al., 2022). Thus, MR and GR have distinct but overlapping physiological functions. Inappropriate activation of MR may mimic or counteract GR actions, promoting obesity and metabolic syndrome (Fallo et al., 2006; Schreier et al., 2022), enhancing inflammation and tissue fibrosis (van der Heijden et al., 2022) or diminishing it (Bigas et al., 2018) in a tissue-specific fashion (Gomez-Sanchez & Gomez-Sanchez, 2014), or modulating brain responses to stress (Paul et al., 2022). MR inhibitors, initially used to treat conditions derived from hyperaldosteronism and situations with excessive water retention have increasingly attracted interest as anti-inflammatory and anti-fibrotic targets (Jaisser & Farman, 2016; Lothar et al., 2022), with important applications to treat cardiovascular disease (Bauersachs & Lopez-Andres, 2022) and recently approved indications to treat patients with chronic kidney disease associated with type 2 diabetes (Barrera-Chimal et al., 2022). In addition to functional crosstalk between MR and GR, there is considerable evidence pointing towards physical interaction and two-way transcriptional modulation between both receptors (Bigas et al., 2018; Carceller-Zazo et al., 2023; Jimenez-

Canino et al., 2016; Liu et al., 1995; Nishi et al., 2004; Pooley et al., 2020; Rivers et al., 2019; Trapp et al., 1994).

Growing interest in the molecular basis of specific MR and GR action and the functional role of their physical interaction make it essential to understand the active conformations of both receptors. The prevailing model of dimers as the final active conformation of steroid receptors has been challenged in the past few years (Jimenez-Panizo et al., 2022; Paakinaho et al., 2019; Presman et al., 2016; Presman & Hager, 2017). Using the Number & Brightness (N&B) assay (Digman et al., 2008) to measure average oligomer size with high spatial resolution in living cells, we have previously reported that agonist-bound GR adopts a dimeric conformation in the nucleoplasm, where the majority of the receptor is soluble, indicating that dimerization precedes high-affinity DNA binding (Presman et al., 2014; Presman et al., 2016). Observation of fluorescently-tagged GR at an array of mouse mammary tumor virus (MMTV) long terminal repeats, containing multiple HRE elements, suggested that the receptor adopts a tetrameric organization upon DNA binding (Presman et al., 2016). The progesterone receptor (PR) adopts a tetrameric conformation regardless of the nuclear compartment, while the androgen receptor (AR) forms larger oligomeric complexes, with an average of 6 subunits in all nuclear compartments (Presman et al., 2016). This paradigm shift in steroid receptor quaternary organization (Fuentes-Prior et al., 2019; Presman & Hager, 2017) and the close evolutionary relationship of GR with MR, in addition to the formation of heterocomplexes between both receptors, bring forward the question of whether MR and GR share a common quaternary structure. In this study, we used the N&B technique to examine MR oligomerization upon ligand binding. We show striking differences between MR and GR, with MR adopting a tetrameric conformation in the nucleoplasm and forming higher order oligomers upon HRE binding. Known or proposed dimerization interfaces conserved between MR and GR have distinct properties in both receptors. In spite of these differences, GR is able to displace MR subunits and incorporate them into heterocomplexes. Our results suggest that modulation of quaternary conformation may be an important parameter to take into consideration during development of selective corticosteroid signaling modulators.

2 | RESULTS

2.1 | Agonist-bound MR forms large oligomers at hormone response elements

MR quaternary structure was investigated in a cell derived from murine C127 adenocarcinoma cell line incorporating in their genome a tandem gene array of

approximately 200 copies of the mouse mammary tumor virus promoter (MMTV array), which contain hormone response elements (HREs) (McNally et al., 2000). This cell line was further modified using CRISPR/Cas9 to knockout the endogenous expression of GR, as previously described (Paakinaho et al., 2019). In addition, these cells do not express endogenous MR (supplementary Figure S1). Therefore, cells transiently transfected with eGFP-tagged MR allow visualization of the receptor in the nucleoplasm and also enriched at a specific nuclear domain (MMTV array), in the absence of any endogenous GR or MR expression. MR oligomerization was studied using number & brightness (N&B) analysis, a technique that has previously been used to study oligomerization of GR and other steroid receptors in live cells (Presman et al., 2014; Presman et al., 2016). N&B estimates the molecular brightness (ϵ) of a fluorophore using the first (mean) and second (variance) moments of the intensity fluctuations observed on each pixel of a raster-scan image (Digman et al., 2008). This way, one can obtain the weighted-average brightness (i.e., oligomeric state) of a protein in the entire nucleus or at a specific region such as the MMTV array. As monomeric and dimeric standards, all experiments included a condition with expression of GR truncated after amino acid 525 (GR-N525), which has been shown to exist in monomeric form in the nucleoplasm and to form dimers at the MMTV gene array (Presman et al., 2016). This allowed us to normalize every experiment and calculate MR oligomerization relative to this mutant. Unstimulated cells show partial localization of MR to the nucleus (Figure 1a), as previously described (Fejes-Toth et al., 1998; Walther et al., 2005). Upon treatment with hormone agonists (either aldosterone or corticosterone), MR fully translocated to the nucleus and produced a bright focus at the MMTV array (Figure 1a, arrows) (McNally et al., 2000). N&B analysis showed that unstimulated nuclear MR exists as a monomer ($\epsilon = 0.96$), but reaches an ϵ of approximately 4 (4.39; Figure 1b) upon stimulation with a saturating concentration of aldosterone (10 nM), suggesting the formation of a tetramer in the nucleoplasm. N&B analysis of MR expressed from a stably integrated locus also provided an ϵ near 4, indicating that tetramerization is not an artifact due to transient overexpression (supplementary Figure S2a). Aldosterone-stimulated MR concentrated at the MMTV array produces an even higher ϵ , which approaches 7 (6.92; Figure 1b), suggesting that higher order oligomerization of MR correlates with chromatin binding and transcriptionally active HREs. Since Aldo binding promotes the oligomerization of MR, we asked whether a sub-saturating concentration of the ligand would produce an intermediate ϵ value, reflecting mixed populations of

fully formed tetramers with monomers and perhaps intermediate quaternary organizations. To that end, we stimulated cells with 1 nM Aldo ($K_d \sim 0.5$ nM), which produced an ϵ of 3.24 in the nucleoplasm, significantly lower than the value obtained with 10 nM Aldo ($\epsilon = 4.39$; $p < 0.0001$, Figure 1b). MR at the MMTV array also appeared to show a lower value ($\epsilon = 6.41$) when compared to 10 nM Aldo ($\epsilon = 6.92$), but this change did not reach statistical significance ($p = 0.264$; Figure 1b). This observation is consistent with required ligand binding for high-affinity interaction with HREs (Groeneweg et al., 2014).

Since both aldosterone and glucocorticoids are endogenous agonists of MR, we tested whether receptor oligomerization varies as a function of the agonist. To that end, we compared the results obtained with aldosterone to those obtained with saturating concentrations of corticosterone (Cort, 100 nM), a dose that produces full receptor activation (Figure 1b, inset). Our results show that both agonists produce indistinguishable ϵ values that are consistent with a tetrameric organization in the nucleoplasm and a higher order oligomer on the MMTV array (Figure 1a,b). To further test the relationship between agonist binding and oligomerization, we took advantage of an important difference between aldosterone and corticosterone. Both hormones bind MR with equal high affinity ($K_d \sim 0.5$ nM), but aldosterone is more effective in activating the receptor ($EC_{50}[\text{aldo}] = 0.5$ nM vs. $EC_{50}[\text{cort}] = 10$ nM). This difference in potency has been ascribed to a higher off-rate of glucocorticoids in the receptor (Lombes et al., 1994). Therefore, we tested a lower concentration of corticosterone (10 nM), which fully saturates the receptor but produces 50% of the maximum activity (Figure 1b, inset, vertical dashed line). Under those conditions, nucleoplasmic MR showed a statistically significant lower ϵ value ($\epsilon = 3.52$, $p < 0.001$, Figure 1b), suggesting a correlation between hormone off-rate and oligomerization. In contrast, MR at the MMTV array still showed a high value ($\epsilon = 6.77$), which again is consistent with the observation that ligand binding is required for high-affinity interaction with HREs (Groeneweg et al., 2014).

We next studied the reversibility of agonist-induced oligomerization of MR. To that end cells were incubated with agonists for 1 h, followed by hormone washout and an additional four-hour incubation before recording. Under those conditions, MR still showed full nuclear localization (i.e., negligible nuclear export), but no binding to the MMTV array (Figure 1a). N&B analysis revealed that after corticosterone washout MR reverted to a monomeric organization in the nucleoplasm (Figure 1b). In contrast, aldosterone washout produced incomplete reversal, with a nucleoplasmic MR ϵ value of

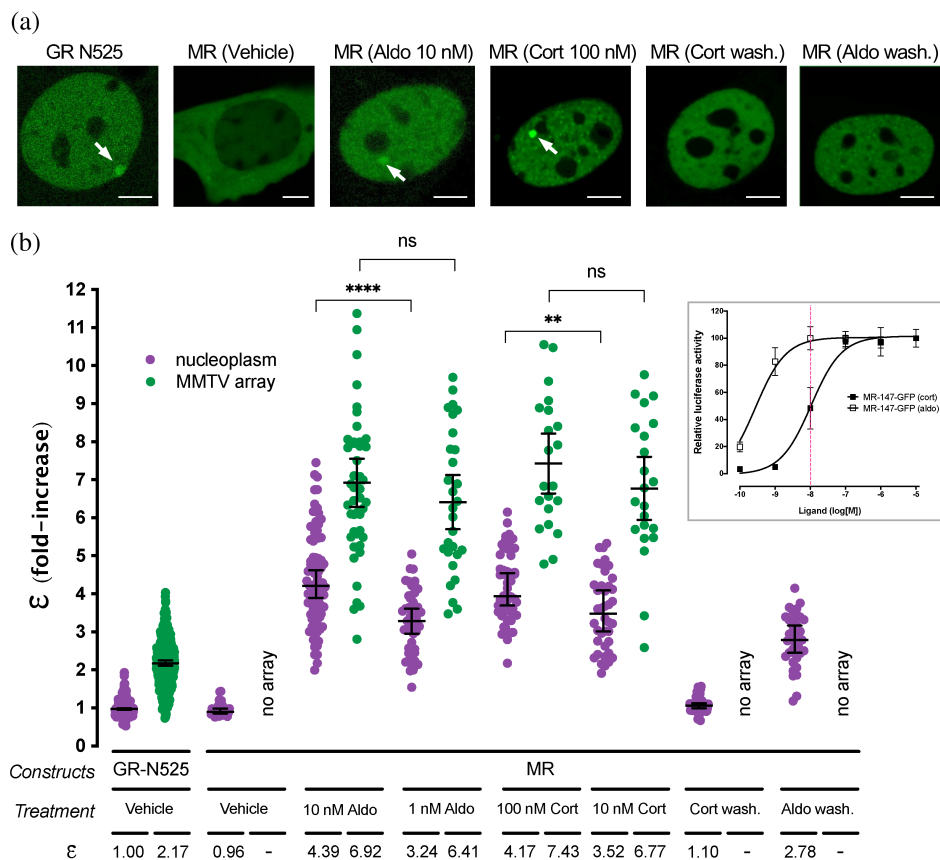

FIGURE 1 Agonist-bound MR adopts a tetramer conformation in the nucleoplasm and forms higher order oligomers at HREs.

(a) Representative images of single cell nuclei expressing GFP-GR-N525 or MR-GFP and treated with vehicle, 10 nM aldosterone (Aldo) or 100 nM corticosterone (Cort). In certain experiments, agonists were washed out after 1 h stimulation (wash.). White arrows point to the MMTV array. Scale bars: 5 μ m. (b) Normalized molecular brightness (ϵ). Each point represents a single nucleus ($n = 490, 307, 26, 82, 47, 45, 29, 50, 21, 40, 22, 55, 36$ cells in each condition, from left to right). Individual points were pooled from the following number of independent experiments for each condition: 25, 2, 5, 3, 3, 3, 3, 2. Horizontal bars represent mean \pm 95% confidence interval (CI). Wash., washout. Statistical analysis for the selected pairs (MR 10 nM Aldo vs. 1 nM Aldo; MR 100 nM Cort vs. 10 nM Cort) was performed using an unpaired t test (**** $p < 0.0001$; ** $p < 0.01$; n.s., not significant). Inset, MR dose-response gene transactivation curves in response to aldosterone (aldo) and corticosterone (cort). Curves were obtained using wild-type mouse MR transiently transfected in COS7 cells co-expressing a luciferase gene reporter system and treated with the indicated concentrations of hormones for 16 h. Dashed red line highlights the difference in MR activity at 10 nM hormone concentration (data adapted from (Jimenez-Canino et al., 2016)).

2.78 (Figure 1b), suggesting a mixed population of tetramers with dimers and/or monomers. This could be explained by the slower off-rate of aldosterone binding to the receptor (Lombes et al., 1994). These results demonstrate that higher order oligomerization depends on agonist binding in a reversible manner.

2.2 | Antagonists induce intermediate-size MR oligomers

Clinically relevant MR antagonists such as spironolactone, eplerenone or the recently approved non-steroidal antagonist finerenone induce nuclear translocation, although with slower kinetics (Amazit et al., 2015; Fejes-

Toth et al., 1998; Gravez et al., 2013). We asked whether these antagonists also facilitate MR binding to HREs and what is the quaternary structure of the receptor under these conditions. Our results showed that all three antagonists induced MR binding to the MMTV array (Figure 2). However, N&B revealed that MR oligomerization in the nucleoplasm and at the MMTV array does not reach the levels detected with agonists. Remarkably, there are clear differences between both antagonists. A saturating concentration of spironolactone produced an ϵ value of 2.04 in the nucleoplasm, consistent with a population mainly formed by MR dimers, and 4.43 at the MMTV array, consistent with tetramerization upon HRE binding (Figure 2). Eplerenone showed lower ϵ , even at high antagonist concentration, with predominantly

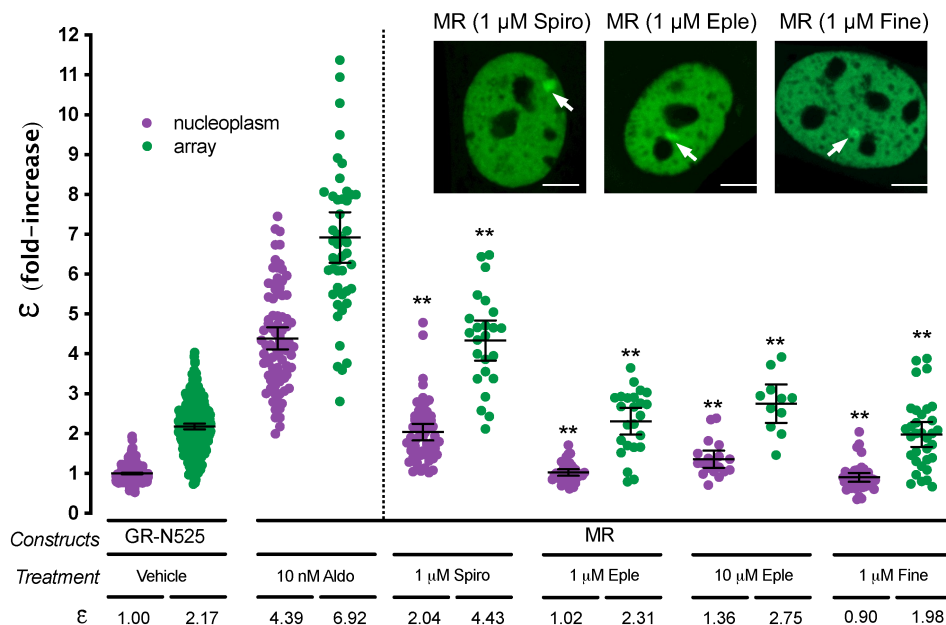

FIGURE 2 MR antagonists produce different MR quaternary configurations. Inset shows representative images of single cell nuclei expressing MR-GFP and treated with 1 μ M spironolactone (Spiro), 1 μ M eplerenone (Eple) or 1 μ M finerenone. White arrows point to the MMTV array. Scale bars: 5 μ m. Plot shows MR molecular brightness (ϵ) assessed using the N&B technique. To facilitate comparison, data from Figure 1 showing ϵ for GR-N525 and MR treated with 10 nM aldosterone are included. Data points correspond to ϵ obtained from a single nucleus ($n = 490, 307, 82, 47, 55, 24, 37, 24, 19, 11, 41$ and 33 cells in each condition, from left to right). Individual points were pooled from the following number of independent experiments for each condition: 25, 5, 4, 2, 2, 2. Horizontal bars represent mean \pm 95% CI. Each ϵ value was compared to its reference value (MR/10 nM Aldo in the nucleoplasm or at the MMTV array) using the Kruskal-Wallis test followed by Dunn's multiple comparisons correction. Symbols refer to statistical differences with MR/10 nM Aldo in the same compartment (nucleoplasm or MMTV array; ** $p < 0.01$).

monomeric MR in the nucleoplasm ($\epsilon = 1.02$ – 1.36 , similar to the unstimulated receptor) and an ϵ of 2.31–2.75 at the MMTV array (Figure 2). Finerenone also induced a predominantly monomeric MR in the nucleoplasm ($\epsilon = 0.90$) and dimeric MR at the MMTV array ($\epsilon = 1.98$) at saturating concentrations. These results suggest that the high-order oligomerization detected with saturating concentrations of agonists represent the fully active conformation of MR, while different antagonists produce intermediate steps in the building of the fully active oligomer. Alternatively, antagonist-induced interactions may represent non-functional oligomers that are not in the pathway of forming active quaternary structures.

2.3 | MR and GR do not share the same dimerization interfaces

MR and GR evolved from a common corticoid receptor through gene duplication (Baker & Katsu, 2019; Bridgham et al., 2006) and have high sequence conservation in the DBD (94% identity) and moderate conservation in the LBD (57% identity; supplementary Figure S3). Both domains harbor key determinants for

GR oligomerization (Presman et al., 2016), including the unstructured *hinge* region connecting these domains (Savory et al., 2001). The results described above uncover a profound difference between ligand-bound GR and MR quaternary conformation in the nucleus, probably reflecting different functionalities of the oligomerization interfaces between both receptors. To test this hypothesis, we analyzed the role of key residues in DBD and LBD in the process (Figure 3a,b; supplementary Figure S4a). To directly test the role of DNA binding, we first introduced the mutation C603S, which completely disrupts the first zinc finger in the DBD (Figure 3a), eliminating the possibility of DNA binding (Cole et al., 2015; Pearce et al., 2002). This mutation produced a receptor that was unable to bind the MMTV array (Figure 3c) and exists as a monomer in the nucleoplasm (Figure 3d), suggesting that the effect of disrupting the first zinc-finger is likely not limited to preventing DNA binding but has additional effects on the structure of the receptor.

The DBD of GR contains a 5 amino acid sequence, named the distal loop (D-loop) (Figure 3a and supplementary Figure S3) that has been proposed to be critical for dimerization (Dahlman-Wright et al., 1991). Mutation A465T in the D-loop of GR, commonly known as GRdim,

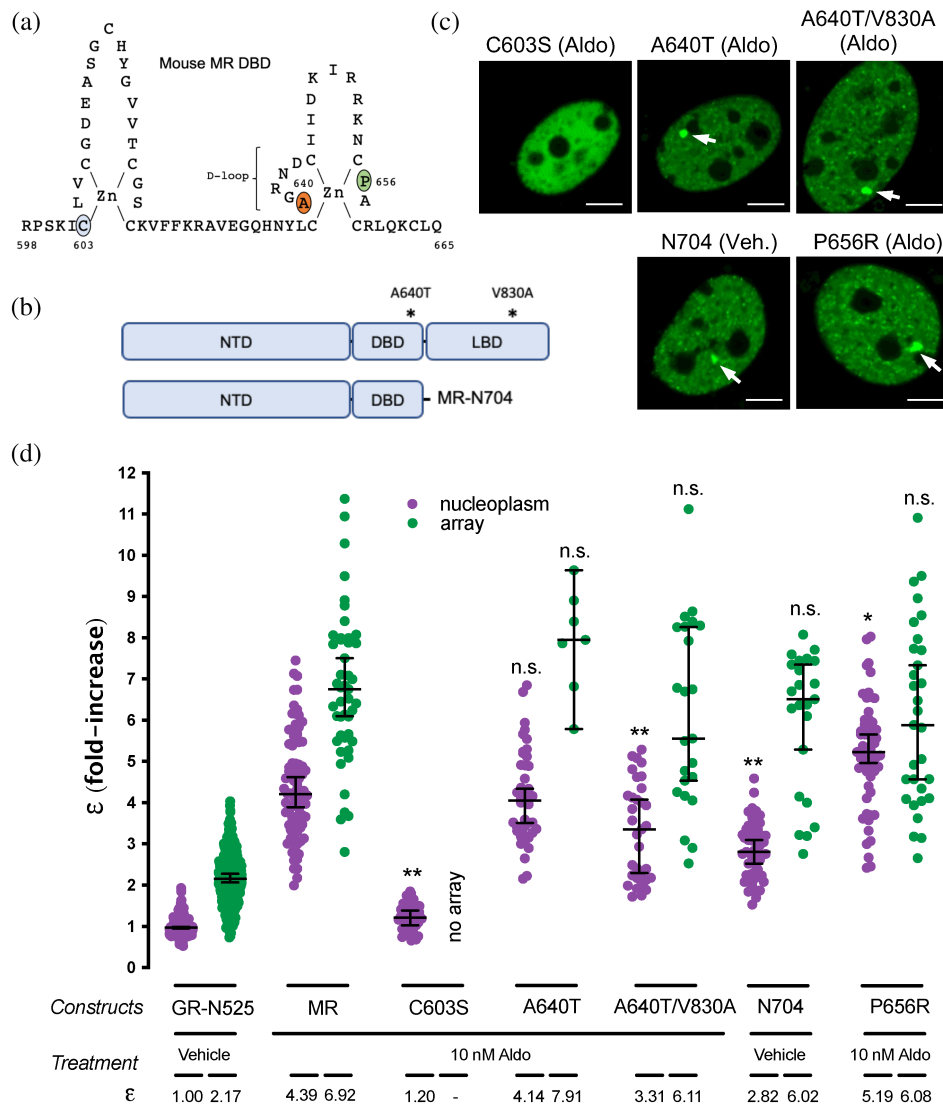

FIGURE 3 The role of predicted MR dimerization interfaces in quaternary structure formation. (a) Schematic representation of MR DBD. (b) Schematic representation of MR double mutant (A640T/V830A) and deletion generating construct MR-N704. NTD, N-terminal domain; DBD, DNA binding domain; LBD, ligand binding domain. (c) Representative images of single cell nuclei expressing the indicated constructs. White arrows point to the MMTV array. Scale bars: 5 μ m. (d) MR molecular brightness (ϵ) assessed using the N&B technique. To facilitate comparison, data from Figure 1 showing ϵ for GR-N525 and MR treated with 10 nM aldosterone are included. Data points correspond to ϵ obtained from a single nucleus ($n = 490, 307, 82, 47, 41, 44, 7, 33, 23, 51, 23, 57$ and 31 cells in each condition, from left to right). Individual points were pooled from the following number of independent experiments for each condition: 25, 5, 3, 3, 2, 4, 3. To facilitate comparison, data from Figure 1 showing ϵ for GR-N525 and MR treated with 10 nM aldosterone are included. Horizontal bars represent mean \pm 95% CI. Each ϵ value was compared to its reference value (wild type MR in the nucleoplasm or at the MMTV array) using the Kruskal-Wallis test followed by Dunn's multiple comparisons correction. Symbols refer to statistical differences with MR wild type in the same compartment (nucleoplasm or MMTV array; n.s., non-significant; * $p < 0.05$; ** $p < 0.01$).

was originally proposed to prevent DNA binding and dimerization of GR. Later work has shown that GRdim still forms dimers (Jewell et al., 2012; Presman et al., 2014), although its activity as transcriptional modulator is severely weakened (Johnson et al., 2021). Combination of A465T mutation with an additional mutation in the LBD (I634A) does produce a monomeric GR (GRmon; [Liu et al., 2020; Presman et al., 2014; Presman

et al., 2016]). In the case of MR, the orthologous mutation equivalent to GRdim (A640T; Figure 3a; supplementary Figure S3) did not produce any effect on receptor oligomerization in the nucleoplasm or the MMTV array (Figure 3d). The combination of point mutations A640T/V830A, equivalent to the double mutant A465T/I634A in GRmon, reduced values to 3.31 in the nucleoplasm but did not significantly affect oligomer size at the array

(Figure 3d). This result indicates that the function of these two well-described dimerization interfaces in GR is only partially conserved in MR, with a minor role in configuring its quaternary structure. To further test this idea, we deleted the whole LBD by truncating MR after amino acid 704 (MR-N704; Figure 3b). MR-N704 is constitutively nuclear and binds the array in the absence of ligand (Figure 3c), as described previously for the equivalent GR deletion, GR-N525 (Presman et al., 2016). MR-N704 produced reduced ϵ values in the nucleoplasm (2.82) but did not significantly affect oligomer size at the MMTV array (6) (Figure 3d), similar to the A640T/V830A mutant. This stands in contrast to the equivalent deletion in GR, which produces monomers in the nucleoplasm and dimers at the MMTV array (Figure 3; [Presman et al., 2016]), further indicating that the functionality of the classic GR dimerization interfaces is not fully conserved on MR.

To continue probing the role of the DBD and LBD dimerization interfaces, we introduced the mutation MR-P656R in the D-loop of the DBD (Figure 3a), located in a residue that is fully conserved in GR (supplementary Figure S3), where it mimics DNA binding, resulting in tetrameric receptors in the nucleoplasm with significantly enhanced binding to response elements inaccessible to wild type receptors (Paakinaho et al., 2019). N&B results showed that mutant MR-P654R shows a higher order oligomerization status in the nucleoplasm ($\epsilon = 5.19$; Figure 3d), approaching the value found at the array, although the effect is not as stark as the one found with GR (Presman et al., 2016). The activity of MR-P656R on enhancing the expression of well-known MR/GR target genes such as *Per1*, *Sgk1* or *Serpine1* was not significantly different from the WT construct (supplementary Figure S5), similar to the effect of the equivalent mutation in GR, which does not significantly change the potency of the receptor but rather expands its set of target genes (Paakinaho et al., 2019).

2.4 | The NTD participates in MR tetramer formation in the nucleoplasm

Altogether, our analysis of highly conserved residues in the DBD and LBD of MR and GR that have been involved in GR dimerization indicates that their impact on MR is significantly lower, pointing to the involvement of other regions of the receptor in the formation of its quaternary structure. Given that the NTD shows low sequence conservation between MR and GR (<15% identity), we first deleted this entire domain, generating a truncated MR with the last 580 amino acids of the sequence (MR-580C, Figure 4a; supplementary Figure S4b). This construct

showed an ϵ value of 1.63 in the nucleoplasm, indicating its essential role in ligand-induced, HRE-independent tetramerization of MR (Figure 4b). In spite of this, MR-580C binds to the MMTV array (Figure 4b), where it still forms higher order oligomers ($\epsilon = 6.61$), almost indistinguishable from the wild type MR. This result suggests that tetramerization in the nucleoplasm is not a pre-requisite to form higher order oligomers at the MMTV array and also that MR DBD and LBD contain oligomerization interfaces that are triggered by HRE binding. Swapping the NTD of MR for the equivalent domain in GR (construct GR-N408/MR-580C, Figure 4a; supplementary Figure S4b) produced an intermediate oligomer size in the nucleoplasm ($\epsilon = 2.96$, Figure 4c), further confirming that ligand-induced tetramerization of MR requires both its NTD and LBD. This construct behaves almost normally at the MMTV array ($\epsilon = 6.38$, Figure 4c), again pointing to the importance of the DBD in higher order oligomerization. We also performed the opposite swap, creating a construct with the NTD of MR and DBD and LBD from GR (construct MR-N579/GR-407C, Figure 4a; supplementary Figure S4b). Since aldosterone binds with lower affinity ($K_d = 14$ nM) and is a very poor activator of GR, we used 100 nM dexamethasone to stimulate this construct (Presman et al., 2016). The MR-N579/GR-407C chimera produced an intermediate oligomer in the nucleoplasm ($\epsilon = 2.57$), but still higher order quaternary organization at the MMTV array ($\epsilon = 7.89$; Figure 4c).

Taken together, our data suggest the possibility that MR has additional oligomerization determinants in the NTD. To further investigate this possibility, we generated a construct with deletion 382–510 (MR- Δ 382-510 [Figure 4a; supplementary Figure S4b]), which eliminates a region that has been previously implicated in a ligand-dependent N/C interaction in MR (Pippal et al., 2009), and should also disrupt the second part of the bi-partite activator function-1 domain (AF-1b; [Fuse et al., 2000; Tallec et al., 2003]). Remarkably, this deletion did not affect nucleoplasm tetramerization but clearly diminished oligomer size at the array (Figure 4c), implicating this region in the formation of the final active conformation of MR.

2.5 | GR is able to incorporate into GR-MR heteromers, displacing MR subunits

GR and MR physically interact (Bigas et al., 2018; Jimenez-Canino et al., 2016; Liu et al., 1995; Nishi et al., 2004; Pooley et al., 2020; Rivers et al., 2019; Savory et al., 2001; Trapp et al., 1994), and their co-expression likely results in the modulation of both of their transcriptional programs (Bigas et al., 2018; Carceller-Zazo et al., 2023; Jimenez-Canino et al., 2016; Liu et al., 1995; Rivers et al., 2019; Trapp

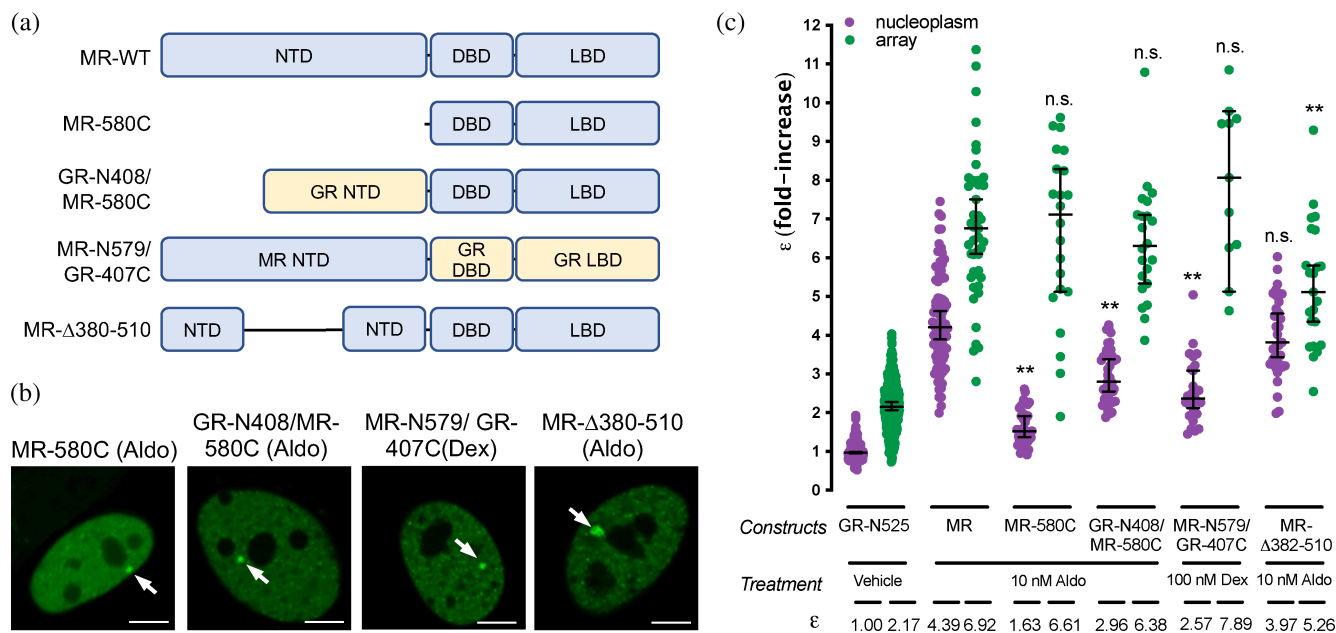

FIGURE 4 The NTD is essential for MR tetramerization in the nucleoplasm. (a) Schematic representation of MR deletion and domain swapping constructs. NTD, N-terminal domain; DBD, DNA binding domain; LBD, ligand binding domain. (b) Representative images of single cell nuclei expressing the indicated constructs. White arrows point to the MMTV array. Scale bars: 5 μ m. (c) N&B results obtained with the indicated constructs. To facilitate comparison, data from Figure 1 showing ϵ for GR-N525 and MR treated with 10 nM aldosterone are included. Data points correspond to ϵ obtained from a single nucleus ($n = 490, 307, 82, 47, 42, 22, 43, 22, 26, 11, 35$ and 23 cells in each condition, from left to right). Individual points were pooled from the following number of independent experiments for each condition: 25, 5, 2, 2, 2, 2. Horizontal bars represent mean \pm 95% CI. Each ϵ value was compared to its reference value (wild type MR in the nucleoplasm or at the MMTV array) using the Kruskal-Wallis test followed by Dunn's multiple comparisons correction. Symbols refer to statistical differences with MR wild type in the same compartment (nucleoplasm or MMTV array; n.s., non-significant; ** $p < 0.01$).

et al., 1994). The differences in quaternary organization between MR and GR raise an additional question. Would co-expressed MR and GR adopt a GR-like tetrameric conformation, an MR-like higher order oligomerization or a combination of both? To address this question, we performed N&B experiments in cells co-transfected with both receptors, eGFP-tagged MR with mCherry-tagged GR, recording data on the eGFP channel only. If GR incorporates into MR complexes, displacing some MR subunits, then MR's ϵ value should drop in the presence of GR (Figure 5a). On the contrary, if GR adds up to MR, then ϵ values should remain the same. Imaging of transfected cells showed that co-expression of both receptors produced simultaneous occupancy of the MMTV array (Figure 5b). GR co-expression significantly reduced ϵ for MR, both in the nucleoplasm and in the array (Figure 5c). Surprisingly, co-binding of both receptors to the MMTV array and the effect of GR lowering the apparent ϵ for MR occurred even when aldosterone was used as an agonist (Figure 5b,c). It is worth noting that even though aldosterone does not activate GR at the concentration used in these experiments (10 nM), it does at least partially occupy the receptor ($K_d = 14$ nM; (Hellal-Levy et al., 1999)), as evidenced by its nuclear translocation and binding to the MMTV array even

in the absence of MR ($\epsilon = 1.35$ in the nucleoplasm and 2.15 at the MMTV array; supplementary Figure S2b). Since these experiments use transiently transfected cells, the effect of co-expressed competing GR would be expected to vary depending on the relative proportion of MR and GR expressed in the cell. Therefore, we measured the ratio of eGFP and mCherry intensities in each cell after each N&B recording and plotted it against ϵ , obtaining a positive correlation between both parameters (Figure 5d). In conclusion, our data indicates that GR and MR can form heterocomplexes in live cells, wherein GR can displace some MR subunits, rendering a complex stoichiometry that requires further study.

3 | DISCUSSION

3.1 | Evolutionary conservation of quaternary structure and its impact on heteromerization

Here we used the N&B fluorescence imaging technique on living cells to study MR quaternary structure and its changes upon ligand binding and high-affinity

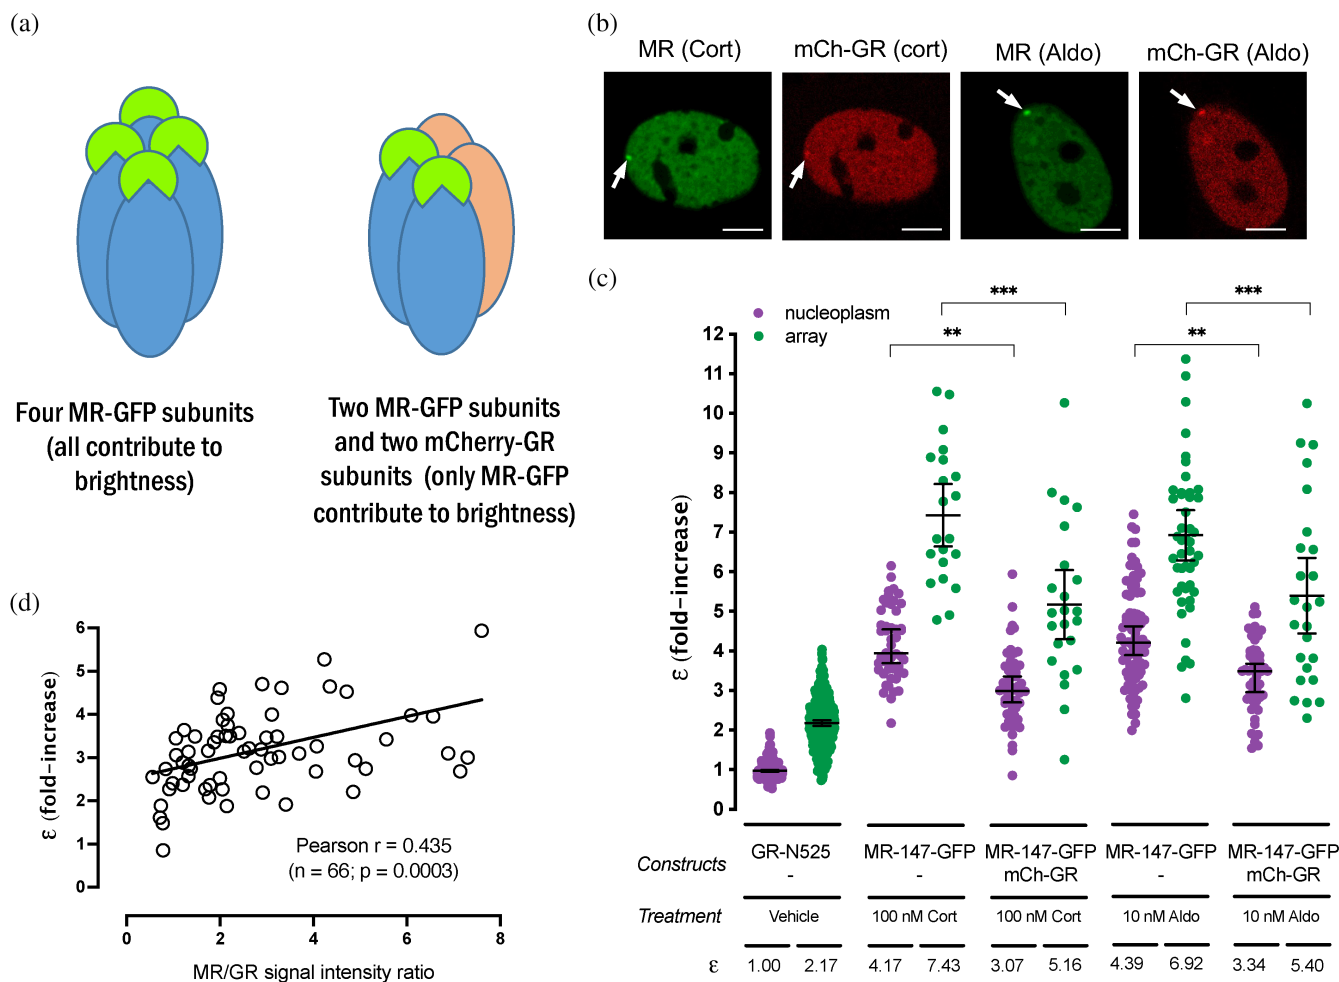

FIGURE 5 GR displaces MR subunits from the oligomer. (a) Representative images of single cell nuclei expressing the indicated constructs. mCh, mCherry. White arrows point to the MMTV array. Scale bars: 5 μ m. (b) Cartoon summarizing the rationale of the experiment. (c) MR molecular brightness (ϵ) assessed using the N&B technique. To facilitate comparison, data from Figure 1 showing ϵ for GR-N525 and MR treated with 100 nM corticosterone or 10 nM aldosterone are included. Data points correspond to ϵ obtained from a single nucleus ($n = 490, 307, 50, 21, 50, 23, 82, 47, 50$ and 25 cells in each condition, from left to right). Individual points were pooled from the following number of independent experiments for each condition: 25, 3, 3, 5, 3. Statistical analysis was performed using one-way ANOVA followed by Tukey test (results are shown only for two selected pairs; * $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$). (d) Linear correlation between eGFP-MR ϵ values and the ratio of MR/GR fluorescence intensity. Each dot represents an individual nucleus. Pearson linear correlation coefficient was computed using Prism 9 (GraphPad).

interaction with HREs. Our results support a unique oligomeric conformation among the steroid receptor subfamily, with results compatible with tetramer formation induced by agonist binding, which generates larger oligomers after binding to specific sites in the DNA. This stands in contrast to the quaternary structure of GR (Presman et al., 2016), the closest relative of MR within the subfamily. It may be assumed that protein divergence during evolution is constrained by selective pressure to maintain protein structure, including stable protein-protein interactions forming quaternary arrangements (Echave & Wilke, 2017; Fornasari et al., 2007). It follows that proteins with closely related evolutionary origin and functions would be expected to share the same

quaternary arrangement. In proteins that share very high sequence identity (>90%), quaternary structure is almost always conserved (Marsh & Teichmann, 2015). However, proteins showing more moderate sequence identity tend to differ more in their quaternary structures. Indeed, it has been calculated that 30%–40% identity correlates with a 70% probability of sharing a quaternary structure (Levy et al., 2008). For instance, the NSAR/OSBS subfamily of enzymes presents an overall sequence identity >40%, but some of its members are dimers and some octamers (Odokonyero et al., 2014). It is also worth noting that the final quaternary structure of proteins might be underestimated due to bias in the techniques used to determine oligomeric states (Ali & Imperiali, 2005). Sequence

conservation between MR and GR, and in general between steroid receptors, differs significantly between domains, with low conservation in the NTD (less than 15% identity), medium conservation in the LBD (approx. 60%) and highly conserved DBD (94% identity). Altogether it is not that surprising that MR and GR adopt different quaternary structures given that the lightly conserved NTD and the moderately conserved LBD play an important role in oligomer formation (Figures 3 and 4).

It has long been known that nuclear receptors in the NR1 subfamily function by forming heteromers with RXR (De Bosscher et al., 2020). However, it is increasingly clear that NR3 subfamily receptors are also able to form so-called “atypical” heteromers, which include NR3 receptors interacting with NR1 receptors and RXR (De Bosscher et al., 2020). In addition, NR3 receptors form heteromers with members of the same subfamily. These include not only MR-GR interactions, but others such as GR association with PR, ER or AR (De Bosscher et al., 2020; Ogara et al., 2019), or MR interaction with ER (Barrett Mueller et al., 2014), just to name a few. Taken together, this suggests that nuclear receptor cross-talk frequently involves formation of heteromers and that this is not hampered by the different quaternary conformations adopted by homomers, as confirmed by our data. This direct interaction model does not necessarily implicate direct binding of both kind of receptors to DNA, but may also involve tethering, looping or simply sequestration of one receptor by the other, preventing its genomic action. In the case of MR-GR interaction, it appears that they exert reciprocal effects on each other. It has recently been shown that MR modulates GR response to a synthetic glucocorticoid in mouse keratinocytes (Carceller-Zazo et al., 2023). In general, co-expression of MR and GR has been shown to alter glucocorticoid responses, although these effects appear to be cell-type and promoter-specific (Kiilerich et al., 2015; Liu et al., 1995; Mifsud & Reul, 2016; Ou et al., 2001; Rivers et al., 2019; Trapp et al., 1994). In addition, it is difficult to tease out whether transcriptional responses are primarily driven by GR, MR or both. It has also been proposed that MR may exert its effects not directly binding to DNA, but through tethering to GR (Rivers et al., 2019). There are few reports examining the role of GR on MR/Aldo function. Tsugita et al. used gene-reporter assays to show that GR co-expression is necessary for MR function, in a process likely involving receptor heteromerization and DNA binding (Tsugita et al., 2009), a model that we have recently confirmed investigating MR genome-wide binding and Aldo-regulated transcriptome (Johnson et al., 2023). It has recently been reported that abnormally high oligomeric forms of GR at the MMTV array, such as D647V that causes Chrousos disease, correlates

with less transcriptional activity (Jimenez-Panizo et al., 2022). In this sense, it is tempting to speculate that MR's higher oligomeric conformation is not optimal, and thus GR might increase MR activity (Johnson et al., 2023; Mifsud & Reul, 2016; Trapp et al., 1994; Tsugita et al., 2009) by reducing its stoichiometry. Nevertheless, whether the different reciprocal actions of MR and GR on their transcriptional activity reflect differences in the quaternary structure of the heterocomplexes requires further investigation.

3.2 | Mechanisms of oligomer formation

Results comparing binding of antagonists and agonists indicate that different ligands promote different average quaternary structures in the receptor population. Spirolactone, eplerenone and finerenone produced oligomers that are roughly multiples of two (Figure 2). In fact, it is thought that an energetically-favorable, ordered pathway underlies formation of most protein complexes, although multiple parallel pathways are also possible (Marsh & Teichmann, 2015). Also, the subcomplexes formed during assembly of larger oligomers appear to correlate with evolutionary precursors (Marsh & Teichmann, 2014). It has been proposed that comparing homologous proteins with differing quaternary structures, such as the NR3 family of steroid receptors ([Presman et al., 2016] and the results presented here) can trace the evolution of a homomeric complex (Levy et al., 2008; Perica et al., 2012). Thus, it is tempting to speculate that building the final active conformation of MR involves an initial dimerization of soluble subunits upon ligand binding, possibly common to all steroid receptors, followed by stepwise doubling of oligomer size, which also appears to take place in other NR3 receptors, such as PR (Presman et al., 2016). The most potent agonist, aldosterone, does not generate an average oligomer size of 8, but reaches an average of 6.92 (Figure 1), suggests that the population being observed could be an uneven combination of tetramers and octamers, with predominant presence of the latter.

Inter-subunit interfaces mediating the different steps in forming MR tetramers or higher order oligomers remain to be studied in detail. Our data indicate that all three domains (NTD, DBD and LBD) play a role, with complex interactions between them. In general, it appears that each domain has a modest contribution on its own, as reflected by small decreases in ϵ when they are disrupted by deletion of point mutations in known GR dimerization interfaces. The only exception is mutation C603S, which completely disrupts the first zinc-finger domain in the DBD. This mutation renders MR

monomeric and unable to bind DNA (Cole et al., 2015; Pearce et al., 2002). However, it is not possible to infer that the DBD is the essential domain for DNA oligomerization, since the impact of this mutation on the structure of the receptor may be wider and also, it precludes DNA binding and possibly allosteric interactions between the DBD and LBD, proposed to play an important role in GR tetramerization (Presman et al., 2016; Presman & Hager, 2017).

3.3 | Functional impact of oligomerization

The correlation between agonist and antagonist binding and the size of the MR oligomer strongly suggests that higher order oligomerization detected only after agonist and DNA binding represents an active conformation of the receptor. Whether the larger oligomer size of MR compared to GR imparts biological differences in the function of these two transcription factors is an open question. We have previously proposed that tetramerization of GR may provide a platform to form bridges between different points of the genome (Presman & Hager, 2017). According to this, a higher order oligomer may provide further opportunities for long-range interactions, for instance in mediating enhancer-promoter communication (Uyehara & Apostolou, 2023). On the other hand, and as discussed above, the possibility remains that GR modulation of MR stoichiometry may increase the activity of the latter. In the case of GR, the “tetra” mutation, P481R, stabilizes the tetrameric conformation of the receptor (Presman et al., 2016), allowing functional dissection of tetramerization, which has been shown to potently drive chromatin interactions and transcriptional activity (Paakinaho et al., 2019). The equivalent mutation in MR, P656R, does increase oligomer size in the nucleoplasm from 4.39 to 5.19, but this is a much more modest change that does not appear to change transcriptional regulation of endogenous genes (supplementary Figure S5). It remains to be examined whether this small increase would produce a genome-wide effect changing MR chromatin binding and/or transcriptional outcomes. Ideally, further investigating the mechanisms of MR oligomer formation will provide tools to manipulate oligomer size in the presence of agonists, making it easier to assess its functional importance.

4 | CONCLUSIONS

In summary, we have shown that MR adopts a distinct quaternary structure, further supporting a model where

close evolutionarily relationships between steroid receptor do not implicate conserved oligomerization patterns within this family. These differences do not appear to preclude formation of heteromeric complexes between NR3C receptors. Large MR oligomers at the MMTV array are reached only with agonists, strongly suggesting a relationship between oligomer size and the final active conformation of the receptor. All three domains of MR contain structural determinants of oligomerization. These results have important implications for the pharmacological modulation of steroid receptor signaling.

5 | MATERIALS AND METHODS

5.1 | Plasmids constructs and mutagenesis

A fully functional mouse MR fluorescent derivative with insertion of enhanced green fluorescent protein (eGFP) after amino acid 147 has been previously described (Aguilar-Sanchez et al., 2012). N-terminus eGFP tagged wild type mouse GR or truncated mutant GR-N525, lacking the entire LBD, (eGFP-GR and eGFP-GRN525, respectively) have been previously described (Meijsing et al., 2007; Presman et al., 2016). A plasmid expressing mouse GR tagged in the N-terminus with mCherry was developed by amplifying mouse GR coding sequence and in-frame cloning in pmCherry-C3 (Clontech). Point mutations and deletions were introduced using the Quickchange XL mutagenesis kit (Agilent) following the manufacturer's instructions. Domain swapped mouse MR/GR constructs were constructed by amplification of the relevant fragments from donor plasmids and directional cloning using ligation-free In-Fusion technology (Clontech) in PCR-mediated linearized vectors. PCRs were performed using high-fidelity Pfu ultra II polymerase (Agilent). All constructs and mutations were confirmed by DNA sequencing.

5.2 | Cell culture, transfection and treatment with ligands

The cell lines used in this study originally derive from mouse mammary carcinoma cell line C127 (RRID: CVCL_6550), which were originally modified introducing approximately 200 copies of a tandem array of the Harvey viral ras (MMTV-v-Ha-ras) reporter, which contains several HREs (McNally et al., 2000). This cell line was then modified using CRISPR/Cas9 to knockout the endogenous expression of GR, as previously described (Paakinaho et al., 2019). When indicated, a cell line with

stable integration of a plasmid containing eGFP-MR driven by the CMV promoter was used. This cell line was developed using the CRISPR/Cas9 procedure, as previously described (Paakinaho et al., 2019). Cells with plasmid insertion were selected by puromycin treatment followed by fluorescence-activated cell sorting (FACS). Since expression of MR in the sorted polyclonal cell population declined over time, we further selected stable lines by single-cell cloning. eGFP-MR expression was confirmed by confocal microscopy previously described (Jimenez-Canino et al., 2016). All cell lines were grown in Dulbecco's modified Eagle's medium (DMEM), 10% fetal bovine serum (FBS), sodium pyruvate, nonessential amino acids and 2 mM glutamine. Culture medium and reagents were obtained from Gibco, except FBS, which was from Gemini. Culture medium also contained 5 µg/mL tetracycline (Sigma–Aldrich) to prevent expression of a stably integrated eGFP-GR (Presman et al., 2014). Cells were maintained at 37°C and 5% CO₂ in a humidified incubator. Forty-eight hours before experiments, cells were plated in 2-well borosilicate glass chambers (Nunc™ Lab-Tek™ II, ThermoFisher #155379) in DMEM supplemented with 10% charcoal/dextran-treated FBS (CS-FBS). Next day, cells were transfected using Jetprime (Polyplus) according to the manufacturer's instructions. Ligands were obtained from Sigma-Aldrich (aldosterone, corticosterone, spironolactone and eplerenone) or MedChemExpress (finerenone). On the day of the experiment, cells were treated for 1 h with ligands dissolved in ethanol (vehicle) and added to the medium at the final concentration indicated in each experiment. Ligand concentrations were generally chosen to fully saturate the receptor (Amazit et al., 2015; Hellal-Levy et al., 1999), except when indicated. Hormone washout was performed by three consecutive ten-minute washes with prewarmed hormone-free complete medium with CS-FBS, followed by incubation in the same medium for 4 h. All ligands were obtained from Sigma-Aldrich.

5.3 | Number and brightness (N&B) analysis

N&B was performed as previously described (Presman et al., 2014; Presman et al., 2016). Briefly, cells were placed in an environmentally controlled chamber in a Zeiss LSM780 (CCR Confocal Microscopy Core Facility, NIH, Bethesda, Maryland, USA) or LSM980 (Hospital Universitario NS Candelaria, Tenerife, Spain) confocal microscopes and maintained at 37°C and 5% CO₂ throughout the duration of the experiment. After approximately 30 min of equilibration, single nuclei were imaged using a 63X oil immersion objective (N.A. = 1.4).

Cells were imaged between 30 min and 2 h after addition of each ligand. Fluorescence excitation was performed with a multi-line argon laser tuned at 488 nm and detection was performed with a gallium arsenide phosphide detector set in photon-counting mode. For each nucleus, stacks of 150 images (256 × 256 pixels) from a single plane were taken, using a pixel size of 80 nm and a pixel dwell time of 6.3 µs. In the case of recordings performed with the LSM980 microscope, we collected stacks of 120 images with a pixel dwell time of 8.19 µs. Recording conditions ensured sampling of independent populations of molecules (Mikuni et al., 2007; Presman et al., 2014; Presman et al., 2016). Data analysis was performed using Globals for Images · SimFCS 2 software (Laboratory for Fluorescence Dynamics, University of California, Irvine, CA). Pixels were classified as nucleoplasm or MMTV array according to their intensity values. Quality control for analysis followed our previously described guidelines (Presman et al., 2014; Presman et al., 2016). Average fluorescence intensity ($\langle I \rangle$) and variance (σ^2) were calculated for each pixel along the image stack. The ratio of σ^2 to $\langle I \rangle$ provides the apparent brightness (B). Real brightness (ϵ) was calculated as $B - 1$ (Presman et al., 2014; Presman et al., 2016). Each experimental condition was repeated independently two to five times, as indicated for each condition in figure legends. Results from all independent experiments for each condition/construct were pooled after normalizing with the internal monomeric control (GR-N525), which was included in every independent experiment. When indicated, mCherry-GR was co-transfected with eGFP-MR and the average intensity of mCherry fluorescence was recorded for the nucleus of interest before performing the N&B experiment.

5.4 | Western blot analysis

Cells were seeded in 12-well plates and transfected as described above. Twenty-four hours after transfection cells were washed twice with ice-cold Dulbecco's Phosphate Buffered Saline (D-PBS, Gibco) and lysed in RIPA buffer (150 mM NaCl, 1% IGEPAL® CA-630, 0.5% sodium deoxycholate, 0.1% SDS, 50 mM Tris–HCl, pH 8.0; Sigma Aldrich) supplemented with protease inhibitors (Complete™, Roche). After 10 min incubation on ice, lysates were recovered and cleared by centrifugation (10 min, 15,000 × g, 4°C). Supernatants were collected and total protein concentration was quantified using the bicinchoninic acid procedure. Equal amounts of total protein were mixed with Laemmli buffer, separated by SDS/PAGE (Mini-PROTEAN TGX Stain-Free precast gels, Biorad) and transferred to PVDF membranes. Before transfer, total protein abundance and separation was

visualized under a Chemidoc imaging system (Biorad) using UV light-induced labeling with the proprietary trihalo compound contained in the gels (Neris et al., 2021). Blots were probed with a rabbit polyclonal anti-GFP (Abcam ab290) or mouse monoclonal anti-MR, clone rMR365-4D6 (Gomez-Sanchez et al., 2006), obtained from the Developmental Studies Hybridoma Bank (Department of Biology, University of Iowa), followed by incubation with horseradish peroxidase-conjugated anti-rabbit secondary antibody (Abcam ab6721). Signals were visualized using an enhanced chemiluminescent kit (Biorad).

5.5 | Gene reporter assays

MR transactivation function assays used a luciferase reporter gene and were performed essentially as described (Aguilar-Sanchez et al., 2012; Jimenez-Canino et al., 2016). Briefly, cells were seeded in 96-well plates and transfected with MR-eGFP or an empty vector in combination with a plasmid encoding the firefly luciferase gene under the control of a synthetic promoter containing two copies of the basic glucocorticoid response element (GRE2X-luc; provided by Dr. Rainer Lanz) and a plasmid containing *Renilla* luciferase under the control of a cytomegalovirus promoter (pSG5-ren; provided by Dr. Fátima Gebauer). Transfected cells were cultured for 24 h in CS-FBS supplemented culture medium and then treated for 16 h with vehicle, 10 nM aldosterone or 100 nM corticosterone. Firefly and *Renilla* luciferase activities were measured sequentially using the Dual-Glo assay kit (Promega, Madison, WI). MR-dependent transcriptional activity was calculated as the ratio between firefly and *Renilla* luciferase enzyme activities.

5.6 | RNA isolation, qPCR and RNA-seq analysis

Transfected cells cultured for at least 24 h on CS-FBS supplemented culture medium were treated with vehicle, 10 nM aldosterone or 100 nM corticosterone for 2 h. Total RNA was purified using a commercially available kit (Macherey-Nagel NucleoSpin RNA isolation) that includes an in-column DNase digestion step. Purified RNA was quantified using spectrophotometry and frozen at -80°C . Single-stranded cDNA was synthesized from 1 μg of total RNA as template using a commercially available kit (iScript cDNA Synthesis Kit, Biorad). RT-qPCR analysis of nascent mRNA abundance was performed in duplicate using iQ SYBR Green Supermix (Biorad #1708880) in a Biorad CFX96 machine. Primers for the

amplification of nascent Per1, Sgk1 and Serpine1 were as described (Johnson et al., 2021).

5.7 | Statistical analysis

Statistical analysis was performed using Prism 9 (Graph-Pad). Gaussian distribution of N&B ϵ values was performed using the D'Agostino-Pearson omnibus K2 normality test. When all conditions analyzed passed the normality test, parametric tests were used (t test when comparing only a selected pair of conditions; one way ANOVA followed by Tukey test when comparing more than two conditions). When not all compared conditions passed the normality test, a non-parametric test was used (Kruskal-Wallis followed by Dunn's multiple comparisons correction).
