Abstract

Traumatic brain injury (TBI) is a risk factor for neurodegeneration, however little is known about how different neuron types respond to this kind of injury. In this study, we follow neuronal populations over several months after a single mild TBI (mTBI) to assess long ranging consequences of injury at the level of single, transcriptionally defined neuronal classes. We find that the stress responsive Activating Transcription Factor 3 (ATF3) defines a population of cortical neurons after mTBI. We show that neurons that activate ATF3 upregulate stress-related genes while repressing many genes, including commonly used markers for these cell types. Using an inducible reporter linked to ATF3, we genetically mark damaged cells to track them over time. Notably, we find that a population in layer V undergoes cell death acutely after injury, while another in layer II/III survives long term and retains the ability to fire action potentials. To investigate the mechanism controlling layer V neuron death, we genetically silenced candidate stress response pathways. We found that the axon injury responsive kinase MAP3K12, also known as dual leucine zipper kinase (DLK), is required for the layer V neuron death. This work provides a rationale for targeting the DLK signaling pathway as a therapeutic intervention for traumatic brain injury. Beyond this, our novel approach to track neurons after a mild, subclinical injury can inform our understanding of neuronal susceptibility to repeated impacts.

Introduction

Close to half the population is expected to experience a mild traumatic brain injury (mTBI) at some point in their life[1]. A common form of mTBI is concussion, a brain injury caused by mechanical force and resulting in temporary neurological dysfunction. Although most people seemingly recover, for some the impact can lead to long term damage. There is increasing evidence that repeated mTBI can cause chronic traumatic encephalopathy (CTE)[2] and is a potential risk factor for other neurodegenerative disorders[3–5]. The primary insult of mTBI triggers a cascade of damage termed 'secondary injury' that involves multiple brain cell types and unfolds during the days and weeks following the impact[1]. Even if symptoms during this time can be relatively mild, it is during this chronic phase that neurons are thought to become more vulnerable to repeated injuries. Despite this, the typical treatment for mild TBI is limited to pain management and rest. It is therefore likely that neuroprotective treatments would be beneficial to stave off risk of permanent damage.

To develop effective treatments, we must first better understand the pathways initiated in particular neurons. Many studies to date have lacked the resolution to discern cell type-specific responses[6–8]. More recent work has examined the effect of injury on particular neuron types[9,10]. We reasoned that a detailed look at a model of single mild TBI would provide important insight into the nature and extent of neuronal injury immediately following a concussion. We previously generated a mouse line to track neurons that are transcriptionally responsive to peripheral nerve injury[11] and wondered if it could be used to investigate mTBI.

Peripheral nerve injuries cause a transcriptional response in sensory neurons that is regulated by *Atf3* (activating transcription factor 3) and is essential for functional recovery[11,12]. In sensory neurons, *Atf3* is responsible for upregulating select regeneration-associated genes while repressing many other genes during the recovery process. We wondered whether a similar transcriptional response might occur in the brain after mTBI. Previous studies have observed neuronal *Atf3* activation following injury to the central nervous system. *Atf3* was activated in cortical neurons by TBI and in corticospinal neurons by axon transection depending on the proximity of the injury to the soma[13,14]. Studies in *Atf3*-deficient mice found worse outcomes following TBI and ischemia[15,16], suggesting a protective role for *Atf3*, but did not distinguish between neuronal and glial activation of Atf3. We therefore hypothesized Atf3 would be activated in neurons after mTBI, but wondered how these neurons would compare to peripheral neurons in their ability to exhibit plasticity and recover.

Using genetic reporter mice, single nucleus RNA-sequencing, and slice electrophysiology, we performed a detailed characterization of the neurons that transcriptionally activate *Atf3* after mTBI. We demonstrate that several subclasses of cortical neurons engage the *Atf3* response, but that these undergo divergent fates (death vs survival) that are linked to their identities. We probe the role of multiple candidate pathways for their contribution to cortical neuron death after mTBI and find that dual leucine zipper kinase (DLK), an upstream regulator of *Atf3*, drives neuron death in layer V, highlighting it as a potential therapeutic target for mTBI. These results underscore a

79   differential vulnerability of cortical neurons to mTBI and emphasize the importance of studying
80   injury-induced pathology at the level of individual neuronal subtypes.
81
82   **Results**
83
84   **Characterizing neurodegeneration in a closed skull model of mild TBI**
85
86   To study mild TBI, we characterized a unilateral closed-skull injury model[17] that provides a
87   clinically relevant view of concussion injury and allowed us to accurately dissect the resulting
88   pathological cascade. We used a controlled cortical impact injury wherein an impact was delivered
89   directly to the surface of the skull at a specified depth and velocity. The impact was provided by
90   a 3 mm diameter tip positioned over the mouse's left sensorimotor cortex (Fig. 1a). Following this
91   injury, mice presented with no overt long-term symptomology and no tissue loss, but did exhibit
92   reproducible cortical astrogliosis in an area approximately 2 mm in diameter and confined to the
93   ipsilateral cortex (Fig. 1b). This model resulted in a loss of righting reflex concordant with mild TBI
94   (righting time < 15 minutes[18,19], Fig. 1c), as well as a small yet consistent increase in the serum
95   biomarker of neuron degeneration, neurofilament light[20] (NfL, average 3-fold higher than baseline
96   between 1-14 dpi, Fig. 1d).
97
98   We started by examining pathology in the Thy1-YFP-H mouse, which sparsely expresses a
99   fluorescent protein in layer V cortical neurons, highlighting their morphology[21,22]. We histologically
100   confirmed cortical neurodegeneration in these mice (Fig. 1e). At 7 days post injury (dpi), we
101   observed hallmarks of degenerating dendrites, cell bodies, and axons specifically in the ipsilateral
102   cortex but not the side contralateral to injury (Fig. 1e-k, Supplementary Fig. 1a). Cortical dendrite
103   fragmentation in the region above layer V was quantified using a degeneration index calculation[23]
104   and revealed significant degeneration of YFP+ dendrites[24] only in the ipsilateral cortex when
105   compared to the contralateral side or the ipsilateral cortex of sham injury controls (Fig. 1f,i). Below
106   layer V there was a significant increase in YFP-positive structures that did not correspond to cell
107   bodies but rather to pathological enlargements of axons (area = 10-250 μm^2, mean = 20 μm^2, Fig.
108   1h,j). Some of these axonal swellings were of comparable size to cell bodies but none contained
109   DAPI-positive nuclei (Supplementary Fig. 1b). The swellings likely correspond to disruption in
110   axon transport leading to organellar and protein accumulations, also called diffuse axonal
111   injury[9,25–27]. We also observed beading of axons (fragments < 10 μm^2) representing axon
112   degeneration. We found that both axon beading and swelling were increased only in the ipsilateral
113   cortex at 7 dpi (Fig. 1h,j).
114
115   Because the Thy1 reporter is stochastically expressed, and because we had specifically observed
116   inflammatory, dendritic, and axonal pathology only on the side ipsilateral to injury, to quantify any
117   potential cell loss, we compared the number of YFP+ neurons in the cortex ipsilateral to the injury,
118   and normalized them to the contralateral cortex of each section. We measured a 15.3% ± 1.8 loss
119   of cell bodies at 7 dpi, and 26.3% ± 7.9 loss at 14 dpi (Fig. 1e,k). Thus, we find that a single
120   unilateral closed head impact over the sensorimotor cortex reproducibly leads to degeneration of
121   layer V projection neurons ipsilateral to the injury and across neuronal compartments.
122

123

mTBI produces an Atf3 response in a subset of cortical neurons

125

Transcription factors play major roles in neuronal responses to injury, and their activation can determine whether a neuron degenerates or regenerates. The transcription factor ATF3, in particular, is a master regulator of the transcriptional response to neuronal injury, and is responsible for driving a transcriptional shift toward an injured cell state[11,12]. We looked for ATF3 expression in brains following mTBI and observed that at 7 dpi, ATF3 immunolabeling localized specifically to the injured side of the cortex (Fig. 2a). We found 10% ± 2.3 of YFP-expressing neurons expressing ATF3 at this timepoint[13] (Fig. 2b). Some ATF3-positive cells were also present in layer II/III (Fig 2a).

134

Our initial attempts to identify the ATF3-positive neurons in layer V using markers of projection neurons such as CTIP2[28] were unsuccessful. We observed no double labeled cells upon staining for ATF3 and CTIP2 (Fig. 2d-f). We reasoned that ATF3 might be repressing marker genes in the cortex after TBI as has been observed in peripheral sensory neurons after axon injury[11,12]. We therefore performed single nucleus RNA sequencing of these neurons to obtain a more comprehensive picture of their repertoire of RNA expression.

141

142

Transcriptional profiling of cells that activate Atf3 in the injured cortex

144

We employed targeted snRNAseq of *Atf3*-expressing neurons using an inducible Atf3-IRES-CreER mouse line[12] crossed to the INTACT nuclear envelope protein reporter[29]. The resulting animals express GFP tethered to the nuclear envelope in cells that are expressing Atf3 at the time of tamoxifen treatment. Tamoxifen was administered at 4 and 5 dpi to induce expression of the nuclear GFP reporter and cortical tissue at the injury site was collected at 7 dpi, enabling the isolation of nuclei for single nucleus sequencing from cells expressing *Atf3* during this acute phase (Fig. 2c).

152

We sequenced 8,065 GFP+ nuclei and found a significant number of microglia (4274, 53.0%), excitatory (2057, 25.5%) and inhibitory (744, %) neurons, and small populations of astrocytes (107, 1.3%), oligodendrocytes (75, 0.9%), and other cells (808, 10%) (Supplementary Fig. 2a-e). In this study we focus on the role of ATF3 as an injury marker in neurons, but we note its role in microglial function as an interesting avenue for future investigation[30,31].

158

159

Specific subclasses of excitatory and inhibitory cortical neurons activate Atf3-associated injury pathways

162

We mapped the neuronal nuclei from this experiment onto a highly annotated mouse motor cortex reference atlas[32] to assign cellular subclasses based on the nuclear transcriptome. Of the 2,801 neuronal nuclei sequenced using the Atf3-CreER approach, we identified excitatory neurons across cortical layers, parvalbumin (Pvalb) and somatostatin (Sst) interneurons, and small

5

numbers of Lamp5, Vip, and Sncg interneurons (Fig. 2d,f, Supplementary Fig. 2a,b, Supplementary Table 1). Using multiplex *in situ* hybridization with markers from the data, we validated the presence of Gfp+ excitatory and inhibitory neurons (Supplementary Fig. 3a-c). Interestingly, all interneuron subclasses expressed the inhibitory neuron marker *Gad2*, but lacked their subclass markers, including *Pvalb* or *Sst* (Fig. 2f). Similarly, neurons assigned to excitatory cortical layer identities lacked the typical expression of *Slc17a7* (VGLUT1), but expressed some layer-specific markers, such as *Cux2*, *Rorb*, and *Foxp2* (Fig. 2f). Thus, in the cortex - similar to the peripheral sensory nervous system[11,12] - Atf3 expression leads to the downregulation of multiple marker genes.

In our experiment, we captured neurons that had expressed *Atf3* at 4 and 5 dpi, and sequenced them at 7 dpi. Some of these still expressed *Atf3*, but many only had low or undetectable *Atf3* expression (Fig. 2g, Supplementary Fig. 3a). In contrast, the damage-induced neuronal endopeptidase *Ecel1*, whose expression is directly downstream of *Atf3*[33], was highly expressed in both excitatory and inhibitory neurons (Fig. 2g, Supplementary Fig. 3a). We investigated the expression of a panel of injury-induced genes across neuronal subclasses and discovered that not all neuron subclasses that activated *Atf3* underwent the same subsequent transcriptional programs (Fig. 2g). For example, pro-apoptotic and endoplasmic reticulum (ER) stress genes such as *Ddit3*[34] were most highly expressed in layer V neurons and low in layer II/III (validated by in situ hybridization, Supplementary Fig. 3d), while *Atf3* and axon growth genes were most highly expressed in Pvalb and other interneuron subclasses. Thus although many neurons upregulate Atf3, their overall transcriptional changes differ according to cell type. Our data thus highlight heterogeneous transcriptional programs and fates among the Atf3-captured neurons.

Genetic labeling of Atf3-expressing neurons highlights layer-specific vulnerability

To visualize and map the neurons that express *Atf3* after mTBI, we generated a neuron-specific *Atf3* reporter mouse (Atf3-GFP) in which GFP is permanently expressed only in neurons once *Atf3* is upregulated. This mouse results from a cross between Atf3-IRES-Cre and a Cre-dependent reporter line expressing GFP under control of the neuron-specific Snap25 promoter (Jax 021879). In control mice, sparse GFP labeling is observed in the cortex and in some hippocampal neurons, likely due to developmental Atf3 expression (Supplementary Fig. 4a). We assessed the extent of Atf3-GFP labeling in the cortex and in other brain regions, observing injury-induced GFP primarily on the ipsilateral side of the cortex, as well as in the ipsilateral anterior thalamic nuclei (Supplementary Fig. 4b). The anterior thalamic neurons project into the cortex around the site of injury, and thus their axons may be damaged in this injury model[35,36].

Because this Cre-dependent system results in permanent labeling of neurons in which *Atf3* is induced, we concluded that loss of GFP-expressing neurons together with signs of neurodegenerative pathology would indicate cell death. Longitudinal quantification up to 70 dpi of GFP-expressing neurons in the ipsilateral cortex revealed that a prominent group of layer V cortical neurons expressed Atf3-dependent GFP between 5 and 10 dpi and subsequently disappeared by 14 dpi, while a population of layer II/III neurons persisted at 70 dpi (Fig. 3a,b).

211   The loss of layer V Atf3-GFP neurons by 14 dpi echoes the layer V neuron loss observed in the
212   Thy1-YFP mouse (Fig. 1e,f). Parallel quantification of ATF3 protein revealed a comparative delay
213   in GFP expression and extensive activation of ATF3 in non-neuronal cells, which was consistent
214   with our snRNAseq data (Supplementary Fig. 5a). Interestingly, amplification of GFP signal with
215   immunolabeling revealed that some layer II/III neurons initially exhibit lower expression of GFP
216   (Fig. 3b).

217
218

219   **Layer V Atf3-expressing neurons undergo cell death and are phagocytosed following mTBI**

220

221   Atf3 activation promotes axon regeneration in peripheral injuries, but here we found its expression
222   in neurons that are unlikely to regenerate. Because GFP+ neurons at 7 dpi were present only on
223   the ipsilateral side of the cortex and primarily in layer V (Supplementary Fig. 5c), we were able to
224   use the stereotyped projection patterns of layer V neurons to inspect the dendrites and axons of
225   these neurons. Similarly to the Thy1-YFP+ layer V neurons (Fig 1e-k), we discovered that the
226   GFP+ dendrites were severely fragmented, indicating dendrite degeneration, while GFP+ axons
227   exhibited axonal swellings typical of diffuse axonal injury (Supplementary Fig. 5a).
228   Morphologically unhealthy neurons that exhibited cell body vacuolization and loss of nuclear DAPI
229   signal were also observed in layer V (Supplementary Fig. 5b, d).

230

231   Neuron death in layer V was confirmed by examining the expression of several types of apoptotic
232   markers in Atf3-GFP tissue. The pro-apoptotic gene *Ddit3*[34] was significantly increased in GFP+
233   neurons compared to GFP-negative neurons either ipsilateral or contralateral to injury. In GFP+
234   neurons with high *Ddit3* expression, we observed high DAPI intensity reflecting chromatin
235   condensation during apoptosis[37] (Supplementary Fig. 5d,e). These apoptotic cells had lower GFP
236   expression and appeared morphologically misshapen (shriveled/deformed, Supplementary Fig.
237   5c). Additionally, the DNA damage marker phospho-H2AX, which is phosphorylated during
238   apoptosis[38], was elevated in GFP+ neurons at 10 dpi but not in GFP- neurons in the ipsilateral or
239   contralateral cortex (Supplementary Fig. 5f,g). The specificity of phospho-H2AX upregulation to
240   GFP+ neurons and not their GFP- neighbors highlights that this mechanism of cell death is
241   specific to neurons undergoing *Atf3*-associated injury responses at this timepoint. Thus, we
242   conclude that layer V neurons that activate *Atf3* undergo apoptosis in the weeks following injury.

243

244   Related to this neuron death, we found that microglia exhibited increased phagocytic activity in
245   the ipsilateral cortex and engulfed debris from dead GFP+ neurons. A significant proportion of
246   CD68+ microglial lysosomes contained GFP+ debris (10% ± 4.2 of at 7 dpi) which increased by
247   14 dpi (15% ± 3.5), and coincided with the maximal loss of layer V neurons (Supplementary Fig.
248   5h,i). Microgliosis occurred specifically in the ipsilateral cortex where it peaked around 10 dpi and
249   returned to baseline by 42 dpi (Supplementary Fig. 6a,b). Astrogliosis occurred in a delayed yet
250   prolonged peak of GFAP expression which remained elevated at 70 dpi (Supplementary Fig.
251   6a,c).

252

253 These findings demonstrate mTBI leads to activation of *Atf3*-associated pathways in layer V
254 cortical neurons, to their degeneration and death within two weeks after injury, and to cortical glial
255 responses.
256
257 **Layer II/III Atf3-expressing neurons survive and remain electrophysiologically active**
258
259 The analysis of Atf3-GFP neurons across cortical layers over time (Fig. 3a) revealed the loss of
260 most GFP-positive layer V neurons, and highlighted those in layer II/III as the main surviving GFP-
261 positive population at 70 dpi. To evaluate whether this resulted from long-term survival of *Atf3*-
262 marked neurons, we used the inducible Atf3-CreER reporter line. By injecting tamoxifen at 4 and
263 5 days post injury, we could permanently label cells expressing *Atf3* at this time point and evaluate
264 their localization over time (Fig. 3c). At 7 dpi, most labeled neurons were located in layer V, while
265 those remaining at 21 dpi were primarily found in layer II/III. These layer II/III *Atf3*-marked neurons
266 persisted until at least 42 dpi (Supplementary Fig. 7a), and likely represent a resilient population
267 of neurons that activate this stress response pathway soon after injury and survive. Additionally,
268 layer II/III neurons at 21 dpi appeared morphologically healthy, unlike the degenerative profiles
269 observed in some layer V neurons at 7 dpi (Supplementary Fig. 7b,c).
270
271 Next, we determined whether Atf3-GFP neurons displayed injury-induced alterations in excitability
272 and basic membrane properties. We hypothesized the neurons would traverse a cellular state
273 with altered electrophysiological properties reflecting the Atf3-response, and that this would differ
274 between neurons from layer V versus layer II/III. We performed whole-cell patch clamp recordings
275 of excitatory neurons from the neuron-specific Atf3-GFP mice at an acute (5-7 dpi) and late (21
276 dpi) timepoint. At the acute timepoint, layer II/III neurons expressed low levels of endogenous
277 GFP and were thus too sparse and poorly defined to record from (Fig. 3b). Therefore, at this
278 timepoint, we only recorded from GFP+ neurons in Layer V.
279
280 Layer V neurons at the acute stage were sufficiently healthy to record from, therefore not yet
281 undergoing apoptosis, but they had clear alterations in electrophysiological properties compared
282 to GFP-negative control neurons in the ipsilateral or contralateral cortex. They exhibited reduced
283 intrinsic excitability: they were unable to sustain repetitive regular firing (Fig. 4a,b), had a higher
284 rheobase (the minimal current required to initiate an action potential), and a significant decrease
285 in the maximum number of spikes produced (Fig. 4c,d). They were also more depolarized (-54
286 mV vs -68 mV in controls, Fig. 4e). However, their lowered excitability did not stem from alterations
287 in passive membrane properties since these were no different from controls (input resistance,
288 Supplementary Fig. 7f, and capacitance, which reflects cell size and/or arborization complexity,
289 Fig 4f).
290
291 GFP-negative neurons in the ipsilateral cortex were indistinguishable from contralateral uninjured
292 neurons by nearly all measures, suggesting the decline in intrinsic excitability observed in GFP+
293 layer V neurons is a specific consequence in Atf3-positive neurons. Consistent with this, in our
294 snRNAseq profiling of Atf3-captured neurons, we noted a pattern of downregulation of ion
295 channels involved in action potential firing and maintenance of membrane potential (Fig. 4g). We
296 confirmed the downregulation of *Scn1a* and *Kcnq5* in GFP+ layer V neurons in the tissue (Fig.

297   4h). The downregulation of these genes provides an explanation for the changes in excitability
298   we observed in the Atf3-marked neurons.
299
300   At the later time point, 21 dpi, Atf3-GFP layer II/III neurons were able to maintain sustained firing,
301   similar to GFP-negative controls (Fig. 4i, j, l). However, they exhibited increased tonic firing
302   (Supplementary Fig. 7h), decreased rheobase threshold (Fig. 4k), increased input resistance
303   (Supplementary Fig. 7j), and depolarized membrane potential (-53 mV vs –66 mV in controls, Fig.
304   4m) - all measures that reflect increased excitability. GFP+ neurons also exhibited a reduced
305   capacitance, suggesting that they might be more compact and/or less complex than GFP- controls
306   (Fig. 4n). Interestingly, amplified hyperpolarization-activated (Ih) current, an inward current that is
307   important in regulating action potential firing frequency, may contribute to enhanced tonic firing in
308   GFP+ neurons in layer II/III[39,40] (Supplementary Fig. 7k, i). Together, these findings suggest that
309   surviving layer II/III Atf3-GFP neurons adapt passive membrane properties to maintain sustained
310   firing.
311
312
313   **Layer II/III neurons undergo axon initial segment reorganization following mTBI**
314
315   Because we found that GFP+ neurons in layer II/III survive but are hyperexcitable, we wondered
316   what the consequences would be on their output. We therefore examined whether their axon
317   initial segment (AIS) underwent alterations. The AIS is a specialized structure at the base of the
318   axon that is essential for generating action potentials[41,42]. Other neuron types have been reported
319   to transiently lose their AIS during regeneration[43–45]. Immunolabeling for Ankyrin-G, a master
320   scaffolding protein of the AIS, suggested that the AIS in layer II/III neurons was lost at 7 dpi but
321   regained by 14 dpi (Supplementary Fig. 8a-c). This transient loss of AIS markers was confirmed
322   with staining for another AIS protein, β4-spectrin (Supplementary Fig. 8d). The hyperexcitability
323   observed at 21 dpi in layer II/III neurons may be linked to a reorganization of the AIS after mTBI.
324   By contrast, layer V neurons did not lose their AIS (Supplementary Fig. 8a-d) — their reduced
325   excitability may be due to lack of necessary machinery for ion flux caused by ion channel
326   dysregulation (Figure 4f). Previous studies of closed skull TBI have described an early loss of
327   activity followed by a stage of hyperactivity[46]. Our observation of the transient disappearance of
328   the AIS in layer II/III neurons may suggest that the observed changes in excitability are inherent
329   to the recovery process. Interestingly, the AIS is also a site of neuronal polarization in
330   development and regeneration[47].
331
332
333   **Atf3 is not required for mTBI-induced layer V neuron degeneration or death, but is required**
334   **for downregulation of ion channels**
335
336   Although *Atf3* is required for regeneration of sensory neurons following peripheral nerve injury[12,48],
337   our finding that Atf3-GFP cortical neurons in layer V die following mTBI suggested *Atf3* may play
338   a pro-degenerative role in the central nervous system. To investigate this, we deleted *Atf3* in layer
339   V neurons using an Rbp4-Cre driver (Rbp4-Cre::Atf3[fl/fl], Atf3 cKO) and quantified degenerative
340   pathology. We confirmed that layer V ATF3 expression was effectively reduced in Atf3 cKO mice

9

341   at 7 dpi (Supplementary Fig. 9a,b), with any remaining ATF3+ nuclei likely representing non-
342   neuronal cells. Layer V deletion of *Atf3* did not affect dendrite degeneration[24] or presence of
343   axonal swellings at 7 dpi, nor did it prevent mTBI-induced cell death or microgliosis
344   (Supplementary Fig. 9d-i, 12c,d).

345

346   Because ATF3 drives downregulation of marker genes[11,12], we wondered if it is required for the
347   loss of ion channel genes following mTBI (Fig. 4g,h). *In situ* hybridization of *Scn1a* in Atf3 cKO
348   tissue (Rbp4-Cre::Atf3$^{fl/fl}$::Sun1-GFP) revealed that the injury-induced loss of *Scn1a* in layer V
349   neurons at 7 dpi is prevented by Atf3 cKO (Supplementary Fig. 10). This demonstration that
350   downregulation of *Scn1a* is *Atf3*-dependent suggests that *Atf3* could also drive transcriptional
351   repression of additional ion channels leading to the observed functional deficits in Atf3-expressing
352   neurons.

353

354   **The integrated stress response and SARM1 pathway are not required for mTBI-induced**
355   **degeneration**

356

357   Several interconnected signaling pathways influence neurodegeneration (Supplementary Fig.
358   11a). The integrated stress response (ISR), which halts translation in response to multiple
359   neuronal stressors, and the SARM1 pathway, which controls Wallerian degeneration have both
360   been shown to play neurotoxic roles in mTBI[6,49–53]. We wondered if we could protect layer V
361   neurons by targeting these pathways. We use three genetic models to manipulate key players: a
362   phospho-dead mutant of eIF2α (knock-in point mutation, serine to alanine substitution, eIF2a^{S51A})
363   that results in approximately 50% reduction of eIF2α and thus reduces ISR function[54], a
364   conditional knockout of the pro-apoptotic effector of the ISR *Ddit3* (Rbp4-Cre::Ddit3$^{fl/fl}$, Ddit3 cKO)
365   in layer V neurons[34], and a global knockout of the executor of Wallerian degeneration Sarm1[55]
366   (Sarm1 KO). We find that targeting each of these pathways on its own is not sufficient to prevent
367   dendrite degeneration, axon beading or swelling, or cell death (Supplementary Fig. 11).
368   Therefore, we conclude that either none of these pathways is important for neuron death following
369   mTBI, or that their collective action is required.

370

371

372   **Layer V deletion of Dlk prevents degeneration and death**

373

374   We had previously noted the upregulation of multiple stress responsive genes in deeper layer
375   cortical neurons (Fig 2g), so it was perhaps unsurprising that deletion of individual pathway
376   effectors was not sufficient to prevent death of layer V neurons. We observed, however, that
377   phosphorylated c-Jun (p-c-Jun), a known binding partner of ATF3, was distributed in a similar
378   pattern as ATF3 in the ipsilateral cortex (Fig. 5a). These transcription factors, ATF3 and p-cJun,
379   are known to be activated by the axon damage sensing protein DLK[56–58] (dual leucine zipper
380   kinase; Supplementary Fig. 11a). DLK can drive ISR activity through phosphorylation of an ISR
381   kinase, PERK[59,60] (Supplementary Fig. 11a, i-k), and promote Sarm1 activation through inhibition
382   of its regulator, NMNAT[61–63] (Supplementary Fig. 11). We thus reasoned that targeting DLK might
383   be protective as a node sufficiently upstream of multiple neuronal stress responses. Furthermore,
384   while the marker of DLK pathway activation p-c-Jun was detected in both layer V and layer II/III

385 neurons, there was significantly higher expression in layer V neurons, correlating with their
386 differential vulnerability (Fig. 5a,b). We thus tested if deleting DLK would promote survival of Atf3-
387 neurons in layer V.

388

389 We conditionally deleted Dlk in layer V neurons using the Rbp4-Cre driver line (Rbp4-Cre::Dlk^fl/fl,
390 Dlk cKO). We validated that *Dlk* transcript was selectively reduced in layer V DLK cKO neurons
391 (Supplementary Fig. 12b,c). DLK deletion completely prevented layer V neuron death, rescuing
392 the ~15% loss of these neurons in the ipsilateral cortex (Fig. 5c,d). This rescue was maintained
393 in Dlk cKO animals at 42 dpi (Supplementary Fig. 12d). By crossing the DLK cKO line with the
394 Thy1-YFP reporter, we also observed that DLK cKO prevented mTBI-induced dendrite
395 degeneration, and significantly reduced (but did not completely suppress) axon beading and
396 swelling (Figure 5e-g).

397

398 DLK signaling is essential in sensory neurons for recruitment of microglia and other inflammatory
399 cells to sites of injury[64–66]. We investigated whether DLK cKO locally reduced microgliosis in the
400 cortex after mTBI. We found that microgliosis was selectively reduced in layer V, where Dlk was
401 depleted (Supplementary Fig. 13a, b). Interestingly, although DLK is required for *Csf1*
402 upregulation in sensory neurons to recruit microglia following peripheral nerve injury, we found
403 that CSF1 does not play a role in mTBI-induced cortical microgliosis (Supplementary Fig. 13e,f).
404 Thus, mTBI-induced layer V microgliosis is not initiated through a neuronal injury response that
405 actively recruits microglia via Csf1. Instead, microgliosis may occur as a response to factors
406 released by apoptotic neurons, such as ATP, and prevention of neuron death by DLK deletion is
407 therefore sufficient to prevent microglial recruitment.

408

409 We thus find that DLK activation is required for the degeneration of layer V neurons following
410 mTBI, and that its differential activation in layer V and layer II/III neurons may be responsible for
411 the differential vulnerability.

412

413

414 **Discussion**

415

416 In this study, we develop and characterize a model of mild TBI in which we follow the cellular and
417 molecular sequelae of a single impact to the skull on specific cortical neuron types during several
418 weeks following injury. We used a closed-skull injury in order to model a clinically-relevant mild
419 trauma to the cortex. We find that despite its mild nature, this single impact injury produces wide
420 ranging consequences to neurons within the cortex, from cell death to survival, with specific
421 neuron types undergoing specific reproducible fates. We used the neuronal injury marker *Atf3* as
422 a reporter to gain genetic access to a subset of neurons that transcriptionally responds to the
423 injury. This allowed us to molecularly and spatially identify these neurons, describe their location
424 and morphology, record their electrophysiological properties, and determine how their cellular
425 states evolve over time. We discovered that the Atf3-responsive population of neurons falls into
426 two categories: one located in layer V that undergoes neuronal death within 2 weeks after injury,
427 and one in layer II/III that survives at least 2 months after injury. We found that the DLK signaling

428   pathway is responsible for the death of the Atf3-responsive neurons in layer V, highlighting its
429   value as a potential target for prevention treatments for TBI.

430

431   One challenge in studying models of mTBI is the ability to accurately quantify events or cell
432   numbers using markers that are transient or altered by the injury itself. For example, commonly
433   used markers to assess apoptosis are quite transient and may be missed. In this study, we
434   demonstrate that many marker genes of cortical neuron types are lost after mTBI, making it
435   impossible to accurately label or quantify the neuronal cell types in which they are normally
436   expressed. This is consistent with other work showing that stress response mechanisms adopted
437   by injured neurons to regain homeostasis after injury often result in the loss of expression of
438   markers genes and proteins[11,12,67]. To overcome this, we relied on genetic labeling to track and
439   record from our neurons of interest. This strategy also facilitated the enrichment of this relatively
440   rare population of cells within the cortex, allowing us to perform single nucleus transcriptomics to
441   molecularly identify them using their transcriptome instead of individual marker genes.
442   Additionally, this novel approach to study injured neurons is applicable to investigating the
443   neuronal Atf3 response in a range of neurodegenerative conditions, beyond TBI.

444

445   The Atf3-reporter strategy highlighted the existence of two main populations of neurons after
446   mTBI, and a striking differential vulnerability between them. The neurons in layer V mostly died
447   within 2 weeks of the injury while those in layer II/III survived. An intriguing aspect of the Atf3-
448   GFP neurons in layer II/III is that they initially express the GFP reporter much more weakly than
449   those in layer V. The initially faint reporter labeling may reflect a stronger translational repression
450   in these neurons than in layer V that is reversed as they regain homeostasis. A question naturally
451   arises: what is it about layer V neurons that makes them more vulnerable to degeneration? Layer
452   V neurons have been highlighted as a vulnerable population within the cortex in multiple diseases
453   and experimental models[4,68–72]. Using machine learning to classify the regeneration potential of
454   neurons, a recent study identified layer V neurons as the least regenerative within the cortex[73]. It
455   may be that their large somas, long axons, and metabolic demands require a molecular make-up
456   that confers an increased vulnerability[74]. Selective vulnerability is seen across neurodegenerative
457   diseases, necessitating further research to identify causative elements.

458

459   We found that DLK is essential for the death of layer V neurons, consistent with the known role
460   of DLK signaling in promoting neuron death[56,57,75–80]. It is reasonable to imagine that the mild
461   concussive TBI in our model produces axotomy of layer V projection neurons, and thus DLK-
462   dependent death. While some layer II/III neurons have corticocortical projections, others project
463   locally; thus, it is less clear whether they activate the Atf3-stress response pathway as a result of
464   axotomy or another mechanism. Regardless, the majority of these layer II/III neurons do not
465   degenerate within 70 days of the injury. Our snRNAseq data clearly demonstrate that, despite
466   sharing the expression of *Atf3* and *Ecel1*, the neurons from each layer express differential
467   transcriptional programs, consistent with their divergent fates.

468

469   Recently, DLK inhibitors have been developed to treat neurodegenerative conditions[57,64,75,81–83],
470   and understanding the role of the DLK pathway in mTBI will be critical for determining if it may be
471   a viable therapeutic target. Recently, a Phase I clinical trial of a DLK inhibitor in ALS patients was

472   halted after weeks of treatment due to observations of adverse effects including low platelet count,
473   ocular toxicity, and altered touch sensation[84]. However, mTBI may be a more appropriate
474   indication for trial as the injury timing can be known or even anticipated and dosing could be acute
475   rather than chronic to reduce undesirable side-effects. Alternate methods to target DLK signaling
476   may also be developed in future.
477
478   This study deepens our understanding of how cortical neurons respond to mTBI, and reveals the
479   heterogeneous nature of their responses. By uncovering the differential vulnerability of distinct
480   neuronal populations and their diverging engagement of multiple stress response pathways, we
481   pave the way for targeted therapeutic interventions. It is possible that the initiation of neuronal
482   stress responses after a single acute injury, as described in this study, can make surviving
483   neurons susceptible to further injury, highlighting the need for therapeutic approaches for
484   populations prone to recurrent injury, such as athletes and military personnel. The identification
485   of the DLK pathway as a potential target for neuroprotection opens new avenues for treatment
486   strategies. Ultimately, these findings offer crucial insights into the complex landscape of neuronal
487   injury responses, providing a foundation for future investigations and potential clinical
488   interventions aimed at mitigating the long-term impact of mTBI on cortical neurons.
489

490   **Limitations**
491   One key limitation of this study is the reliance on a Cre-dependent labeling strategy, which
492   requires functional translational machinery and sufficient time for reporter expression. Using the
493   Atf3-Cre line, we may have missed Atf3-positive neurons that are unable to produce the reporter
494   and/or that die too rapidly. Our analyses using the inducible Atf3CreER mouse are limited to the
495   specific times of tamoxifen delivery. The use of the Atf3-CreER line for snRNA sequencing of
496   injured neurons also meant that we lacked the appropriate set of control nuclei, so we relied on a
497   reference atlas to analyze the data. Finally, our conditional deletion experiments using Rbp4-Cre
498   result in late embryonic deletion of genes which may have affected layer V neuron development.
499

500   **Methods**
501

502   **Mice**
503   All animal care and experimental procedures were performed in accordance with animal study
504   proposals approved by the *Eunice Kennedy Shriver* National Institute of Child Health and Human
505   Disease Animal Care and Use Committee. Adult (>7 weeks of age) male and female mice were
506   used for all experiments, but were not analyzed separately. Thy1-YFP mice were acquired from
507   The Jackson Laboratory (B6.Cg-Tg(Thy1-YFP)HJrs/J, Jax Stock No. 003782) Atf3-Cre mice, as
508   previously described[11], were generated via knockin of an IRES-Cre sequence after the stop codon
509   of Atf3 at the endogenous locus, such that endogenous Atf3 would remain intact. Atf3-CreER and
510   Atf3 fl/fl mice were obtained from Dr. Clifford Woolf. Dlk fl/fl mice were obtained from Dr. Aaron
511   DiAntonio. For sequencing studies, Atf3-CreER mice were crossed to Sun1-sfGFP (B6;129-
512   Gt(ROSA)26Sortm5(CAG-Sun1/sfGFP)Nat/J, Jax Stock No. 021039) and bred to heterozygosity
513   for both alleles. For visualization of Atf3-expressing neurons, Atf3-Cre or Atf3-CreER mice were
514   crossed to Snap25-LSL-eGFP (B6.Cg-Snap25tm1.1Hze/J, Jax Stock No. 021879) or Ai14
515   (B6.Cg-Gt(ROSA)26Sortm14(CAG-tdTomato)Hze/J, Jax Stock No. 007914) and bred to

13

516 heterozygosity for both alleles. For all conditional knockout experiments, Rbp4-Cre mice (Rbp4-
517 Cre (B6.FVB(Cg)-Tg(Rbp4-cre)KL100Gsat/Mmucd, MMRRC Stock No. 037128-UCD) were
518 crossed to the flox line such that the floxed allele would be homozygous and Cre-negative
519 littermates could be used as controls (this was for Dlk-fl, Atf3-fl and Csf1-fl lines). Chop fl mice
520 (B6.Cg-Ddit3tm1.1Irt/J, Jax Stock No. 030816), Csf1 fl mice (shared by Dr. Sherry Werner[85]) and
521 Sarm1 KO (C57BL/6J-Sarm1em1Agsa/J, Jax Sock No. 034399) were used for knockouts. For
522 Sarm1 KO, heterozygote littermates were used as controls, as heterozygous KO is not sufficient
523 to prevent Wallerian degeneration. For ISR manipulation, we used Eif2-S51A mice (B6;129-
524 Eif2s1tm1Rjk/J, Jax Stock No. 017601). Because homozygosity in this mutation is lethal,
525 heterozygotes were used for experiments, and WT littermates were used as controls. For
526 inducible Cre experiments, mice were dosed intraperitoneally with 75 mg/kg of a 20 mg/mL
527 solution of tamoxifen mixed in corn oil at 4 and 5 dpi.
528

Mild traumatic brain injury

529
530 Closed-skull mild traumatic brain injury was administered using the Leica Impact One (Leica
531 Biosystems, Cat. No. 39463920) controlled cortical impact (CCI) device. Mice receiving injury
532 were anesthetized with 2-2.5% isofluorane and positioned in a nose cone on foam pad. No
533 stereotaxic restraint was used, however neonatal ear bars were used to loosely stabilize the head
534 to enhance consistency while maintaining movement upon impact. Mice were shaved and
535 depilated around bregma. The 3 mm piston tip, mounted on the stereotax at an angle of 10
536 degrees from the vertical plane, was centered roughly at bregma and moved 2 mm lateral to the
537 midline. The impactor was driven at a velocity of 5 m/s, depth of 1.5 mm, and dwell time of 200
538 ms. Animals receiving sham injuries were shaved, depilated, and anesthetized for the same
539 amount of time as those receiving TBI, but were not administered the injury. Animals were given
540 5 mg/kg Meloxicam subcutaneously for analgesia immediately after injury and monitored after
541 removal of anesthesia to evaluate righting reflex. Mice exhibiting tissue deformation following
542 injury were excluded.
543

Serum collection and Neurofilament Light Simoa Assay

544
545 Animals were lightly anesthetized using isofluorane until response to painful stimuli was lost.
546 Blood was collected at baseline, 1, 9, and 14 dpi. The retro-orbital sinus of one eye was
547 penetrated with a sterile unfiltered P1000 pipette tip. Blood was collected into BD Microtainer
548 Capillary Blood Collector tubes (Cat. No. 365967) and allowed to clot at room temperature for 10
549 min. No more than 10% of the animal's body weight by volume was collected per session. Tubes
550 were spun down at 6500 rpm for 10 minutes at 4 °C and the supernatant was aliquoted for storage
551 at -80 °C. The Quanterix Neurology 4-plex A (Item 102153) assay was run following manufacturer
552 instructions. Briefly, standards were plated in triplicate and test samples were plated in duplicate.
553 Only neurofilament-light measurements were detectable and consistent between replicates. The
554 average of the two replicates were reported as the final sample NfL measurement.
555

Single nucleus RNA isolation and sequencing

556
557 Mice were anesthetized using 2.5% avertin and decapitated, and the brain was rapidly dissected.
558 Ipsilateral cortical regions, roughly 4-5 mm diameter and centered around the injury site (as shown
559 in Fig 1a), were collected and rapidly frozen in pre-chilled tubes on dry ice, then stored at -80 °C.

560 For the dissection of the desired cortical region, the ipsilateral hemibrain was rapidly isolated from
561 the skull. Brain tissue anterior, posterior, and lateral to the area of interest (as visualized in Figs
562 1b and Supp Fig 4b) was removed, as well as any tissue below the corpus callosum. Nuclei
563 isolation and sequencing was performed as previously described[86]. Ipsilateral cortical regions
564 from 4 animals were pooled for each sequencing run to remove individual variability. Two datasets
565 were integrated for the study, one collected from male animals and one from female animals. Sex
566 differences were not observed. Samples were homogenized in a dounce homogenizer (Kimble
567 Chase 2 ml Tissue Grinder) containing 1 ml freshly prepared ice-cold lysis buffer. The
568 homogenate was filtered through a 40 µm cell strainer (FisherScientific #08-771-1), transferred to
569 a DNA low bind microfuge tube (Eppendorf, #022431048), and centrifuged at 300×g for 5 min at
570 4 °C. The washing step was repeated, and the nuclei were resuspended in 1× PBS with 1% BSA
571 and 0.2 U/µl SUPERaseIn RNase Inhibitor (ThermoFisher, #AM2696) and loaded on top of a
572 1.8 M Sucrose Cushion Solution (Sigma, NUC-201). The sucrose gradient was centrifuged at
573 13,000×g for 45 min at 4 °C for extra cleanup. The supernatant was discarded, the nuclei were
574 resuspended in 1× PBS with 1% BSA, 0.2 U/µl SUPERaseIn RNase Inhibitor, and filtered through
575 a 35 µm cell strainer (Falcon #352235). Before FACS sorting, 5 mM DRAQ5 (ThermoFisher
576 #62251) was added to label nuclei.

577

578 GFP+/DRAQ5+ nuclei were sorted and collected on a Sony SH800 Cell Sorter with a 100 mm
579 sorting chip, and 10k GFP+ nuclei were loaded for sequencing. Using a Chromium Single Cell 3′
580 Library and Gel Bead Kit v3 (10X Genomics), GFP + nuclei were immediately loaded onto a
581 Chromium Single Cell Processor (10X Genomics) for barcoding of RNA from single nuclei.
582 Sequencing libraries were constructed according to the manufacturer's instructions and resulting
583 cDNA samples were run on an Agilent Bioanalyzer using the High Sensitivity DNA Chip as quality
584 control and to determine cDNA concentrations. The samples were combined and run on an
585 Illumina HiSeq2500. There were a total of 370 million reads passing the filter between the two
586 experiments (replicate 1 = 187,823,841, replicate 2 = 183,968,050). Reads were aligned and
587 assigned to Ensembl GRm38 transcript definitions using the CellRanger v7.0.1 pipeline (10X
588 Genomics). The transcript reference was prepared as a pre-mRNA reference as described in the
589 Cell Ranger documentation.

590

591 **Single nucleus RNA sequencing data analysis**
592 Following the CellRanger pipeline, filtered sequencing data were analyzed using the R package
593 Seurat version 4.1.3 following standard procedures. Outliers were identified based on the number
594 of expressed genes (nFeature > 6000) and mitochondrial proportions (percent.mt > 5) and
595 removed from the data. The data were normalized and scaled with the SCTransform function,
596 dimensional reduction was performed on scaled data, significant principal components (PCs)
597 were identified, and 30 significant PCs were used for downstream clustering. Clustering was
598 performed using the Seurat functions FindNeighbors and FindClusters (resolution = 0.6). Clusters
599 were then visualized with t-SNE or UMAP. Datasets were integrated with the IntegrateData
600 function, and integrated data were then processed by the same methods. Data was visualized
601 with the SCT assay or the RNA assay for dot plots, and plots were generated using Seurat
602 functions. To assign cell types in an unbiased manner, sequenced nuclei were mapped onto a
603 published and annotated mouse motor cortex snRNAseq reference dataset[32,87]using the Seurat

604 MapQuery function. Clusters containing under 10 nuclei were removed from subsequent
605 analyses. Comparisons to the nuclear reference dataset were made by merging it with our
606 sequencing dataset and visualizing the RNA assay.
607
608 **Quantification of cell subtype similarity across the datasets**
609 The similarity across cell subtypes between the reference and Atf3-CreER datasets was assessed
610 using MetaNeighbor[88] v1.22.0 in R v4.3.3. After annotating the cells using reference mapping,
611 cell subtypes and genes absent in one or both of datasets were removed. This pre-filtering
612 process resulted in an input count matrix consisting of 17,642 genes and 7,079 cells.
613 MetaNeighbor is designed to quantify the degree to which cell subtypes replicate across the
614 datasets based on the expression profiling of highly variable genes (HVGs). The HVGs were
615 computed using the variableGenes function provided in MetaNeighbor with default argument
616 setting. Briefly, a gene was selected as an HVG if it was in the top quartile of variable genes and
617 the top decile of expression bins for each dataset.
618
619 MetaNeighbor scored subtype-to-subtype similarity using the area under the receiver operator
620 characteristic curve (AUROC). This computation was performed using the MetaNeighborUS
621 function provided in MetaNeighbor with the fast_version and node_degree_normalization
622 arguments set to TRUE. Technically, the function builds a cell network based on the Spearman
623 correlation computed using the raw counts of HVGs between all pairs of cells in both datasets.
624 Here, a node represents a cell, and an edge represents the strength of the correlations between
625 nodes. For each cell (node), the cell subtype is predicted by accounting for the connectivity to
626 neighboring cells using neighbor-voting algorithm. This algorithm creates a weighted matrix of
627 predicted cell subtypes by performing matrix multiplication between the network and the binary
628 vector (0,1) indicating cell subtype membership. Afterwards, this matrix is divided by the node
629 degree, which returns a score for each cell equal to the fraction of its neighbors. The classification
630 of cell subtype is performed subsequently by computing the AUROC scores for each cell. This
631 score is interpreted as the probability that the classifier correctly predicts that a cell subtype in
632 membership ranked higher than that one not in membership. The AUROC ranges from 0 to 1,
633 where 1 represents perfect classification and 0.5 represents a prediction as poor as random
634 guessing. The output AUROC values are returned by averaging all pairs within a subtype.
635
636 **Fixed tissue harvest and immunostaining**
637 Mice were anesthetized with 2.5% avertin and transcardially perfused with saline, followed by 4%
638 paraformaldehyde. Tissue was post-fixed overnight and cryopreserved in 30% sucrose prior to
639 sectioning. Thirty micrometer thick coronal slices were collected free-floating using a Leica
640 CM3050 S Research Cryostat and stored in antigen preservation solution at 4 °C. For
641 immunostaining, tissue was washed and permeabilized in 0.1% Triton-X100 in 1× PBS (PBSTx),
642 then blocked in 5% normal donkey serum in 0.1% PBSTx. Primary antibodies were diluted in
643 0.5% normal donkey serum in 0.1% PBSTx and tissue was incubated overnight at 4 °C. Tissue
644 was washed in 0.1% PBSTx and incubated in secondary antibody (ThermoFisher) diluted in 0.1%
645 PBSTx for 1 h, washed in 1× PBS, mounted on positively charged slides, and coverslipped with
646 Prolong Diamond (ThermoFisher #P36961). NeuroTrace (1:500, Life Tech. N21483) was applied

16

647 following washes for 30 min. Primary antibodies: guinea pig anti-Ankyrin-G (1:500, Synaptic
648 Systems, 386-005), rabbit anti-ATF3 (1:500, Novus Biologicals, NBP1-85816), rat anti-CD68
649 (1:500, Bio-Rad, MCA1957), rat anti-CTIP2 (1:500, abcam, ab18465), mouse anti-GFAP (1:500,
650 Sigma-Aldrich, G3893), chicken anti-GFP (1:500, Invitrogen, A10262), chicken anti-IBA1 (1:500,
651 Synaptic Systems, 234-006), rabbit anti-phospho-cJun Ser63 (1:300, Cell Signaling Tech., 9261),
652 rabbit anti-phospho-H2AX (1:400, Cell Signaling Tech., 2577), rabbit anti-Olig2 (1:500, Millipore,
653 AB9610). A custom made rabbit anti-β4-Spectrin was shared by Dr. Damaris Lorenzo.
654

655 **Multiplexed in situ hybridization**
656 Tissue was sectioned coronally at 16 µm onto positively charged slides using a Leica CM3050 S
657 Research Cryostat. Slides were dried in the cryostat, then stored at −80 °C. Multiplexed in situ
658 hybridization was performed according to the manufacturer's instructions for PFA fixed sections
659 (ACD v2 kit). Probe targets were visualized using Opal dyes 520, 570, 690, or 780 (Akoya). Each
660 in situ analysis was performed in at least n = 2 mice. Probes: Atf3 (Cat. No. 426891), Atf4 (Cat.
661 No. 405101), Ddit3 (Cat. No. 317661), Dlk (Cat. No. 458151), Ecel1 (Cat. No. 475331), Gad2
662 (Cat. No. 439371), Kcnq5 (Cat. No. 511131), Satb2 (Cat. No. 413261), Scn1a (Cat. No. 556181),
663 Tubb3 (Cat. No. 423391).
664

665 **Electrophysiology brain slice preparation**
666 Mice were anesthetized using Pentobarbital Sodium (NIH Veterinarian Services) and
667 subsequently decapitated. Brains were swiftly removed and placed in an ice-cold cutting solution
668 containing (in mM): 92 NMDG, 20 HEPES, 25 glucose, 30 NaHCO3, 2.5 KCl, 1.2 NaPO4
669 saturated, 10 Mg-sulfate, and 0.5 CaCl2 with 95% O2/5% CO2. The solution had an osmolarity
670 of 303-306 mOsm (Wescorp). The extracted brain was promptly blocked, dried on filter paper,
671 and affixed to a platform immersed in ice-cold NMDG-based cutting solution within a chamber of
672 a Leica VT1200 Vibratome. Coronal slices (300 µm thick) encompassing the somatosensory
673 cortex, were cut at a speed of 0.07 mm/s. Post-slicing, sections were incubated in an NMDG-
674 based cutting solution in a chamber for 5-10 min at 34°C. Slices were then transferred to a
675 chamber filled with a modified holding aCSF saturated with 95% O2/5% CO2. The solution
676 contained (in mM): 92 NaCl, 20 HEPES, 25 glucose, 30 NaHCO3, 2.5 KCl, 1.2 NaPO4, 1 mM
677 Mg-sulfate, and 2 mM CaCl2, with an osmolarity of 303-306 mOsm, at room temperature for a
678 minimum of 1 hr. Slices were kept in the holding solution until being transferred to the recording
679 chamber.
680

681 **Ex-vivo Whole-Cell Electrophysiology**
682 Whole-cell patch-clamp electrophysiology studies were conducted following the methodology
683 previously described[89]. Cells were visualized using infrared-differential interference contrast (IR-
684 DIC) optics on an inverted Olympus BX5iWI microscope. The recording chamber was perfused
685 at a flow rate of 1.5-2.0 ml per minute with artificial cerebrospinal fluid (aCSF) comprising (in mM):
686 126 NaCl, 2.5 KCl, 1.4 NaH2PO4, 1.2 MgCl2, 2.4 CaCl2, 25 NaHCO3, and 11 glucose (303-305
687 mOsm), using a pump from World Precision Instruments. For whole-cell recordings of intrinsic
688 excitability, glass microelectrodes (3-5 MΩ) were employed, containing (in mM): 135 K-gluconate,
689 10 HEPES, 4 KCl, 4 Mg-ATP, and 0.3 Na-GTP. GFP-positive and GFP-negative cells were

690 identified based on the presence or absence of GFP fluorescence in the DIC. Data were filtered
691 at 10 kHz and digitized at 20 kHz using a 1440A Digidata Digitizer (Molecular Devices). Series
692 resistance (<20 MΩ) was monitored with a -5 mV voltage step. Cells exhibiting >20% change in
693 series resistance were excluded from further analysis. For intrinsic excitability, following
694 membrane rupture in voltage clamp, cells were transitioned to the current clamp configuration
695 without holding current injection. Intrinsic excitability was evaluated by applying hyperpolarizing
696 and depolarizing current steps (25 pA steps: 1-sec duration), and changes in voltage and action
697 potential firing were measured. Whole-cell recordings were conducted using a potassium
698 gluconate-based internal solution. For all experiments, cells experiencing a 20% or higher
699 increase in access resistance or high max spike rate consistent with interneurons were excluded
700 from analysis.
701
702 **Imaging and quantifications**
703 Images were collected using either a Zeiss slide scanner, Zeiss Axiocam 506, or Zeiss confocal
704 LSM800. Images were quantified using FIJI. For cell counts, slide scanner images were cropped
705 to equivalent contralateral and ipsilateral area for 3-4 sections and cells were counted by a blinded
706 observer. For dendrite degeneration quantifications, 63X confocal images were collected from 3-
707 4 sections (3 regions of interest (ROIs) per section per side). A FIJI macro was created to turn
708 each image to binary and use the 'Analyze Particles' feature to collect circular area (circularity >=
709 0.2) and total area. For axon pathology area measurements, the magic wand tool in the Arivis
710 Vision 4D software was used to manually select all axon blebs (YFP-high, DAPI-negative) for 3-
711 4 sections per animal. Objects with a 3-10 μm^2 area were defined as axon beading, and those
712 with area > 10 μm^2 were defined as axon swellings. For intensity quantifications, Z-planes were
713 summed and ROIs were drawn around cells of interest based on either GFP expression, DAPI
714 expression (specifically large nuclei > 40μm^2 to select for neurons), or *Tubb3* expression for
715 RNAscope, depending on the analysis. For normalized mean intensity, mean intensities were
716 collected for background ROIs (negative for any signal), and cell mean intensity values were
717 normalized to average background intensity. For percent area quantifications for IBA1 and GFAP,
718 ROIs were drawn around the ipsilateral or contralateral cortex, an automated threshold (Triangle
719 method) was set and images were turned to binary, then percent area was calculated using the
720 'Analyze Particles' feature. For all layer-specific quantifications, either DAPI or NeuroTrace was
721 used to determine layers. Layer V was defined as the cortical layer with larger and more dispersed
722 cells. Layer II/III was defined as everything above layer V, and layer VI is everything below.
723
724
725 **Statistical analysis**
726 Wherever possible, quantification of microscopy images was performed blinded. Statistical
727 analyses were performed using GraphPad Prism 9, except in the case of mixed models analyses.
728 Normality tests were performed and non-normal data were analyzed using non-parametric tests,
729 as reported in figure legends. For supplementary figures 10 and 11, in which our comparison of
730 interest was *ipsi vs contra* in WT *vs cKO* (interaction), we used R package *nlme* and its function
731 *lme* for the mixed effect modeling. The fixed effects were *Genotype*Side*, with a random effect
732 being Side of each animal (i.e., *Side|animal*). We considered models with fixed variances among
733 all the groups as well as models allowing for separate variances for either each Side and

734   Genotype, or each Side and animal. Model selection criteria (AIC, BIC and LRT) all pointed to
735   models allowing for different variances as the best (given that there are typically hundreds of
736   values per each side of each animal). The comparison of interest was the interaction: change
737   between cKO and wt genotypes in intensity differences between the sides, (ipsi - contra). For
738   supplementary figure 5, we were looking at differences between ipsi_pos & contra, and between
739   ipsi_pos & ipsi_neg (GFP+ neurons and GFP- neurons of the ipsilateral and contralateral cortices;
740   there is no contra+/-, just contra). To assess the differences between ipsi_pos & contra, and
741   between ipsi_pos & ipsi_neg, we used R package *nlme* and its function *lme* for the mixed effect
742   modeling. The fixed effects were the side and GFP status (i.e., ipsi_pos, ipsi_neg and contra),
743   with each one having a random component for each animal. Each data group (data for a given
744   side and GFP status of each animal) was allowed to have its own variance. Reported are Holm-
745   adjusted p-values of Tukey contrasts for multiple comparisons of means.
746

768   **Data availability**
769   The datasets generated in the current study are available from the corresponding author on
770   reasonable request. Data will be deposited to GEO and accession codes will be available before
771   publication.
772

773   **Code availability**
774   Code used in analyzing nuclear sequencing data will be uploaded to GitHub before publication.

Figure 1

Figure 1. Closed-skull mTBI induces layer V neuron degeneration and death. a. Schematic of injury model and location. A controlled cortical impact injury is delivered lateral to bregma. Coronal view (top) shows 3 mm tip positioned over left cortex. Horizontal view (bottom) shows 3 mm impact site relative to bregma. **b.** Example of extent of injury, representative of > 50 samples in which immunostaining for neuroinflammation was performed. GFAP staining is shown across sections from anterior to posterior. For each section, approximate mm from Bregma on the anterior-posterior axis is shown on the right. **c.** Quantification of righting times (time to wake from anesthesia) demonstrating loss of righting reflex in TBI animals consistent with mild TBI. N = 25 Sham, 218 mTBI. All wildtype mice in the study included, excluding those for which righting time was not accurately recorded. **d.** Longitudinal measurement of neurofilament light in serum of mTBI animals. Each shape represents the average of two replicates per mouse. * p = 0.0421 (1 dpi), p = 0.0352 (9 dpi), and p = 0.0381 (14 dpi) by Tukey's multiple comparisons test for each timepoint compared to baseline. **e.** Low magnification image of ipsilateral and contralateral cortex in Thy1-YFP-h mice. Layer V is outlined. High magnification images of **f.** dendrites, **g.** cell bodies, and **h.** axons in the contralateral and ipsilateral cortices. For ipsilateral cell bodies and axons, insets show DAPI expression in cell bodies, and lack of DAPI expression in axon swellings. **i.** Quantification of dendrite degeneration at 7 dpi in ipsilateral, contralateral, and sham (* p = 0.0302, *** p = 0.0007 by Kruskal-Wallis test). **j.** Quantifications of axon beading (fragments with area < 10 μm^2, *** p = 0.0009 by Kruskal-Wallis test) and axon swellings (fragments with area > 10 μm^2, ** p = 0.007 by Kruskal-Wallis test) at 7 dpi. **k.** Quantification of YFP+ neurons in ipsilateral compared to contralateral cortex in sham animals and at 7 and 14 dpi compared to sham (* p = 0.0378, ** p = 0.0073 by Kruskal-Wallis test). For **i-k,** points represent the average of 3-4 sections per mouse. ns: not significant, by unpaired t-test. Scale bars: b. 1 mm, e. 200 µm, f-h (shown in h). 50 µm.
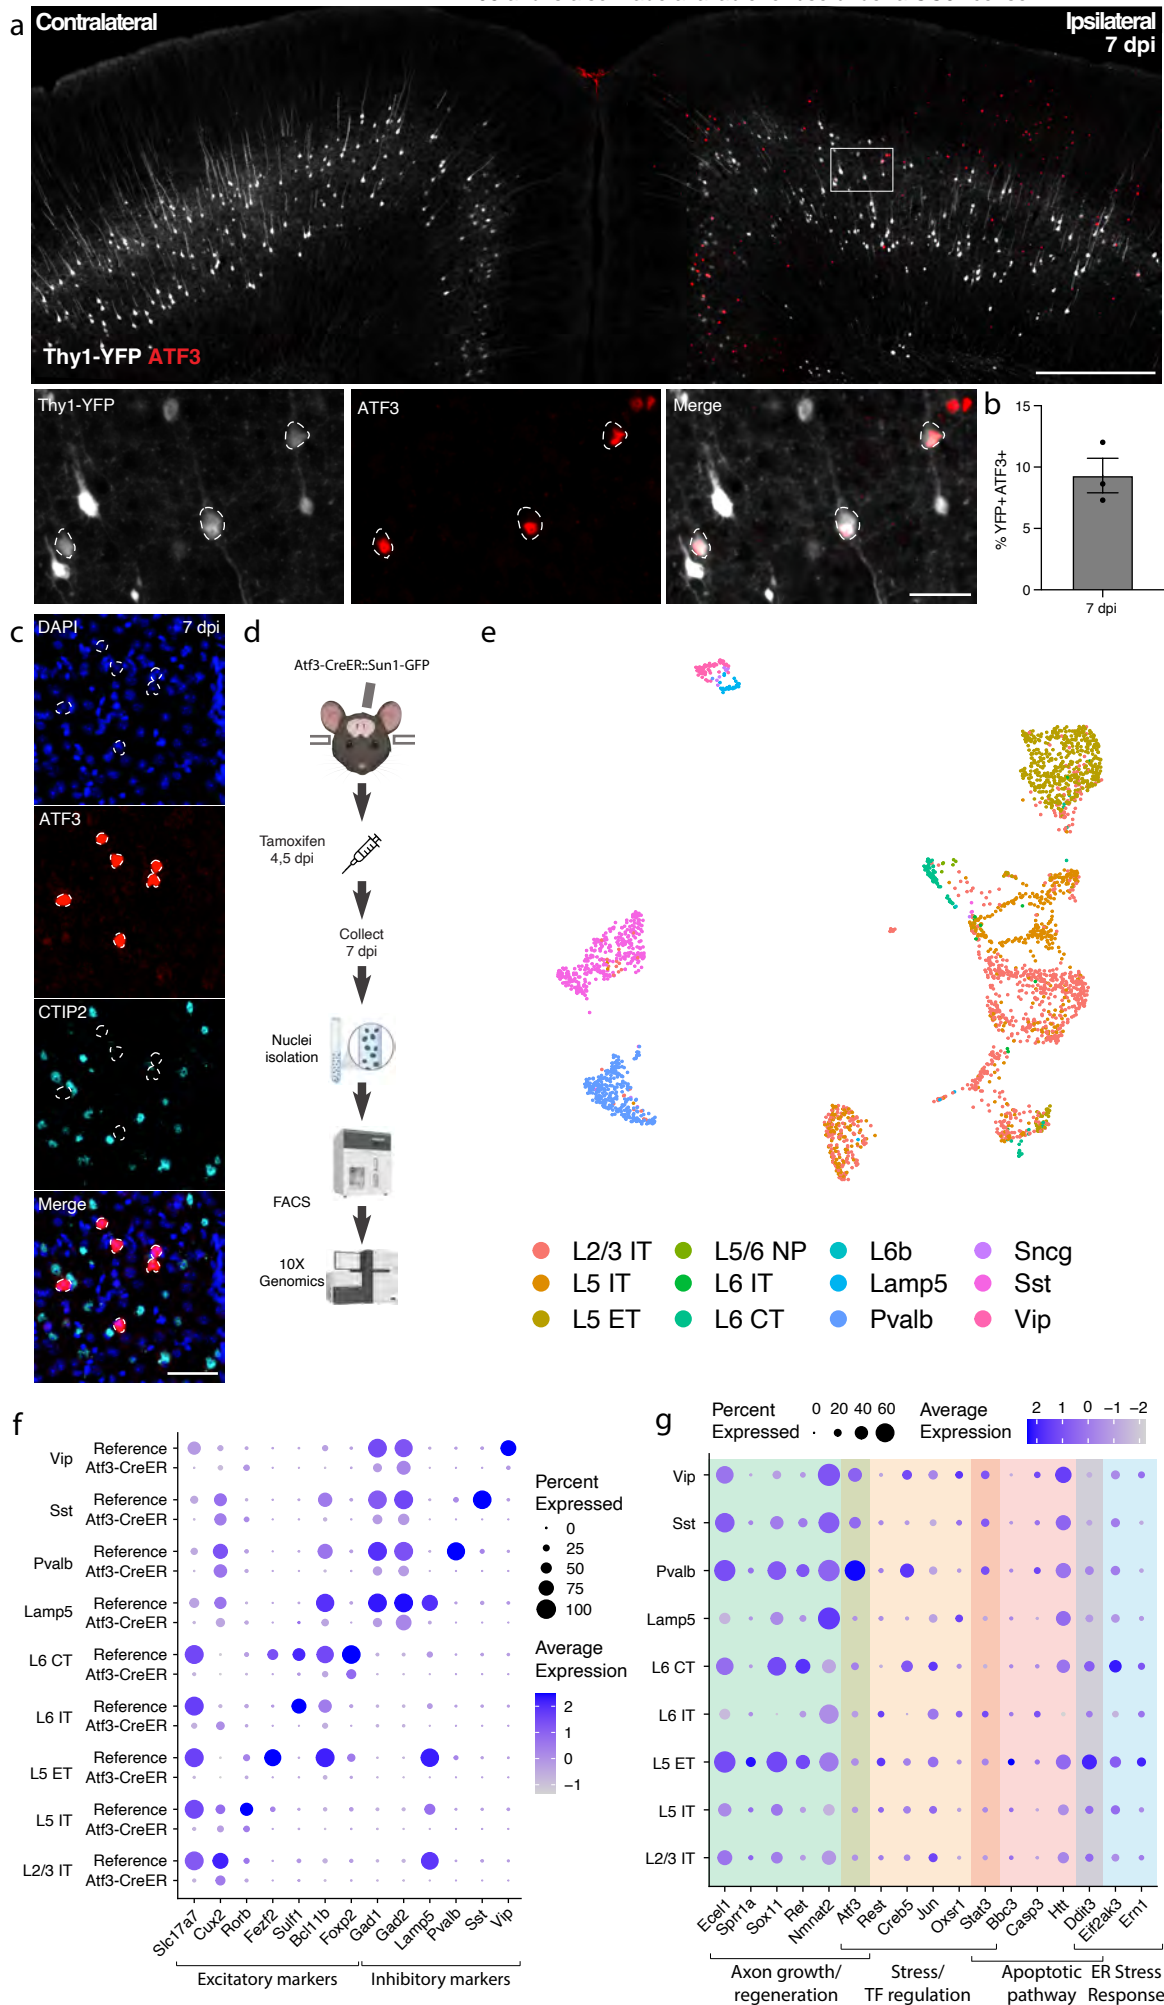

Figure 2

Figure 2. mTBI activates an Atf3-associated transcriptional response in different subclasses of cortical neurons. a. Immunostaining of ATF3 (red) in a Thy1-YFP (white) mouse showing specific expression in the ipsilateral cortex, with higher expression in layer V. Inset highlights YFP+ ATF3+ neurons. ATF3+ neurons are outlined. **b.** Quantification of percent of YFP+ neurons expressing ATF3 at 7 dpi in the ipsilateral cortex. Points represent the average of 3-4 sections per animal. **c.** Immunostaining showing that CTIP2 (cyan) is not expressed in layer V ATF3+ (red) nuclei. ATF3+ nuclei are outlined. **d.** A schematic representation of the single nucleus RNA sequencing workflow, including unilateral closed-skull CCI, tamoxifen dosing, nuclear isolation and FACS, following by 10X Genomics sequencing. **e.** UMAP showing neurons collected by snRNAseq of ipsilateral cortex from pooled Atf3-CreER animals, annotated by mapping to a reference atlas. For subsequent analyses, cell types with fewer than 20 nuclei are excluded. **f.** Dotplot of marker genes for layer-specific excitatory neurons and subclasses of inhibitory neurons, showing downregulation of some markers in Atf3-CreER animals compared to the reference dataset. **g.** Dotplot of a panel of known stress response genes involved in axon growth and regeneration, cell stress and transcription factor regulation, apoptosis, and ER stress highlighting different responses between *Atf3*-expressing neuron subclasses. Genes were selected based on altered expression compared to reference dataset. Low magnification scale bars, 500 μm. High magnification scale bars, 50 μm.

Figure 3

a **Atf3-Cre::Snap25-eGFP** — Avg Count vs dpi; Layer 2/3, Layer 5, Layer 6

b 7 dpi / 21 dpi; Atf3-Cre::Snap25-eGFP; Layer II/III, Layer V

c Atf3-CreER::Ai14; Tamoxifen 4,5 dpi; Collect 7 dpi; Collect 21 dpi

d Atf3-CreER::Ai14; 7 dpi / 21 dpi; Layer II/III; Layer V; Layer II/III, Layer V

Figure 3. Atf3-expressing neurons in layer V die, while those in layer II/III survive following mTBI . a. Quantification of the average count per section of Atf3-GFP neurons by cortical layer at 3, 5, 7, 10, 14, 21, 42, and 70 dpi. N=6 per timepoint, 3-4 sections counted per animal. **b.** Examples of Atf3-GFP endogenous labeling (left) at 7 and 21 dpi. Layer V is outlined. High magnification examples of GFP-immunolabeled neurons (right) in layer II/III (top) and layer V (bottom) at 7 and 21 dpi. Panels a and b use the Atf3-Cre::Snap25-eGFP mouse, which labels all neurons in which Atf3 has ever been expressed. **c.** Schematic representation of tamoxifen dosing and tissue collection. The Atf3-CreER mouse was crossed to the Ai14 RFP reporter (not neuron-specific). **d.** Representative images of Ai14 signal in ipsilateral cortex at 7 dpi and 21 dpi. Layer V is outlined. Insets highlight neurons and other labeled cells in layer II/III and layer V. Insets for layer II/III suggest an earlier loss of projection complexity that is regained by 21 dpi. Inset for layer V at 21 dpi includes a neuron (left) and a glial cell (right). Panels **c** and **d** use the Atf3-CreER::Ai14 mouse, which labels any cell in which *Atf3* is activated in the presence of tamoxifen. For **a**, error bars represent standard error of the mean (SEM). Scale bars: b. Low magnification, 50 μm, high magnification, 10 μm; d. Low magnification, 500 μm, high magnification, 50 μm.
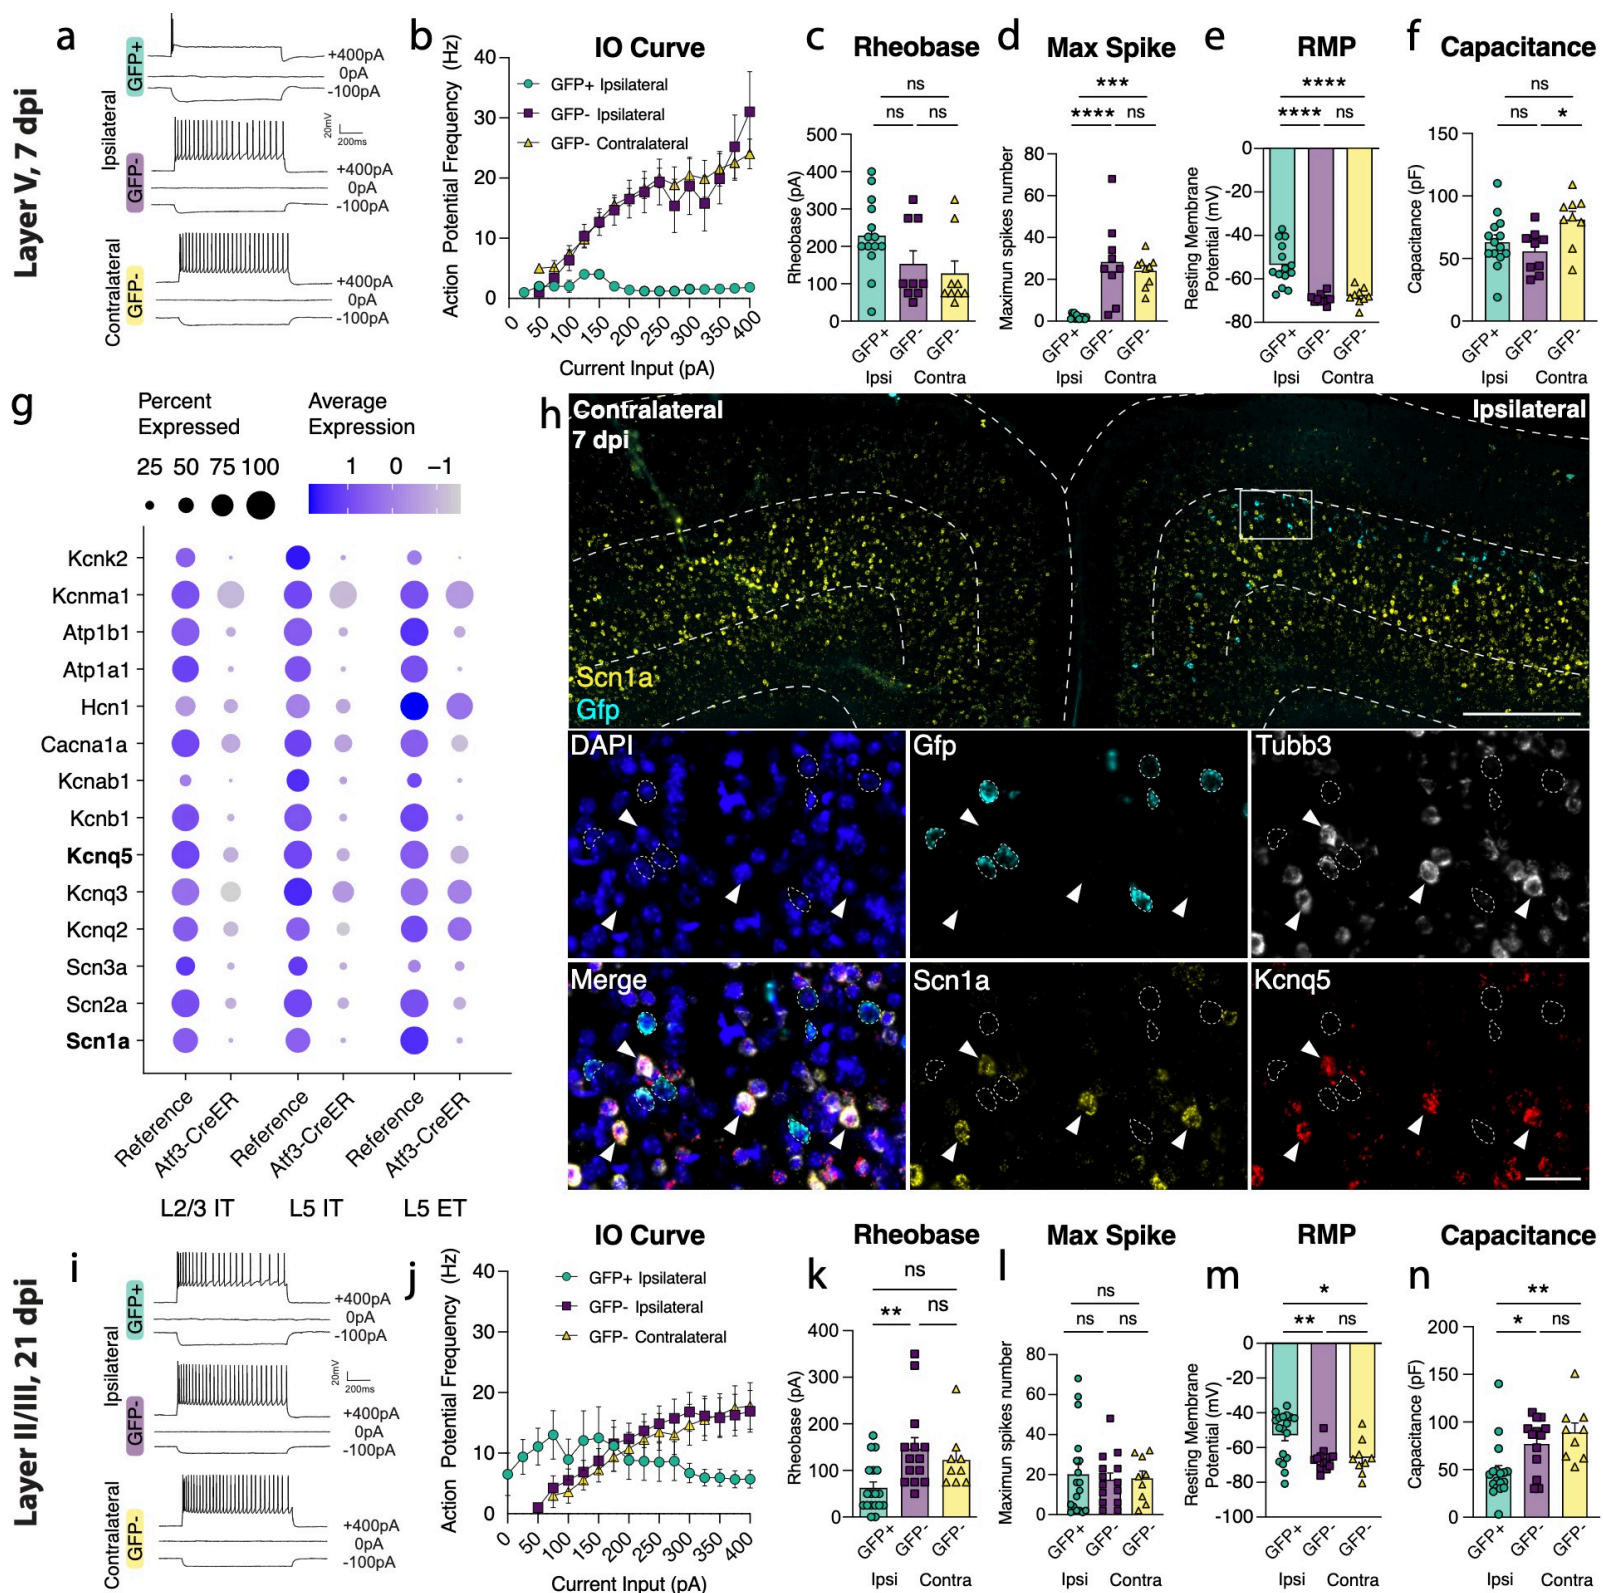

Figure 4

Figure 4. Layer V Atf3-GFP neurons are unable to fire and downregulate ion channels while layer II/III Atf3-expressing neurons are electrophysiologically functional following mTBI. a. Examples of electrophysiological traces from 7 dpi layer V ipsilateral GFP+ and GFP- neurons and contralateral GFP- neurons. Quantifications of **b.** IO curve, **c.** rheobase, **d.** max spike count (*** p = 0.0002, **** P <0.0001), **e.** resting membrane potential (**** p = <0.0001), and **f.** capacitance (* p = 0.0307) in 7 dpi layer V neurons. **g.** Dot plot of select ion channels in the reference dataset compared to the Atf3-CreER dataset collected in this study showing dysregulation of ion channels in layer II/III and layer V neurons. Genes in bold were validated by in situ hybridization. **h.** In situ hybridization validating downregulation of ion channels. Low magnification image of bilateral cortices from an Atf3-Cre::Snap25-GFP mouse at 7 dpi showing mRNA expression of Gfp (cyan) and Scn1a (yellow). Layer V is outlined. Inset shows mRNA of Gfp (cyan), Tubb3 (white), Scn1a (yellow), and Kcnq5 (red). Gfp+ neurons (outlined) lack expression of Scn1a and Kcnq5 and have little to no expression of Tubb3. Arrowheads highlight Tubb3+ Gfp- neurons with high expression of Scn1a and Kcnq5. A single Z-plane is shown in the insets. **i.** Examples of electrophysiological traces from 21 dpi layer II/III surviving ipsilateral GFP+ and GFP- neurons and contralateral GFP- neurons. Quantifications of **j.** IO curve, **k.** rheobase (** p = 0.0050), **l.** max spike count, **m.** resting membrane potential (* p = 0.0191, ** p = 0.0041), and **n.** capacitance (* p = 0.0217, ** p = 0.0034) in 21 dpi layer II/III neurons. For b and j, points represent the average of all neurons per group, error bars represent SEM. For **c-f** and **k-n**, each point represents one neuron recorded from N=2 or 3 animals. ns: not significant. Significance was determined by Tukey's multiple comparisons test. Low magnification scale bar, 50 μm. High magnification scale bar, 500 μm.
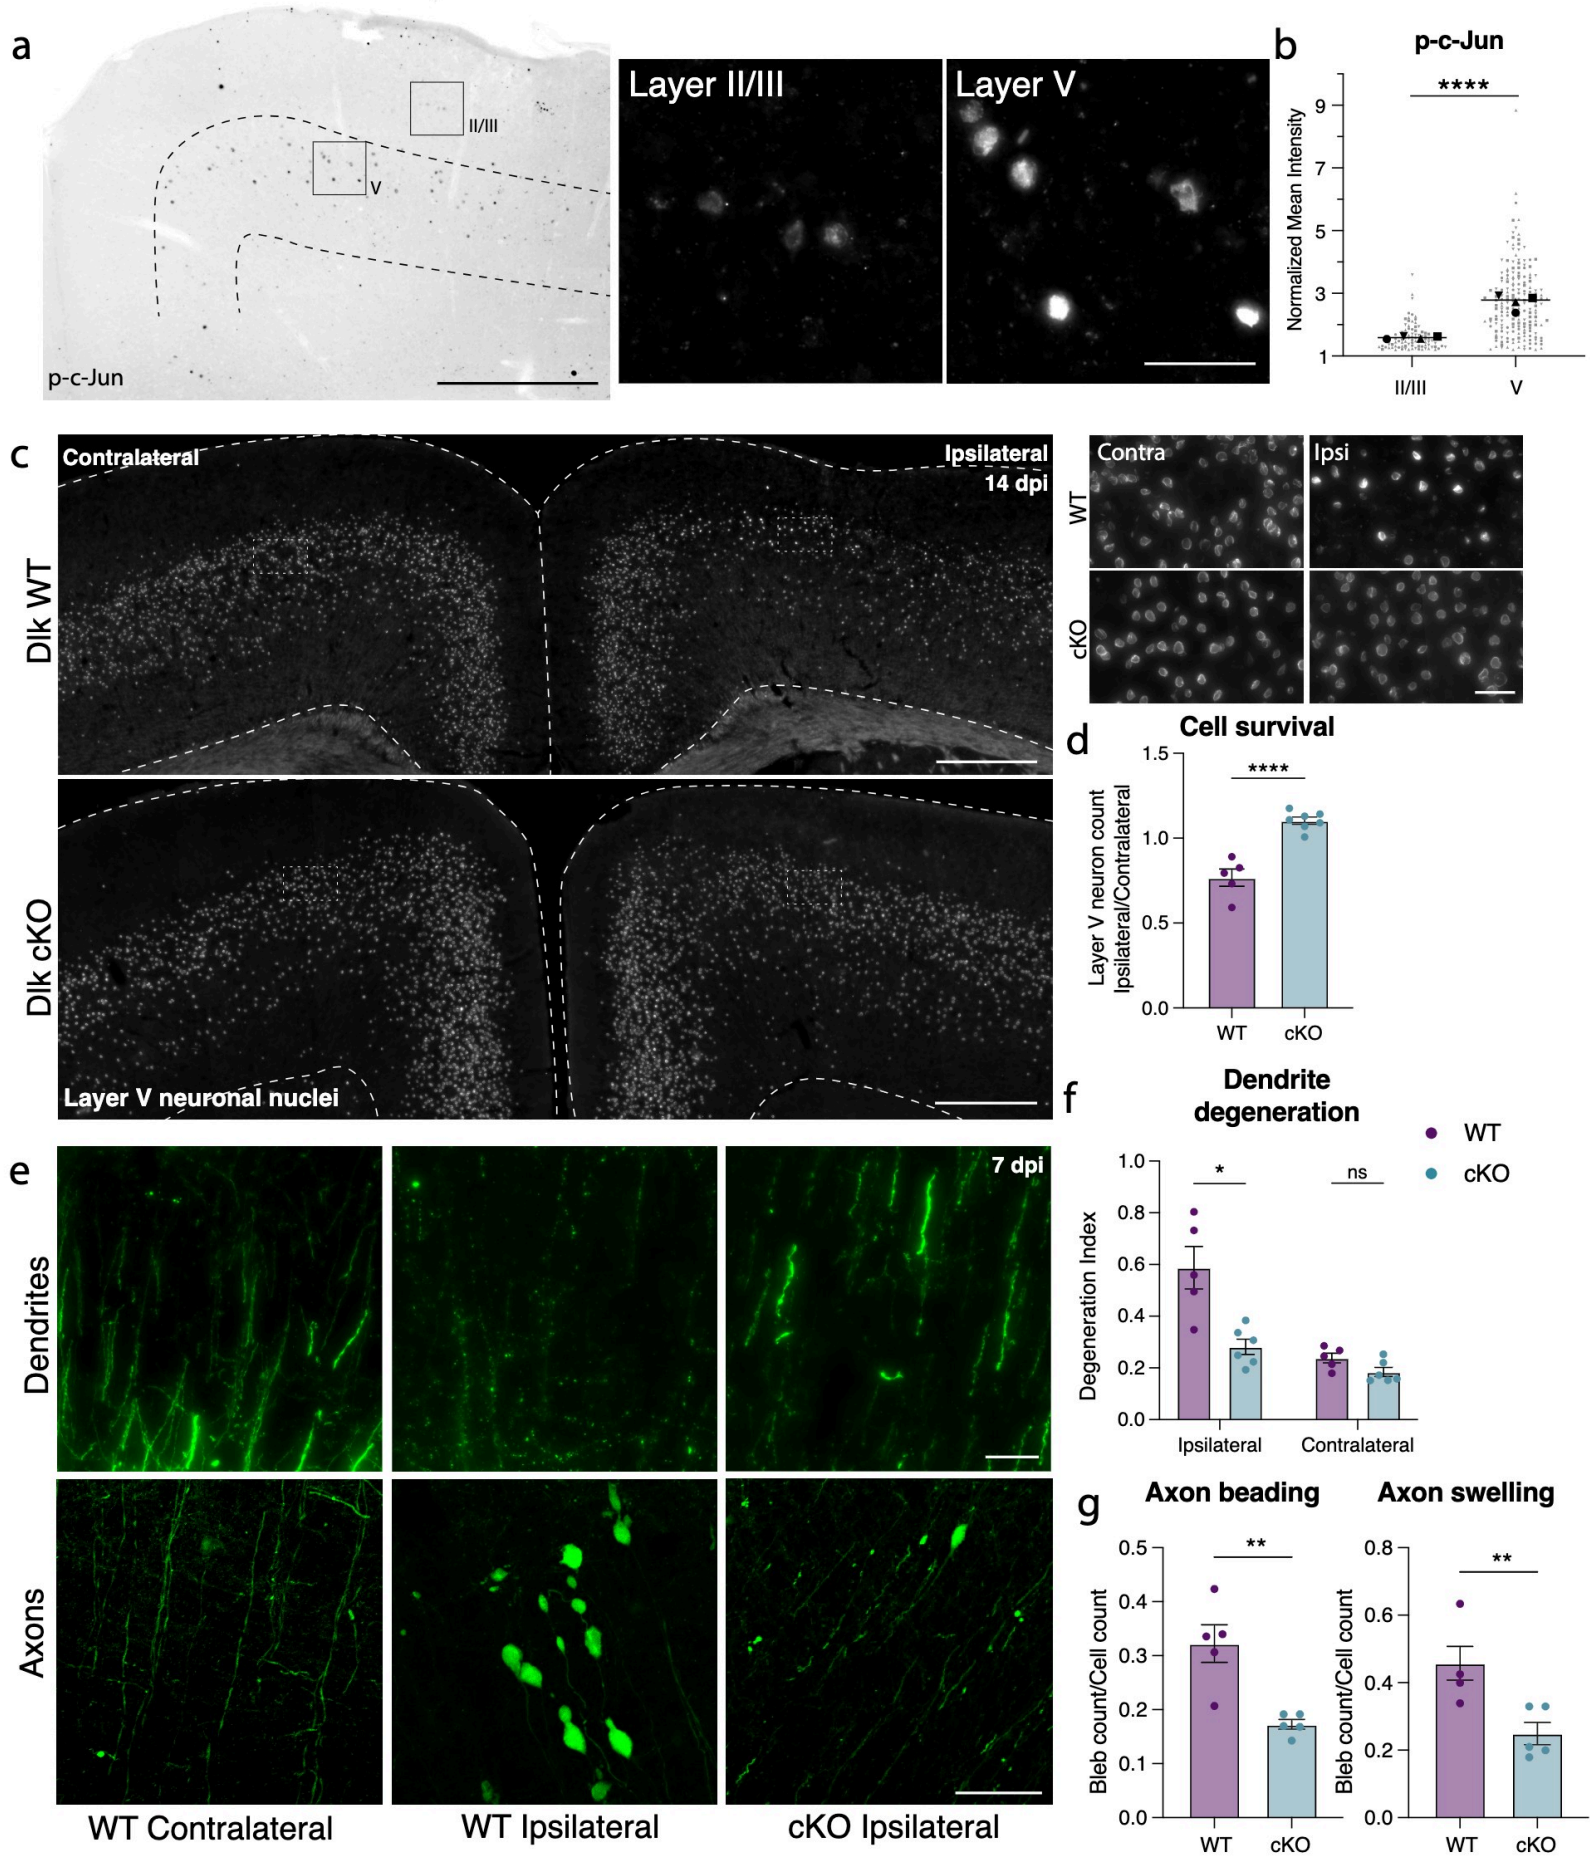

Figure 5

Figure 5. Layer V neurons can be rescued from mTBI-induced death and degeneration by deletion of DLK. a. P-c-Jun immunolabeling in the ipsilateral cortex of WT mice at 7 dpi (left). Layer V is outlined. Insets show high magnification images of immunolabeling in layer II/III and layer V. **b.** Quantification of p-c-Jun intensity in layer II/III and layer V at 7 dpi (** p = 0.0016 by paired t-test). Only p-c-Jun+ cells are included based on a threshold of 1.2-fold expression compared to background. Average per animal and value per cell are displayed. Each shape represents one animal. N=4, 2 sections per animal, 11-53 nuclei per animal. **c.** Overview of ipsilateral and contralateral cortices in DLK WT and DLK cKO mice showing layer V GFP+ nuclei. Insets shown on the right. **d.** Quantification of GFP+ neurons in ipsilateral compared to contralateral cortex in WT and cKO mice at 14 dpi based on Sun1-GFP expression shown in c (** p = 0.0025 by Mann-Whitney test). **e.** High magnification images of YFP+ dendrites (top) and axons (bottom) in WT contralateral and ipsilateral cortex, and cKO ipsilateral cortex. **f.** Quantification of dendrite degeneration at 7 dpi in WT and cKO mice (** p = 0p =0.0087 by Mann-Whitney test). **g.** Quantification of axon beading (** p = 0.0079) and swelling (** p = 0.0079 by Mann-Whitney test) at 7 dpi in WT and cKO mice. For **d, f, g,** each point represents the average of 3-4 sections per animal. Low magnification scale bars, 50 μm. High magnification scale bars, 500 μm.
