Different Roles of Tocopherols and Tocotrienols in Chemoprevention and Treatment of Prostate Cancer

Qing Jiang

Department of Nutrition Science, Purdue University, West Lafayette, IN, United States

ABSTRACT

The vitamin E family contains α -tocopherol (α T), β T, γ T, and δ T and α -tocotrienol (TE), β TE, γ TE, and δ TE. Research has revealed distinct roles of these vitamin E forms in prostate cancer (PCa). The ATBC trial showed that α T at a modest dose significantly decreased PCa mortality among heavy smokers. However, other randomized controlled trials including the Selenium and Vitamin E Cancer Prevention Trial (SELECT) indicate that supplementation of high-dose α T (≥ 400 IU) does not prevent PCa among nonsmokers. Preclinical cell and animal studies also do not support chemopreventive roles of high-dose α T and offer explanations for increased incidence of early-stage PCa reported in the SELECT. In contrast, accumulating animal studies have demonstrated that γ T, δ T, γ TE, and δ TE appear to be effective for preventing early-stage PCa from progression to adenocarcinoma in various PCa models. Existing evidence also support therapeutic roles of γ TE and its related combinations against advanced PCa. Mechanistic and cell-based studies show that different forms of vitamin E display varied efficacy, that is, δ TE \geq γ TE $>$ δ T \geq γ T \gg α T, in inhibiting cancer hallmarks and enabling characteristics, including uncontrolled cell proliferation, angiogenesis, and inflammation possibly via blocking 5-lipoxygenase, nuclear factor κ B, hypoxia-inducible factor-1 α , modulating sphingolipids, and targeting PCa stem cells. Overall, existing evidence suggests that modest α T supplement may be beneficial to smokers and γ T, δ T, γ TE, and δ TE are promising agents for PCa prevention for modest-risk to relatively high-risk population. Despite encouraging preclinical evidence, clinical research testing γ T, δ T, γ TE, and δ TE for PCa prevention is sparse and should be considered.

Statements of significance

This article is the first comprehensive and critical review assessing distinct roles of α -tocopherol and other members in the vitamin E family in chemoprevention and therapy of prostate cancer, which is the most common and second most lethal cancer in males.

Introduction

Prostate cancer (PCa) is the most common cancer and the second most lethal cancer in males [1]. Since 2014, the incidence rate of PCa has increased by 3% per year overall and by \sim 5% per year for advanced-stage PCa, according to the American Cancer Society. Although androgen deprivation therapy is effective for

treating locally advanced or metastatic PCa, the cancer may eventually relapse and progress to metastatic castration-resistant prostate cancer (CRPC). CRPC is associated with poor prognoses and has the mean survival time of only 16–18 mo [2,3]. There is no effective treatment for advanced-stage cancer. The lack of effective therapies for late-stage cancer underscores the importance of early detection and intervention for reducing PCa

Abbreviations: ATBC, α -Tocopherol, β -Carotene Cancer Prevention; α T, α -tocopherol; β T, β -tocopherol; CEHC (3'-COOH), carboxyethyl-hydroxychroman; CRPC, castration-resistant prostate cancer; CSC, cancer stem cell; CYP, cytochrome P-450; δ T, δ -tocopherol; DNMT, DNA methyltransferase; DRE, digital rectal examination; γ T, γ -tocopherol; γ -TmT, γ T-rich mixed tocopherol; HMGCR, HMG-CoA reductase; LNCaP, Lymph Node Carcinoma of the Prostate; LOX, lipoxygenase; LT, leukotriene; NF, nuclear factor; PCa, prostate cancer; PD-L, programmed cell death ligand; PIN, prostatic intraepithelial neoplasia; PSA, prostate-specific antigen; PTEN, phosphatase and tensin homolog deleted on chromosome 10; PXR, pregnane X receptor; RCT, randomized controlled trial; RWPE-1, HPV-18 immortalized prostate epithelial; SELECT, Selenium and Vitamin E Cancer Prevention Trial; TE, tocotrienol; TRAMP, transgenic adenocarcinoma of the mouse prostate; TRAP, transgenic rat for adenocarcinoma of prostate.

mortality [4,5]. Although primary prevention emphasizes healthy life styles among general population with no increased risks, secondary and tertiary prevention includes chemoprevention using natural and synthetic compounds to inhibit progression of early-stage cancer to advanced disease among moderate-risk or high-risk population, for example, those with driver mutations or early-stage cancer [6]. Many efforts have been made to search for effective and safe chemopreventive agents for PCa prevention including vitamin E. Natural forms of vitamin E consist of 8 lipophilic antioxidants, including α -tocopherol (α T), β T, γ T, and δ T and α -tocotrienol (TE), β TE, γ TE, and δ TE. Research on vitamin E and PCa was initially focused on α T in cell, animal, and epidemiologic/population studies. Noticeably, some large randomized controlled trials (RCTs) have also been carried out to evaluate the effect of α T supplementation on PCa. Subsequently, potential effects of other forms of vitamin E such as γ T, δ T, γ TE, and δ TE on PCa have also been assessed in preclinical cell and animal studies. Although the roles of tocopherols and TEs in cancer prevention have been reviewed elsewhere [7–10], it is worth assessing distinctive functions of these compounds for secondary and tertiary chemoprevention of PCa and even therapy against advanced PCa. In this article, I focus on current knowledge of α T and other members, that is, γ T, δ T, γ TE and δ TE, with respect to their roles in PCa prevention and treatment via critically reviewing cell-based and mechanistic studies, preclinical research in PCa animal models, and RCTs, without including epidemiologic data that have been recently summarized in a systematic review [11].

Current Status of Knowledge

Different forms of vitamin E and bioavailability

The structures of all vitamin E isoforms share a chromanol ring with a phenolic group at the 6-position, which offers antioxidant activities capable of terminating lipid radical chain reactions. Tocopherols have a phytyl side chain, whereas TEs have

a similar side chain with 3 double bonds (Figure 1) [12]. The α , β , γ , and δ isoforms differ at the 5 or 7 positions occupied with either a hydrogen or methyl group (Figure 1). Vitamin E forms are naturally synthesized by plants and mainly found in seeds, nuts, and plant oils [12–15]. For instance, α T is the predominate vitamin E in almonds, peanuts, and sunflower seeds, and γ T and δ T are the main vitamin E in walnuts, pecan, and sesamin seeds. γ TE is rich in barley and palm oil, and δ TE is mainly found in annatto plants.

Although all vitamin E forms are believed to have similar antioxidant activities, these compounds have greatly different bioavailability. For instance, α T is the major form of vitamin E in the blood and tissues and considered the bona fide vitamin E as deficiency of α T results in vitamin E deficiency-associated ataxia [16]. Serum concentrations of α T in humans have been reported ranging from ~ 20 μ M to >50 μ M varying with intake doses and other dietary components such as fat contents [17]. The half-life ($T_{1/2}$ = time needed from C_{max} to 50% C_{max}) of α T in response to supplementation has been documented to be ~ 30 h [17]. γ T is often the second abundant vitamin E found in tissues with serum concentrations of γ T at 1–3 when γ T is provided from foods. On supplementation, γ T may transiently reach to 20–30 μ M or even higher [18–20] with $T_{1/2}$ of 6–8 h [21]. Although relatively low in the plasma, γ T appears to be accumulated in peripheral tissues including adipose and muscle with concentrations of 176 and 107 nmol/g, respectively, as documented by Burton et al. [22]. Two-week supplementation of γ T-rich tocopherols has recently been reported to result in an increase of γ T and δ T in the prostate of patients undergoing radical prostatectomy [23]. In response to oral supplementation of 200–3200 mg γ TE and δ TE, these TEs appeared to transiently increase in the blood to C_{max} of 5–10 μ M with half-time of 2–4 h [24,25]. In summary, based on above-cited literature, vitamin E forms have highly varied bioavailability with the order of α T \gg γ T \gg γ TE, δ TE, and this order is inversely associated with their relative degree of being catabolized in vivo, as discussed in the next section.

FIGURE 1. Chemical structures of natural forms of vitamin E.

Vitamin E metabolism and metabolites

As extensively discussed in previous reviews [12,26], varied bioavailability of vitamin E forms is regulated by their differential affinity to α -tocopherol transport protein (TTP) and different degree of catabolism. In particular, high bioavailability of α T in tissues is a result of its high-affinity binding to TTP, which facilitates α T to be incorporated into VLDLs and prevents it from being catabolized in the liver [12,26]. Consequently, only a small portion of α T (<1%) is metabolized [26]. In contrast, other vitamin E forms have much lower affinity to TTP than α T and are readily catabolized via cytochrome P-450 (CYP; CYP4F2 or murine *Cyp4f14*)-catalyzed side chain hydroxylation and oxidation of the terminal carbon 13' in the endoplasmic reticulum to form 13'-hydroxychromanol (13'-OH) and 13'-carboxychromanol (13'-COOH) (Figure 2). CYP4F2 has been shown to have differential catabolic activities toward different forms of vitamin E with the order of δ TE, γ TE > δ T, and γ T >> α T [26]. 13'-COOHs are further metabolized through β -oxidation to intermediate-chain and short-chain carboxychromanols including 11'-,9'-,7'-,5'-COOH (also called carboxymethylbutyl hydroxychromans) and 3'-COOH [also called 3'-carboxyethyl-hydroxychroman (CEHC)] (Figure 2). Conjugated metabolites including sulfated long-chain carboxychromanols and sulfated CEHCs are detected in human cells and in the plasma of rodents, indicating that sulfation takes place parallel to side chain oxidation [27,28].

The bioavailability of different vitamin E metabolites has also been documented in humans and rodents. For instance, γ -CEHC may transiently reach to $\leq 15 \mu\text{M}$ in the serum of humans as a result of γ T supplementation [18–20,29]. Supplementation of δ TE at 400 to 3200 mg/d has been shown to result in an increase of δ -CEHC to ≤ 10 – $15 \mu\text{M}$ and 5'-COOH (δ -carboxymethylbutyl hydroxychromans) to 4–5 μM in the plasma and excretion of δ -CEHC ($\leq 91 \mu\text{M}$) in the urine [30]. As to long-chain metabolites, sulfated 11'-COOHs have been reported in the circulation in rodents supplemented with tocopherols and TEs [28]. 13'-COOHs, which are low in the circulation, appear to be the predominant metabolites in feces of rodents fed with tocopherols or TEs [28,31–34]. These bioavailability data of metabolites are useful for assessing potential contribution of metabolism to the activities of different forms of vitamin E in vivo, especially considering that CEHCs and 13'-COOHs have been shown to have anticancer and anti-inflammatory effects (see further sections).

α T and PCa

α T is the only vitamin E that has been investigated for cancer prevention in large RCTs. In this section, I focus on RCTs that assessed the impact of α T supplementation on PCa as either the primary or a secondary end point and analyze key differences of these studies concerning α T's dosing, participants' characteristics, and disease stages (Table 1) [35–41]. Moreover, I will

FIGURE 2. Vitamin E (tocopherols as the example) metabolism: tocopherols are metabolized by CYP4F2-initiated side-chain oxidation to form various carboxychromanols and sulfated carboxychromanols. CEHC (3'-COOH), carboxyethyl-hydroxychroman; CMBHC (5'-COOH), carboxymethylbutyl hydroxychroman.

TABLE 1

The effects of supplementation of α -tocopherol on PCa (primary or secondary end point) in randomized, placebo-controlled intervention trials

Study and duration	Characteristics of participants	Intervention	Major end points/outcomes
The α -Tocopherol, β -Carotene Cancer Prevention Study (ATBC), Southwestern, Finland [35]; 5–8 y (1985 to 1993)	29,133 men, 50–69 y, all heavy smokers, healthy (no previous cancer or other serious diseases)	50 mg/d <i>dl</i> - α -tocopheryl acetate (<i>dl</i> - α -TA), 20 mg/d β -carotene, or their combination	1': Lung cancer. 2': Prostate, bladder, colon and rectum, stomach cancer. Outcomes: <i>dl</i> - α -TA \downarrow PCa death; \uparrow deaths from hemorrhagic stroke
Heart Protection Study MRC/BHF (HPS), United Kingdom [36]; 5 y (1994–2001)	20,536 individuals, 40–80 y with coronary disease, other occlusive arterial disease, or diabetes	600 mg synthetic vitamin E, 250 mg vitamin C, 20 mg β -carotene daily	1': Coronary events and fatal or nonfatal vascular events 2': Cancer and other major morbidity Outcomes: no benefit
The Heart Outcomes Prevention Evaluation (HOPE) and The Ongoing Outcomes (HOPE-TOO), multi-European countries and United States [37]; median 7 y (1993–2003)	7030 patients aged 55 y or older with vascular disease or diabetes mellitus from the initial HOPE trial (1993–1999) and the HOPE-TOO extension (1999–2003)	400 IU/d RRR- α -tocopherol acetate	1': Cancer incidence, cancer-related deaths, and major cardiovascular events Outcomes: no benefits (including PCa incidence) and \uparrow rates of heart failure
Physician's Health Study II (PHS-II), United States [38]; 8 y (1997–2007)	14,641 physicians, men aged 50 y or older including 1307 men with a history of cancer including PCa	400 IU synthetic α -tocopherol every other day and vitamin C 500 mg daily	1': PCa for vitamin E and total cancer for vitamin C 2': Total cancer for vitamin E Outcomes: no effects on prostate or total cancer incidence or death
Progression from HGPIN to PCa, Canada [39]; 3 y of supplements plus 3-y follow-up (2003–2010)	303 patients (the median age of 62.8 y), confirmed with HGPIN, median PSA \sim 5.41 ng/mL	Soy (40 g), <i>dl</i> - α -tocopherol (800 IU), selenium (200 μ g) daily vs. placebo	1': Progression from HGPIN to invasive PCa Outcomes: supplementation did not show beneficial effects
Selenium and Vitamin E Cancer Prevention Trial (SELECT), Canada, Puerto Rico, United States [40,41]; 7–12 y (2001–2011)	35,533 men, 50 y or older for African American and 55 y or older among other races. PSA \leq 4 ng/mL and not diagnosed or suspicious for PCa based on DRE screening	400 mg IU <i>dl</i> - α -TA, 200 μ g/d L-selenomethionine, or their combination	1': PCa. 2': Lung, colorectal, and overall primary cancer. Outcomes: \uparrow incidence of early-stage PCa; no effects on other types of cancer

Abbreviations: 1', primary end point; 2', secondary end point; DRE, digital rectal examination; HGPIN, high-grade prostatic intraepithelial neoplasia; PCa, prostate cancer; RCT, randomized controlled trial; Se, selenium; \downarrow , suppress or inhibit; \uparrow , increase or enhance.

correlate RCT data with evidence from preclinical cell and animal studies concerning the role of supplementation of high-dose α T in PCa prevention.

The impact of α T supplement on PCa in randomized, double-blinded, and placebo-controlled intervention studies

From 1985 to 1993, the Alpha-Tocopherol, Beta-Carotene Cancer Prevention (ATBC) study was carried out in Finland to evaluate the effect of daily supplementation of α T, β -carotene, or their combination on the incidence of lung (the primary outcome) and other cancers including PCa (secondary outcomes) in male heavy smokers smoking 20 cigarettes/d [35]. Randomly assigned participants received 50 mg/d *dl*- α -tocopheryl acetate ($n = 7286$), 20 mg/d β -carotene ($n = 7282$), or both compounds ($n = 7278$) and placebo ($n = 7287$) capsules. Compared with the placebo controls, α T did not show a significant effect on the incidence of lung cancer, whereas β -carotene unexpectedly increased the risk of lung cancer and total mortality [35]. Interestingly, participants receiving α T had 32% (95% CI: -47% , -12%) and 41% (95% CI: -65% , -1%) reduction of PCa incidence and mortality ($P < 0.05$), respectively, compared with those not receiving it [35,42]. It is also noteworthy that α T supplementation appeared to decrease the incidence of clinical PCa (stage II–IV) but not stage 0–I [42] while had more death from hemorrhagic stroke when compared with no- α T group. In

the 6–8 y ATBC postintervention follow-up study, no significant beneficial effect of α T was observed on posttrial PCa incidence [43]. However, in the 18-y ATBC postintervention follow-up study, Virtamo et al. [44] observed that although neither α T nor β -carotene supplement had significant effects on posttrial cancer incidence, the preventive effect of α T on PCa appeared to continue as α T decreased posttrial PCa mortality (RR: 0.84; 95% CI: 0.7, 0.99).

Given the promising data observed from ATBC trial, the SELECT was conducted to evaluate the effects of α T (400 IU/d), selenium (200 μ g/d) or their combination on PCa from 2001 to 2011 [40]. In the SELECT, participants mainly included healthy nonsmoking men (92% not current smokers) who did not have elevated prostate-specific antigen (PSA, ≤ 4 ng/mL) or PCa as assessed by digital rectal examinations (DREs). After 5.46-y supplementation, $>95\%$ diagnosed PCa was in early stages, for example, $\sim 70\%$ and 25% in stage T1 and T2, respectively, and there was a nonsignificant ($P = 0.06$) increase in stage I PCa in α T-alone group [40]. After the initial publication in 2009, participants' follow-up continued, and by 2011, additional cases of PCa were diagnosed. At this time, compared with placebo, the hazard ratios concerning PCa in the α T, selenium, and α T+Se groups were estimated to be 1.17 (99% CI: 1.004, 1.36; $P = 0.008$), 1.09 (99% CI: 0.93, 1.27; $P = 0.18$), and 1.05 (99% CI: 0.89, 1.22; $P = 0.46$), respectively [41]. All identified PCa cases

were at early stages, that is, 70%–75% stage I (clinically inapparent) and 25%–30% stage II (clinical cancer with tumor confined in prostate). It was therefore concluded that α T supplement increased the risk of early-stage PCa.

In addition to the SELECT, 4 additional RCTs were conducted between 1993 and 2011 aiming to examine the effects of α T (400 IU) on the incidence of cardiovascular diseases and cancer including PCa, that is, MRC/BHF (HPS) [36], HOPE/HOPE-TOO [37], PHS-II [38], and Canadian high-grade prostatic intraepithelial neoplasia (PIN) progression to invasive cancer study [39]. Like the SELECT, these studies did not observe beneficial effects of α T (400–800 IU) on cancers including PCa (Table 1) [35–41].

Key differences between ATBC and other RCT trials

Although all above-mentioned RCT trials (Table 1) [35–41] are randomized and placebo-controlled intervention studies assessing potential preventive effects of α T supplement on cancer including PCa, there are some key differences between the ATBC and other trials including the SELECT. First, all participants in the ATBC study were heavy smokers, whereas low percentage of participants in other RCTs are heavy smokers. For instance, the SELECT had <8% current smokers. Second, the ATBC trial tested modest supplementation of α T (50 mg), whereas the SELECT and other trials used high supplements of α T at 400 IU or higher. Third, unlike the SELECT, there was no comprehensive pretrial screening for PSA or DRE in the ATBC trial. Additionally, the ATBC trial reported that α T decreased the incidence of clinical (stage II–IV) PCa and PCa-associated mortality, but not stage 0–I PCa, whereas the SELECT exclusively focused on the impact on early-stage PCa (>70% latent and 25%–30% stage II PCa) incidence. Because of these distinct features including α T dosing, smoking status of participants, and PCa stage, it is hardly surprising that the ATBC trial revealed different outcomes from other studies concerning the role of α T in PCa.

It is noteworthy that the lack of PSA and DRE screening, together with PCa as a secondary end point, may be potential sources of biases for the ATBC trial. However, the number of participants diagnosed with prostatic hyperplasia between α T and non- α T groups was similar in the ATBC trial. Further, there was no difference between α T and non- α T groups with respect to the increase in serum PSA [42]. Moreover, the observation that α T supplementation decreased PCa-associated mortality in the ATBC trial also suggests a true effect of α T. For these reasons, the result from the ATBC trial that moderate supplementation of α T appears to be beneficial to heavy smokers for preventing clinical PCa is important and should be paid attention to.

Preventive effects of high doses of α T on PCa in preclinical animal studies

From early 1990s, the role of α T or its combinations with other antioxidants in PCa prevention has been evaluated in animal models including carcinogens-induced PCa and genetically engineered spontaneous tumor-developing models. In 1991, Nakamura et al. [45] studied the effect of the α T (1% diet)-supplemented diet together with other antioxidants on 3, 2'-dimethyl-4-aminobiphenyl-induced prostate carcinogenesis in rats but did not observe beneficial effects on the incidence of tumors in the prostate or any other organs analyzed [7]. In another study, Ozten et al. [46] reported that *dl*- α T at 0.2% and

0.4% in diet failed to block PCa stimulated by testosterone plus estradiol in NBL rats. Similarly, α T at 2% and 4% or its combinations with selenomethionine did not decrease the incidence of PCa induced by sequential administration of cyproterone acetate, testosterone propionate, and N-methyl-N-nitrosourea as well as chronic androgen stimulation with subcutaneous implantation of testosterone capsules in rats [47]. In addition, the effects of α T on PCa have been assessed along with other forms of vitamin E in different PCa models including phosphatase and tensin homolog deleted on chromosome 10 (PTEN) knockout ($Pten^{P-/-}$) and transgenic rat for adenocarcinoma of prostate (TRAP) mice [48,49]. Most of these studies revealed that α T at doses ranging from 0.05% to 0.2% was ineffective for inhibition of PCa development (Table 2) [45–65].

α T and its combination with lycopene have also been assessed in PCa cell-implanted models representing advanced PCa. In the orthotopic human PC-346C prostate xenograft model in NMRI nu/nu mice, combining α T (*all-rac*- α -tocopheryl acetate) and lycopene [5 mg/kg body weight (BW) of each component by oral gavage], not either agent alone, suppressed the growth by 75% of the prostate xenograft and increased median survival by 40% [57]. Interestingly, in Copenhagen rats injected with MatLyLu Dunning PCa cells, dietary α T or lycopene but not their combination increased prostate tumor necrotic areas, whereas none of the treatments significantly affect tumor weight [56]. In addition, α T did not show significant impact on the growth of LNCaP tumors [64].

These preclinical animal studies indicate that α T at relatively high supplement doses do not exhibit preventive effects on early-stage or advanced PCa. Although combining α T with lycopene was shown to block advanced PCa in one animal study, additional research is needed to further test this combination in different PCa models.

The effects of α T on PCa in cell studies

Numerous studies have evaluated the impacts of α T and other forms of vitamin E on PCa cells and shown that α T is the least effective among members of the vitamin E family in blocking proliferation of PCa cells, as summarized in Table 3 [55,61,62, 64,66–80]. In some studies, α T was found to promote the growth of transformed prostate epithelial cells. Specifically, Njoroge et al. [74] reported that α T promoted the growth of HPV-18 immortalized prostate epithelial (RWPE-1) organoids but did not affect healthy prostate epithelial organoids, whereas decreased malignant LNCaP organoids. Vivarelli et al. [81] showed that *dl*-*all-rac*- α T at 100 μ M, a high pharmaceutical dose, markedly upregulated the expression of phase I CYP enzymes including activators of polycyclic aromatic hydrocarbons and CYP1A1, CYP1A4, CYP2B6, CYP2C9, and CYP4F2 in the RWPE-1 cell line and in rats. Further, α T at this high concentration also enhanced reactive oxygen species and mRNA of cyclooxygenase-2 as well as prostaglandin E₂, suggesting pro-oxidant and proinflammatory activities. Consistently, supplementation of α T at 100–200 mg/kg BW resulted in increased expression of drug-metabolizing CYP enzymes and oxidative stress markers in rats and even promoted cell transformation frequency, suggesting procarcinogenic potentials [81]. Additionally, α T was recently shown to either counteract or promote immunotherapy. Specifically, α T was shown to increase programmed cell death ligand (PD-L) 1 in PCa DU-145 cells and

TABLE 2
Chemopreventive and potential therapeutic effects of tocopherols and tocotrienols in preclinical PCa models

Time	Vitamin E forms and doses	PCa models	Key observations
Chemopreventive effects on carcinogen-induced PCa in rodents			
1991	1% α T along with catechol (0.8%), resorcinol (0.8%), hydroquinone (0.8%), selenium (2 ppm), γ -orysanol (2%) for 40 wk [45]	DMAB-induced prostate carcinogenesis in male F344 rats	No significant effects on atypical hyperplasias and carcinomas of the prostate
2010	<i>dl</i> - α T at 2000 and 4000 mg/kg diet (equivalent to 0.2% and 0.4% diet), or L-selenomethionine (1.5 or 3 mg/kg) [46]	Testosterone plus estradiol-treated NBL rats	No effects on development of prostate carcinomas, whereas α T \uparrow the incidence of adenocarcinomas of the mammary glands
2010	<i>dl</i> - α T at 2000 and 4000 mg/kg diet, or α T (500 or 2000 mg/kg) plus L-selenomethionine (3 mg/kg) for 13 mo [47]	Intravenous injection of MNU plus androgen stimulation in Wistar-Unilever (W/U) rats	No significant effects on PCa incidence or development
2013	γ T-enriched diet (20 mg/kg) for 16 wk [50]	MNU plus testosterone (subcutaneously)-induced epithelial dysplasia in the ventral prostate of Wistar rats	γ T \downarrow MNU-induced epithelial dysplasia by 38%, epithelial proliferation, COX-2, and MMP-9 in the ventral prostate
2016	γ TmT (0.3%) or individual tocopherols, i.e., γ T, δ T, or α T at 0.2% in diet [51]	PhIP-induced prostate carcinogenesis in the CYP1A-humanized (hCYP1A) mice	γ TmT and individual tocopherols \downarrow PhIP-induced mouse PINs by 66%. δ T (\downarrow 60% PINs) is stronger than γ T or α T (\downarrow ~20% PINs) for this effect
Chemopreventive effects on PIN development or PIN to adenocarcinoma in genetically engineered models			
2009	γ T at 50-mg/kg, 100-mg/kg, and 200-mg/kg diet for 7–10 wk; α T at 50-mg/kg diet [49]	The transgenic rat for adenocarcinoma of prostate (TRAP) driven by probasin/SV40 T antigen	γ T, in contrast to α T, \downarrow multiplicity of prostate adenocarcinoma without affecting PIN, and \uparrow caspase 3 and caspase 7 in prostate tissue
2009, 2012	γ TmT at 0.1% in diet for 24 wk [52,53]	Oncogenic SV40-driven transgenic adenocarcinoma of mouse prostate (TRAMP) mice	γ TmT \downarrow palpable tumor incidence by 75% and \downarrow % high-grade PINs, and \uparrow Nrf2 and its targeted genes by \downarrow CpG methylation
2010	γ TE-rich tocotrienols (TEs) at 0.1%, 0.3%, and 1% containing α TE, β TE, γ TE, δ TE, and α T at 13, 1, 19, 5, and 13%, respectively, in AIN-76A diet [54]	TRAMP mice	TEs dose-dependently \downarrow tumor incidence (50%–70%), weight (by 75%) and high-grade neoplastic lesions, whereas \uparrow BAD, caspase 3, p21, and p27
2018	δ T or α T at 0.2% in diet from the age of 6 or 12–40 wk [48]	Male prostate-specific PTEN-knockout (Pten ^{P-/-}) mice	δ T (intervention starting at 6 or 12 wk of age), but not α T, \downarrow % and multiplicity of prostate adenocarcinoma by 43%–53%, p-AKT and Ki67, and \uparrow caspase 3, without affecting HGPINs
2022	δ TE at 0.05% diet from age of 6 wk to 20 to 40 wk [55]	Male prostate-specific PTEN-knockout (Pten ^{P-/-}) mice	δ TE \downarrow % prostate adenocarcinoma by 32.7%, proliferation (Ki67), angiogenesis (CD31 and VEGFd), and \uparrow apoptosis (caspase 3)
Effects on the growth of relatively advanced PCa			
2004	540 ppm α T (originally from Rovimix E 50 from DSM), 200 ppm lycopene, or their combination for 4-wk pretreatment and 18-d posttumor implantation [56]	1×10^5 MatLyLu Dunning prostate cells were injected into the ventral prostate of male Copenhagen rats	α T or lycopene but not their combination \uparrow % of necrotic area in a cross-sectional view of prostate tumor tissue; α T \downarrow androgen signaling and lycopene \downarrow 5- α -reductase, both \downarrow prostatic spermine-binding protein
2006	<i>dl</i> - α T acetate at 5 or 50 mg/kg BW, or lycopene at 5 or 50 mg/kg BW, or lycopene+ α T (5 mg/kg BW each) [57]	Orthotopic PC-346C prostate xenograft model in NMRI nu/nu mice	Lycopene+ α T but not either agent alone suppressed orthotopic growth of PC-346C prostate tumors by 73% and increased median survival time by 40%
2006	γ TE at 400 mg/kg BW was injected subcutaneously in the neck of nude mice, which were then irradiated at the rear part of the body including the location of tumor [58]	Human PCa bone metastasizing PC3 cells implanted in athymic mice	The size of the tumors was \downarrow by ~40% only in γ TE-injected and γ TE-irradiated mice, whereas there was \uparrow lipid peroxidation in tumors and kidney (potential side effect at kidney)
2010	γ T at 200 mg/kg or its combination with lycopene (250 mg/kg diet) [59]	Dunning R3327H adenocarcinoma cells implanted in male Copenhagen rats	Neither γ T nor its combination with lycopene had significant impact on tumor growth
2010	γ TE at 50 mg/kg via intraperitoneally 5 times a week alone or coadministered with docetaxel (7.5 mg/kg via intraperitoneally) [60]	PC-3 human androgen-independent PCa in xenograft model	γ TE and γ TE+docetaxel \downarrow tumor growth by 52% and 61%, respectively. γ TE was accumulated in tumors, \uparrow apoptosis, and \downarrow proliferation

(continued on next page)

TABLE 2 (continued)

Time	Vitamin E forms and doses	PCa models	Key observations
2011	γ T or γ TE at 125 mg/kg BW by oral gavage 3 times a week for 5 wk [61]	Human LNCaP PCa xenograft model in nu/nu mice	γ TE was stronger than γ T in \downarrow the growth of LNCaP xenograft (by 50%) min nude mice
2011	γ TE (100 mg/kg daily) orally for 3 wk, and PCa cells were subcutaneously injected for another 4 wk; γ TE-pretreated PCa cells injected subcutaneously or orthotopically in nude mice [62]	PC3-Luc cells subcutaneously or orthotopically injected in nude mice	γ TE-pretreated cells resulted in \downarrow tumor incidence; γ TE given orally also \downarrow tumor incidence
2014	Methaneseleninic acid (MSA) (40.95 μ g/kg BW), γ T1 (20.83 mg/kg) or γ T2 (41.66 mg/kg BW) in corn oil, alone or in combinations by gavage (5 d/wk) for 14 d [63]	Human PCa 22Rv1 cell-implanted tumor in Nu/J mice	MSA+ γ T1 or γ T2 but not other treatments \downarrow tumor weight (~25%); MSA+ γ T1 or MSA \downarrow PSA
2014	α T or δ T at 0.3% diet for 48 d [64]	LNCaP xenograft model in nude mice	δ T, but not α T, \downarrow LNCaP tumor size and weight, and induced apoptosis in tumors
2016	mTEs containing α TE, β TE, δ TE, γ TE, and α T (at 8.3, 1.5, 4.6, 11.4, and 6 g out of 100 g, respectively) at 200 or 400 mg/kg BW, by gavage 3 times a week for 8 wk [65]	VCaP human hormone-refractory PCa xenograft model in NCr-immunodeficient mice	The mTEs dose-dependently \downarrow tumor growth and caused \uparrow CDK inhibitors p21 and p27 and \uparrow H3K9 acetylation at their promoters with decreased expression of histone deacetylase

γ TmT is γ T-rich tocopherol mixtures often containing 57%–60% γ T, 21%–24% δ T, 12%–13% α T, and 0.5%–1.5% β T.

Abbreviations: DMAB, 3,2'-dimethyl-4-aminobiphenyl; HGPIN, high-grade prostatic intraepithelial neoplasia; MNU, N-methyl-N-nitrosourea; Nrf2, nuclear factor erythroid 2-related factor 2; PCa, prostate cancer; PhIP, 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine; PIN, prostate intraepithelial neoplasia; mTEs, mixed tocotrienols; TRAMP, transgenic adenocarcinoma of the mouse prostate; TRAP, transgenic rat for adenocarcinoma of prostate; TRF, tocotrienol-rich fraction; \downarrow , suppress or inhibit; \uparrow , increase or enhance; \leftrightarrow , show no effect.

consistently promote lung tumor development potentially via immunosuppression [78]. In a sharp contrast, potential immunotherapy-promoting effect of α T was suggested in another study where α T at 50 mg/kg enhanced immunotherapy against mammary tumors via reinvigorating dendritic cells [82].

Preclinical cell and animal data support and explain results from large RCTs concerning the effects of high-dose α T supplements on PCa

Preclinical data concerning the impact of α T on PCa (given in previous 2 sections) are largely in agreement with the results from RCTs and may offer explanations of adverse effects observed in the SELECT and HOPE-TOO trials. First, results from RCTs indicate that supplementations of α T at a relatively high dose, that is, 400 IU (364 mg *dl*- α T) or higher, do not offer beneficial effects on PCa prevention among noncurrent smokers. Consistently, α T at 0.05%–0.2% (or higher), which are equivalent to ~230–920 mg *dl*- α T daily for 60-kg adults, did not show preventive effects on PCa in animal models. Second, preclinical studies showed that α T increased proliferation of transformed prostate epithelial organoids [74] and promoted DNA damage, inflammation, and even benzo[a]pyrene-induced cell transformation [81]. These observations suggest procarcinogenic activities and may explain adverse effects reported in the SELECT where high-dose α T supplementation increased the incidence of early-stage PCa [40]. Third, α T has been reported to elevate the expression of cytochrome P450 enzymes such as CYP3a11 (equivalent to human CYP3A4) via activating pregnane X receptor (PXR) [83,84]. Consistently, α T at 100 μ M upregulated several CYP enzymes in human prostate epithelial RWPE-1 cells and in rats. These observations potentially explain side effects of α T in the HOPE/HOPE-TOO trial. Specifically, most participants in the HOPE-TOO trial took multiple medicines including aspirin and β -blockers because of their pre-existing medical conditions. Elevation of drug-metabolizing CYP enzymes by α T (at 400 IU)

may counteract therapeutic outcomes of medicines in patients and consequently may contribute to increased hospitalization and rates of heart failure among patients taking α T in the HOPE/HOPE-TOO [37].

In summary, α T at a modest dose (50 mg) is observed to decrease PCa death among heavy smokers. However, supplementation of relatively high doses of α T appears to be ineffective for PCa prevention in RCT trials, which is supported by findings in preclinical cell and animal studies. Preclinical studies also provide rationales for high-dose α T-associated side effects including increased early-stage PCa and hospitalization.

Chemopreventive and Therapeutic Roles of γ T, δ T, γ TE, and δ TE in PCa: Evidence From Preclinical Animal Studies

During the last 20 y, the effects of γ T, δ T, and γ -tocopherol-rich mixed tocopherols (γ TmTs) as well as TEs especially γ TE and δ TE on PCa development have been investigated in various PCa animal models. These models are believed to recapitulate different-stage PCa development, including formation of PIN, which is precursor lesion of PCa, and progression from PIN to adenocarcinoma [85], as well as the growth of late-stage PCa tumors derived from implanted PCa cells [86]. Consequently, these studies have revealed both preventive and treatment capabilities of these tocopherols and TEs, as summarized in Table 2 [45–65].

Chemopreventive effects of γ T, δ T, and γ TmT as well as TEs in preclinical PCa models in rodents

Potential chemopreventive abilities of γ T, δ T, and γ TmT, in comparison with α T, have been assessed in preclinical animal models mimicking early-stage PCa development in rodents. For instance, γ T was found to inhibit N-methyl-N-nitrosourea plus

TABLE 3
Anti-PCa effects and mechanisms of tocopherols and tocotrienols in cell-based studies

Year and cells	Vitamin E forms	Key finding (IC50s)	Signaling/mechanisms
2002; DU-1145, LNCaP, CaCo-2, SaOs-2 [66]	α T, γ T, β T	\downarrow DU-145 cell growth by α T (25–50 μ M), γ T (12–25 μ M), and β T (50 μ M)	NA
2004; LNCaP, PC-3, PREC (normal prostate cells) [67]	γ T, α T, γ T+ δ T, γ T+ γ TE	\downarrow LNCaP, PC-3 cell growth by γ T (25–50 μ M) or γ T+ δ T (20+10 μ M), γ T+ γ TE (20+2.5 μ M), but not α T; \uparrow apoptosis in LNCaP cells; no effects on normal cells	\uparrow cytochrome C release, caspase-9 cleavage; \uparrow dihydroceramides and dihydrosphingosine, which contributes to anti-PCa
2004; PC-3 [68]	α T, γ T, α -CEHC, γ -CEHC, trolox	\downarrow PCa cell growth by γ -CEHC \approx γ T (<10 μ M) > α -CEHC> α T	\downarrow cyclin D1
2004; DU-145, LNCaP [69]	γ TE	Combining γ TE and statin synergistically \downarrow PCa cell growth	NA
2008; LNCaP, PC-3, PZ-HPV-7 [70]	α T, β T, γ T, δ T, α TE, β TE, γ TE, δ TE	\downarrow PCa (but not immortalized cells) growth by δ TE (41 μ M), γ TE (32 μ M), β TE (54 μ M) > γ T, δ T> α T, α TE; γ TE+docetaxel showed synergy	\uparrow apoptosis, G1 arrest; \downarrow NF- κ B, EGF-R and Id family proteins
2011; LNCaP, PC-3; [61]	γ T, γ TE	\downarrow LNCaP, PC-3 cell growth by γ TE (10–20 μ M); \uparrow apoptosis, autophagy and necrosis; \uparrow cytochrome C, PARP cleavage, LC-3; \downarrow p-AKT after apoptosis started	\uparrow dihydroceramides and dihydrosphingosine prior to cell death; inhibiting synthesis of sphingolipids counteracted γ TE's anti-PCa
2011; PC-3, DU145 [62]	γ TE	γ TE (7–12 μ M) \downarrow CD133/CD44 (CSC markers), spheroid formation; CSC-rich population is sensitive to γ TE	γ TE may target prostate CSCs
2011; PC-3, LNCaP [71]	α T, γ T, δ T, α TE, γ TE, δ TE	\downarrow PC-3 cell growth by δ TE (~23 μ M), γ TE (30 μ M) >> γ T, δ T> α T, and LNCaP is also sensitive to γ T or δ T; \uparrow caspase 3	\uparrow PPAR- γ , 15-LOX-2 mRNA and protein; \downarrow TGF β 2, NF- κ B and p-p38
2014; LNCaP, VCaP, and CWR22Rv1 [64]	α T, γ T, δ T, or γ -TmT	δ T > γ T, γ TmT > α T \downarrow PCa cell growth, PSA and AR reporter activity; \uparrow apoptosis	NA
2016; DU145, PC-3, C4-2, LNCaP, CWR22Rv-1 [72]	α T, δ T, γ T	\downarrow PCa cell growth, δ T (30 μ M) > γ T (>50 μ M) >> α T; δ T \uparrow caspase 3; \downarrow phosphorylation of AKT (p-AKT)	δ T \downarrow EGF/IGF-induced p-AKT possibly via blocking EGFR-stimulated PI3K/AKT signaling
2017; LNCaP [73]	γ T, δ TE	γ T+ δ TE strengthened anti-PCa and enhanced apoptosis	NA
2017; PREG, LNCaP, RWPE-1 [74]	α T	α T (40 μ M) \uparrow the growth of RWPE-1 organoids, but not healthy prostate epithelial organoids, \downarrow LNCaP organoids	α T rescue detachment associated decrease in ATP synthesis and fatty acid oxidation in RWPE-1
2019; PC-3, C4-2B [75]	γ TE	\downarrow Angiopoietin (Ang)-1 mRNA and protein; \downarrow CD49f and Bmi-1 (stemness markers); synergy of γ TE+Tie-2 inhibitor for \downarrow cell growth and \uparrow p-AMPK	γ TE+Tie-2 inhibitor may be a novel anti-PCa agent
2019, 2020; PC-3, DU145 [76,77]	δ TE	δ TE \uparrow ER stress, autophagy and related p-JNK and p-p38; \uparrow vacuolation and apoptosis; \uparrow Ca ²⁺ overload in cytosol and mitochondria, \downarrow mitochondria function	NA
2022; PTEN-Cap8, PC-3, DU145, 22Rv1, LNCaP [55]	α T, γ T, δ T, γ TE, δ TE	\downarrow PCa cell growth by δ TE (12 μ M) > γ TE (17 μ M) > α TE (26 μ M), δ T (24 μ M) > γ T (49 μ M) > α T; \uparrow apoptosis (caspase 3)	δ TE did not show strong inhibition of p-AKT
2022; DU145 [78]	α T	α T (10–30 μ M) \uparrow cell migration and proliferation, prosurvival signaling, and PD-L1	Upregulation of PD-L1 by α T via activating ERK and STAT3
2022; DU145 [79]	β TE	β TE dose-dependently \downarrow PD-L1 and JAK2/STAT3, and T cell-mediated toxicity against DU145	NA
2024; DU145 [80]	α T, γ T, δ T, β T, α TE, γ TE, δ TE, β TE	γ TE, δ TE, β TE dose-dependently \downarrow PD-L1; δ TE promoted T cell toxicity against DU145	δ TE (20 or 30 μ M) \downarrow glycosylated PD-L1 in cells and exosome

Abbreviations: C4-2B/22RV1, CRPC cells; CRPC, castration-resistant prostate cancer; CSC, cancer stem cell; ER, endoplasmic reticulum; p-JNK, phosphorylated c-Jun N-terminal kinase; PD-L1, programmed death ligand 1; PREG, healthy prostate epithelial cells; prostate cancer cell lines, LNCaP (androgen dependent); PC-3, DU145 (androgen independent); RWPE-1, HPV-18 immortalized prostate epithelial cells; \downarrow , suppress or inhibit; \uparrow , increase or enhance; \leftrightarrow , show no effect.

testosterone-induced PIN in rats' prostate [50]. In another study, α T, γ T, δ T, and γ TmT are shown to inhibit the number of PINs induced by 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine in the CYP1A-humanized mice, and δ T was more effective than γ T or α T for this effect [51]. Further, in the genetically engineered TRAP and transgenic adenocarcinoma of the mouse prostate (TRAMP) models that spontaneously develop PIN to

prostate adenocarcinoma, γ T, or γ TmT but not α T suppressed prostate adenocarcinoma and decrease palpable tumor incidence, and these anticancer effects were accompanied by increased expression of antioxidant regulator nuclear factor erythroid 2-related factor possibly via modulating DNA methylation [49,52,53]. Interestingly, despite blocking adenocarcinoma, γ T did not affect the number of PINs in the TRAP model

[49]. In addition, δ T but not α T (at 0.2%) has recently been reported to decrease prostate adenocarcinoma but did not have significant impacts on the multiplicity of high-grade PINs in prostate PTEN-knockout mice, whereas α T did not show significant anticancer effects [48]. These observations indicate that γ T, δ T, and γ TmT, but not α T, can inhibit carcinogen-induced hyperplasia and block progression of PIN to prostate adenocarcinoma in spontaneously tumor-developing models.

In addition to tocopherols, TEs have been tested for their chemopreventive effects on PCa in genetically engineered animal models that spontaneously develop PCa. For instance, γ TE-rich mixed TEs suppressed prostate tumor development in the TRAMP model [54]. Moreover, δ TE (0.05% diet) at a much lowered dosage than δ T (0.2% diet) displayed similar inhibitory effects on adenocarcinoma in mice with prostate-specific PTEN knockout [55].

Anticancer effects of tocopherols and TEs against late-stage PCa in preclinical animal studies

In addition to research on cancer prevention, studies have also been conducted to assess potential treatment effects of tocopherols on late-stage PCa progression in xenograft models bearing implanted PCa cells. Studies assessing potential effects of α T and its combination with lycopene on PCa-implanted tumor development revealed inconsistent results (see “Preventive effects of high doses of α T on PCa in preclinical animal studies” section). In androgen-sensitive human prostate adenocarcinoma LNCaP-implanted xenograft models, γ T and δ T but not α T modestly suppressed tumor growth [61,64]. γ T (~42 mg/kg BW) or its combined with methaneselenic acid also modestly inhibited the growth of human 22RV1 tumors that represent CRPC [63]. On the contrary, in a study with Dunning R3327H adenocarcinoma rats, which represents slow growing PCa (adenocarcinoma or beyond), γ T or its combination with lycopene did not affect tumor growth [59] possibly because of relatively low dose of γ T (0.02% diet \approx 20 mg/kg BW) as at this dose, γ T alone did not suppress 22RV1 tumor growth either [63].

The effects of γ TE on relatively late-stage PCa have also been assessed. For instance, γ TE was found to inhibit tumor development in nude mice implanted with LNCaP xenografts and was stronger than γ T for this effect [61]. Furthermore, γ TE alone inhibited androgen-independent PC3 prostate tumor growth in nude mice and its combination with docetaxel showed even stronger inhibition of tumor growth [60]. In another xenograft model, mixed TEs in diets inhibited prostate tumor development and increased cyclin-dependent kinase inhibitors p21 and p27 possibly via elevating H3K9 acetylation of their promoters [65]. In addition, TEs have been shown to enhance the efficacy of cancer radiation therapy. Specifically, Kumar et al. [58] reported that γ -irradiation combined with γ TE at 400 mg/kg BW (via subcutaneous injection in the neck), but not radiation or γ TE alone, reduced the size of established tumors and increased lipid peroxidation in tumors in athymic mice implanted with human PCa PC-3 cells. Moreover, although not specifically related to PCa treatment, γ TE and δ TE at 200–400 mg/kg BW administered subcutaneously prior to radiation protected hematopoietic stem and progenitor cells in mice after total-body irradiation and accelerated the recovery of white blood cells in irradiated mice [87–90]. These observations suggest that γ TE may inhibit advanced PCa tumor progression and potentially be useful for adjuvant therapy for improving treatment efficacy of irradiation and chemotherapy, and γ TE and δ TE may alleviate irradiation-associated adverse effects.

In summary, γ T and γ T-rich tocopherols, but not α T, are capable of inhibiting carcinogen (N-methyl-N-nitrosourea and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine)-induced prostate epithelial dysplasia. γ T, δ T, γ TE and δ TE, although largely not for α T, suppressed progression of PINs to adenocarcinoma in spontaneously tumor-developing models. δ TE at a lower dose showed similar anti-PCa efficacy to δ T at a much higher dose, indicating stronger chemopreventive effects of δ TE (Figure 3) [85]. As to the impact on advanced PCa, γ TE is found to be stronger than γ T for inhibiting the growth of PCa tumors in xenograft models. Therefore, it can be concluded that γ T, δ T,

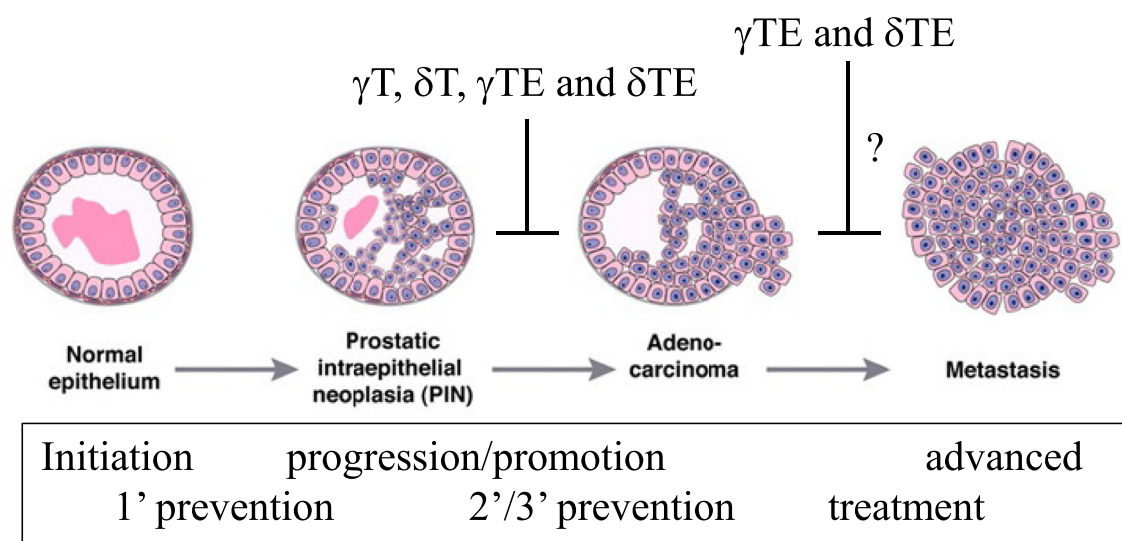

FIGURE 3. Chemopreventive effects of γ T, δ T, γ TE, and δ TE: γ T, δ T, γ TE, and δ TE have been shown to block development of prostatic intraepithelial neoplasia (PIN, noncancerous lesion), especially progression from PIN to adenocarcinoma in various PCa animal models. These results suggest that these vitamin E forms may be useful for secondary and tertiary chemoprevention among relatively moderate-risk or high-risk population. This figure is modified based on [85] with permission. 1', 2', and 3' stand for primary, secondary, and tertiary preventions, respectively.

γ TmT, γ TE and δ TE, rather than α T, at supplement doses are promising chemopreventive agents for inhibiting relatively early-stage PCa including adenocarcinoma development. Moreover, existing data support that γ TE may be useful for treatment or adjuvant therapies for PCa. Despite these data, one noticeable gap is lack of data concerning the effects of δ TE on advanced PCa cell growth in animal models. Future studies are needed in this area as δ TE appeared to be the strongest among vitamin E forms in blocking PCa cell proliferation in cell-based studies (see further).

Anticancer Effects of Tocopherols and TEs in PCa Cells

Sustaining cell proliferation and resisting cell death are hallmarks of cancer [91]. Specific vitamin E forms have been shown to inhibit the growth and induce death of PCa cells, as summarized in Table 3 [55,61,62,64,66–80]. In particular, γ T and δ T but not α T have been shown to inhibit proliferation of PCa cells such as LNCaP, PC-3, and LU145, in a dose-dependent manner, and δ T was stronger than γ T for blocking PC-3 cell growth [48, 67,71]. γ T was found to induce apoptosis in LNCaP, but not PC-3 cells, as indicated by DNA fragmentation, increased annexin V translocation to the outside of cytoplasmic membrane, caspase-9 cleavage, and poly (ADP-ribose) polymerase (PARP) cleavage [67]. δ T was shown to induce caspase-3 activation and S phase arrest in PC-3 cells and inhibit receptor tyrosine kinase-induced AKT activation [72], although other vitamin E forms including δ TE and γ TE do not directly target phosphatidylinositol-3-kinase (PI3K)/AKT [48,61]. Compared with tocopherols, TEs displayed stronger anticancer effects in PCa cells. For instance, Jiang et al. [61] showed that γ TE is much stronger than γ T for blocking PC-3 and LNCaP proliferation and induction of apoptosis and autophagy as well as the growth of LNCaP xenograft tumors. Moreover, δ TE was found to be the strongest among all vitamin E forms in inhibition of the growth of PCa cells [55]. Overall, for antiproliferation and induction of apoptosis, γ T, δ T, γ TE, and δ TE display stronger anticancer effects than α T, and the relative antiproliferation potency appears to be δ TE (IC₅₀ ~12 μ M) \geq γ TE (15–20 μ M) $>$ δ T (25–40 μ M) $>$ γ T (30–50 μ M) based on the IC₅₀s (parentheses) observed in the aforementioned studies. In contrast, α T has been shown to have no or weak impact on proliferation of cancer cells except for 1 study [66]. These differences among different vitamin E forms were also observed in other type of cancer cells [92].

The mechanisms underlying the differential effects of tocopherols or TEs on PCa cell growth are not fully understood. Nevertheless, as previously discussed [92], differential uptakes of these vitamin E forms into cells may be a factor. For instance, we show that γ TE was accumulated at much higher concentrations in human PCa cells than γ T, correlating with much stronger anticancer effects of γ TE than γ T [61]. However, intracellular δ T concentrations were found to be comparable with those of α T, but δ T was more potent than α T in induction of death in macrophages [93]. Interestingly, γ TE and δ TE are known to have shorter half-life and lower C_{max} in the plasma than tocopherols in rodents [33] and humans (refer “Different forms of vitamin E and bioavailability” section). Nevertheless, TEs have been found to be accumulated in tumors but not normal tissues in animals [94,

95]. In addition, TEs have been proposed to be more uniformly distributed in the membrane bilayer and stronger in disordering of membrane lipids than their tocopherol counterparts [96], which may also contribute to their stronger antiproliferative effects on cancer cells.

γ T, δ T, γ TE, and δ TE as well as Metabolite 13'-COOHs: Molecular Mechanisms Relevant to Prevention and Therapy of PCa

Although all vitamin E forms are considered potent lipophilic antioxidants, the role of antioxidants in cancer prevention is not straightforward and vitamin E forms showed differential anticancer effects in cell and animal models. A reasonable explanation is that different vitamin E forms exert cancer-preventing effects via mechanisms independent of antioxidant activities. Indeed, existing evidence indicates that γ T, δ T, γ TE, and δ TE, in contrast to α T, can modulate pathways promoting development and progression of PCa and drug resistance. Moreover, these vitamin E forms, compared with α T, are preferentially metabolized in vivo. 13'-COOHs have been shown to have anticancer and anti-inflammatory effects that may also contribute to anti-PCa effects of the vitamin precursors. In this review, I will focus on the effects and mechanisms of these vitamin E forms and 13'-COOHs on PCa relevant pathways, while anticancer mechanisms relevant to other types of cancer have been reviewed elsewhere [9,92].

5-Lipoxygenase is a significant player in PCa development and drug resistance; vitamin E forms and 13'-COOHs block 5-LOX-mediated leukotrienes via distinct mechanisms

5-Lipoxygenase (LOX) is a proinflammatory enzyme catalyzing oxidation of arachidonate to form 5-hydroperoxyeicosatetraenoic acid and subsequently leukotriene (LT) A₄, which is then converted to LTB₄ and other LTs [97]. LTB₄ has been shown to promote PCa [98] and render PCa cells resistance to anoikis [99]. Further, increased 5-LOX expression is found in PCa tissues and associated with worsened prognosis and survival of patients with PCa [100] (The Human Protein Atlas). Consistently, inhibition of 5-LOX has been found to block invasion and induce apoptosis in bone-invading PCa cells [101] and decrease the expression and transcriptional activities of c-Myc [102]. Moreover, knockdown or inhibition of 5-LOX has been shown to kill enzalutamide-resistant CRPC cells [101,103]. In addition, inhibition of 5-LOX has also been shown to downregulate PCa stemness and kill PCa stem cells [104].

We demonstrated that tocopherols and TEs block 5-LOX-catalyzed formation of LTB₄ via different mechanisms. Specifically, γ T, δ T, γ TE, and δ TE are much stronger than α T in blocking calcium ionophore-stimulated elevation of LTB₄ in neutrophils, showing IC₅₀s of ~4 μ M for γ TE and δ TE, 2–7 μ M for δ T, 5–10 μ M for γ T, or >60 μ M for α T [105,106]. Mechanistically, γ T and δ T have been shown to inhibit ionophore-induced Ca²⁺ increase and phosphorylation of JNK (c-Jun N-terminal kinase), the upstream signaling essential for activation of 5-LOX and 5-LOX-mediated LT formation in cells, but these tocopherols do not inhibit human recombinant 5-LOX at physiologically relevant concentrations [105]. γ T has also

been shown to decrease LTB₄ or LTC₄ production in various animal models [107,108]. Unlike tocopherols, γ TE and δ TE inhibit 5-LOX activity with IC₅₀s of $\sim 4 \mu\text{M}$ [106], which is achievable in humans and animals [25,33]. γ TE and δ TE are stronger than α TE for this activity [106]. Consistent with direct inhibition of 5-LOX, γ TE and δ TE can block both ionophore-stimulated or thapsigargin-stimulated LTB₄ in neutrophils but do not affect 5-LOX translocation [106]. Enzyme kinetic studies revealed that γ TE and δ TE are competitive inhibitors of 5-LOX with K_i of $2.2 \mu\text{M}$ [106]. These data indicate that γ TE and δ TE can compete with arachidonate at the active site of the enzyme.

In addition to the vitamin precursors, we demonstrated that 13'-COOHs are strong inhibitors of 5-LOX with IC₅₀s ranging from 0.1 to 1 μM . Specifically, δ T-13'-COOH, a metabolite from δ T, can inhibit human 5-LOX activity with IC₅₀ of $\sim 1 \mu\text{M}$ [105]. δ TE-13'-COOH, a metabolite of δ TE, more strongly inhibits 5-LOX (IC₅₀ $\sim 0.6 \mu\text{M}$) than its precursor [106,109]. Consistently, Pein et al. [110] reported that α T-13'-COOH, a metabolite from α T, and δ TE-13'-COOH (purified from *Garcinia kola*) inhibit 5-LOX with IC₅₀s $\sim 0.1 \mu\text{M}$ and decreased LTs in vivo [110]. In addition, our enzyme kinetic data showed that δ T-13'-COOH and δ TE-13'-COOH are competitive inhibitors of human 5-LOX with K_i of 1.6 and 0.8 μM , respectively [106].

γ TE and δ TE can block nuclear factor- κ B that plays significant roles in PCa

Nuclear factor (NF)- κ B is a transcriptional factor regulating prosurvival and proinflammatory genes. In particular, it has been shown that NF- κ B is the third most activated pathway out of >100 pathways in metastatic and primary PCa where it correlates with disease progression, poor prognosis, and treatment resistance [111–113]. In particular, NF- κ B signaling and its target genes are upregulated in CRPC tumors and associated with shorter time to death from disease recurrence [113]. Furthermore, NF- κ B activation contributes to development of CRPC and resistance to enzalutamide, an androgen receptor antagonist, or chemotherapy drug docetaxel, and inhibition of NF- κ B restored responsiveness to these treatments [114,115].

We have shown that γ TE and δ TE can inhibit TNF α -stimulated NF- κ B activation via induction of A20. Specifically, δ TE and γ TE are stronger than tocopherols (γ T, δ T, or α T) and δ TE is stronger than γ TE in blocking TNF α -stimulated phosphorylation of I κ B α and nuclear translocation of P65 in macrophages and cancer cells including PCa PC-3 cells [116,117]. Mechanistic studies revealed that δ TE and γ TE inhibited NF- κ B via induction of A20, which is also known as TNF α -induced protein 3 and an endogenous negative regulator of NF- κ B [118]. In particular, γ TE and δ TE treatment elevated A20 mRNA and protein in macrophages and PC-3 cells [116,117]. In A20^{-/-} cells, anti-NF- κ B by these compounds diminished compared with that in A20^{+/+} cells, supporting a causative role of A20 upregulation in blocking activation of NF- κ B [116,117]. Further research indicates that induction of A20 was caused by modulation of sphingolipids by these TEs, including accumulation of dihydroceramides and dihydrosphingosine [116,117]. Consistent with these mechanistic studies in cells, γ TE and δ TE have been shown to inhibit NF- κ B in preclinical cancer models [119,120].

Cholesterol synthesis, HMG-CoA reductase, and CRPC progression

Cholesterol is essential in maintaining membrane physical properties, and its metabolism is involved in steroid hormone biosynthesis. Cancer cells rely on cholesterol to satisfy their increased nutrient demands and support their uncontrolled growth, thus promoting tumor development and progression [121]. Advanced PCa including CRPC is shown to express increased HMG-CoA reductase (HMGCR), the rate-limiting enzyme for cholesterol biosynthesis [122], and have higher cholesterol ester concentrations than normal cells, which may play a role in intratumoral steroidogenesis in CRPCs [123]. Moreover, increasing evidence supports an inverse association between the use of statin (HMGCR inhibitor) and advanced PCa risk, although its association with general PCa risk is not consistent [124]. This observation supports the importance of steroidogenesis in advanced PCa. Besides steroidogenesis, excessive lipids and cholesterol in cancer cells appear to be stored in lipid droplets, and intratumor cholesteryl ester accumulation is associated with cancer aggressiveness and recurrence [125–127]. Consistently, simvastatin, a potent inhibitor of HMGCR, promoted apoptosis in PCa cells, and this anticancer effect was reversed by replenishing cell membrane with cholesterol [128]. Additionally, knockdown of HMGCR or statin sensitized drug-resistant CRPC cells and tumors [122]. These results suggest that HMGCR may be a target of advanced PCa. Interestingly, δ TE and γ TE but not tocopherols have been shown to induce degradation of HMGCR in liver cells [129], and combining γ TE or δ TE with statin synergistically inhibited the growth of many types of cancer cells including PCa DU-145 cells [130]. However, the underlying mechanism of such synergy remains to be determined including whether these TEs can degrade HMGCR in PCa cells, potential contributions from other activities by TEs (e.g., blocking 5-LOX), and the possibility that γ TE can reverse statin-induced increase of HMGCR [131]. It is also not clear whether combining γ TE and δ TE with statin could synergistically block PCa in vivo.

Anti-PCa cells via modulation of sphingolipids

γ T and γ TE have been shown to induce apoptosis and inhibit proliferation of PCa and other cancer cells at least in part by modulating sphingolipids [9,92,132]. Sphingolipids such as dihydroceramides, dihydrosphingosine, and ceramides have been recognized to play important roles in regulating cell death and survival, as elevation of these sphingolipids has been shown to cause stress, inhibit cell growth, and induce apoptosis [133–135]. To this end, γ T, γ TE, and 13'-COOHs have been shown to elevate dihydrosphingosine and dihydroceramides as well as ceramides in prostate and other types of cells. Importantly, the modulation of these sphingolipids has been observed prior to manifestation of cell death such as PARP cleavage [109, 132,136]. This is important for supporting the notion that modulation of sphingolipids may be the cause instead of the consequence of cell death. Mechanistic studies have revealed that γ TE and 13'-COOHs inhibited the activity of dihydroceramide desaturase, a key enzyme in the de novo synthesis of sphingolipids pathway [109,136]. Prolonged treatment with γ TE or 13'-COOHs are found to elevate ceramides possibly via activation of sphingomyelinase [109,136]. Consistent with the idea

that modulation of sphingolipids contributes to induction of death, pharmacologic inhibition of the de novo synthesis of sphingolipids partially counteracted γ T-induced or γ TE-induced anticancer effects in cancer cells [67,136]. These observations support molecular interaction between these compounds and sphingolipids, although whether these vitamin E forms can modulate sphingolipids in vivo remains to be investigated.

Additional mechanisms: PI3K/AKT, angiogenesis, cancer stem cell, and epigenetic modulation as well as potential implications in immunotherapy

PI3K/AKT signaling is believed to contribute to PCa [137]. Potential impact of vitamin E forms on PI3K/AKT signaling has been investigated in PCa cells. For instance, γ TE was found to reduce phosphorylation of AKT (p-AKT), a key target of PI3K, after apoptosis induced by γ TE was evident [61]. This observation suggests that inhibition of PI3K/AKT is not likely a cause of death induction by γ TE. Similarly, δ TE did not appear to strongly inhibit PI3K/AKT in PCa cells [55]. On the contrary, δ T was found to block EGF/IGF-induced phosphorylation of AKT in PCa cells [72]. Interestingly, stably expressing dominant active AKT or PI3K resulted in diminished anticancer effects by δ T, supporting PI3K/AKT as a target of δ T [72]. Consistently, δ T also decreased AKT phosphorylation in the prostate in Pten^{P-/-} mice [48]. These results indicate that δ T, but no other vitamin E forms, can target PI3K/AKT pathway.

Angiogenesis is a hallmark of cancer [91]. Hypoxia-inducible factor (HIF)-1 α , and its downstream genes like vascular endothelial growth factor (VEGF), IL-8, and cyclooxygenase 2 play critical roles in neovascularization. Interestingly, γ TE and δ TE have been shown to be stronger than α TE or β TE in inhibition of hypoxia-induced VEGF mRNA and its secretion. δ TE at 2 μ M was also reported to reduce HIF-1 α protein expression and/or increase its degradation and decrease IL-8 [138]. In addition, γ TE was shown to suppress angiopoietin (Ang-1)/Tie-2, a well-recognized signaling pathway involved in regulation of angiogenesis [75,139]. These observations suggest that δ TE and γ TE may exert anticancer effects via blocking angiogenesis, although it remains to be determined whether this mechanism plays a role in inhibition of PCa in vivo.

γ TE may target cancer stem cells (CSCs) that are recognized to contribute to resistance to cancer therapy [140]. Specifically, γ TE has been shown to downregulate the expression of CD133/CD44, CSC markers, in androgen-independent PCa cells. Consistently, γ TE inhibited the formation of spheroids [62]. Interestingly, although CSC-enriched PC-3 cells (CD133+) are resistant to docetaxel, these cells and CD133-negative cells appeared to be sensitive to γ TE treatment [62]. Given that blocking 5-LOX has been shown to decrease PCa stemness and kill CSCs [104], γ TE's antistemness effect may be partially rooted in its inhibition of 5-LOX [106].

Evidence suggests that vitamin E forms may be capable of modulation of gene expression via epigenetic mechanisms. In particular, γ T-rich mixed tocopherols have been shown to decrease the expression of DNA methyltransferases (DNMTs) including DNMT1, DNMT3A, and DNMT3B in the prostate of mice in the TRAMP model [53], suggesting the possibility of modulating DNA methylation and consequently gene expression. Consistently, in the TRAMP model, γ T-rich mixed tocopherols were found to inhibit CpG methylation in the promoter of

nuclear factor erythroid 2-related factor 2 compared with controls [53]. In addition, a TE mixture was reported to induce epigenetic modification including acetylation of cyclin dependent kinases (CDK) inhibitors p21 and p27 in mice [65]. Despite these observations, the mechanism underlying decreased expression of DNMT or modulating acetylation by γ TmT remains to be determined.

Recently, vitamin E forms have been reported to potentially influence immunotherapy via immunomodulatory activities. To this end, contradictory roles of α T in immunotherapy have been reported. On the one hand, α T was found to increase PD-L1 in PCa DU-145 cells, which may contribute to α T-associated promotion of tumorigenesis [78]. On the other hand, α T was also shown to enhance immunotherapy against mammary tumors via reinvigorating dendritic cells [82]. Recently, β TE and δ TE have been shown to dose-dependently suppress the expression of PD-L1 in PCa DU145 cells and enhance T cell-mediated toxicity against these cells [79,80]. Further mechanistic investigations show that treatment of δ TE (20–30 μ M) reduced glycosylated PD-L1 [80], which is essential for interaction between PD-L1 and programmed cell death protein 1 and therefore immunosuppression [141,142]. δ TE treatment also decreased exosomal PD-L1 and glycosylated PD-L1 [80].

In summary, accumulating research has indicated that γ T, δ T, γ TE, and δ TE can inhibit cancer hallmarks and enabling characteristics including uncontrolled cell proliferation, resistance to apoptosis, angiogenesis, and inflammation by blocking PCa-promoting signaling including NF- κ B, 5-LOX, sphingolipids, and possibly cholesterol synthesis as well as epigenetic modulation (Figure 4). Emerging evidence suggests potential roles of vitamin E forms in immunotherapy, an area warranting further investigation.

The Impact of Vitamin E Forms and 13'-COOHs on PXR and CYP Enzymes: Relevance to PCa and Drug Interactions

PXR is an adopted orphan nuclear receptor and plays a major role in the metabolism and clearance of drugs in the liver and intestine via induction of drug-metabolizing enzymes such as CYPs and transporting proteins including intestinal P-glycoprotein (P-gp), a member of the ATP (adenosine triphosphate) binding cassette transport family (ABC transporter) [143,144]. In

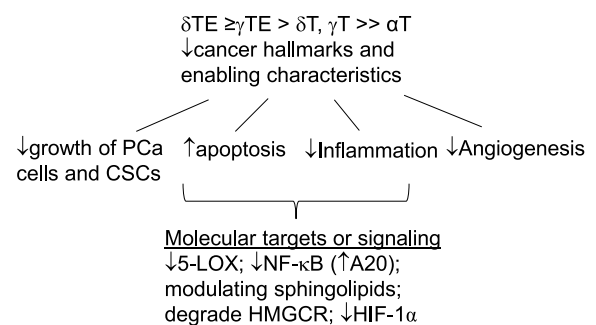

FIGURE 4. Anti-PCa effects and mechanisms of vitamin E forms: γ T, δ T, γ TE, and δ TE inhibit several cancer hallmarks (uncontrolled proliferation, evading apoptosis, and angiogenesis) and enabling characteristics (inflammation) via targeting 5-LOX, NF- κ B, sphingolipids, and HMGCR. 5-LOX, 5-lipoxygenase; HMGCR, HMG-CoA reductase.

addition to regulation of drug metabolism, the role of PXR in cancer including PCa has also been extensively studied and believed to be context specific as evidence supporting pro-PCa and anti-PCa roles of PXR has been documented [143]. On the one hand, increased expression of PXR has been observed in PCa tissues [145]. On the other hand, higher PXR expression and its targeted gene *CYP3A4* appear to correlate with favorable prognosis and increased survival in PCa patients [146]. Consistently, reduced PXR was found to correlate with a loss of a tumor suppressor protein in CRPC [147].

Vitamin E forms and 13'-COOHs have been shown to differentially affect PXR and CYPs. For instance, α T but not γ T or γ TE-induced *CYP3a11* (the murine homolog to human *CYP3A4*) in mice, whereas α TE and γ TE were stronger than α T in induction of a report gene driven by PXR [83]. Further, α T supplementation activated PXR in human leukocytes [84] and increased many drug-metabolizing enzyme genes in prostate epithelial cells [81]. α TE, γ TE, δ TE, and β TE but not tocopherols were found to activate PXR in HepG2 cells [148]. In addition to the vitamers, 13'-COOHs appear to be potent activators of PXR. α T-13'-COOH and γ TE have been shown to increase PXR activity and its regulated P-gp expression [149]. 13'-COOHs including δ TE-13'-COOH are shown to be agonist of PXR with EC50s of 1.5–3.3 μ M and mice treated with δ TE-13'-COOH had increased expression of PXR, *CYP3A4* and multidrug resistance protein (MDR1) [150]. These observations indicate that TEs, α T and 13'-COOHs are capable of modulating drug metabolism via interacting with PXR, suggesting their potential impacts on drug metabolism. Therefore, activation of PXR and regulated drug-metabolizing enzymes should be considered when combinatory drugs are developed. In addition, given that PXR may play context specific roles in PCa, interacting with PXR and its regulated genes may be a mechanism underlying modulatory effects of vitamin E forms on PCa.

The Effects of γ T-Rich Tocopherols on PCa and TEs on Other Types of Cancer in Human Clinical Studies

Although existing preclinical evidence supports that non- α T vitamin E forms are promising for PCa prevention, there is only 1 publication so far documenting supplementation of γ T-rich mixed tocopherols in patients with PCa in a phase 0 trial (NCT00895115). Specifically, 59 men diagnosed with localized PCa were randomized to receive no supplementation or daily supplements of γ TmT (containing α T, γ T, and δ T at 128, 200, and 71 mg twice a day, respectively) for 1 wk, or the supplements for 2 wk, before undergoing radical prostatectomy. Upon completing the study, Goodin et al. [23] reported that although there were no significant changes of tocopherols in the fasting plasma, patients taking γ TmT supplements had significantly increased γ T and δ T in the prostate tissue after 2 wk of supplementation. Meanwhile, supplementation of γ TmT resulted in elevation of γ -CEHC, δ -CEHC, and 5'-COOHs in the plasma and prostate as well as urine [23]. In addition to these bioavailability results, supplementation of γ TmT was found to be safe and resulted in a nonsignificant decrease of PSA [23].

Despite scarcity of human studies on PCa, the use of TEs and δ TE as adjuvants for chemotherapies have been tested in several

intervention trials for treating pancreatic, breast, colorectal, and cervical cancers. Specifically, in a double-blinded controlled clinical trial, a combination of TE-rich fraction and tamoxifen did not significantly improve breast cancer specific survival rate compared with tamoxifen-placebo controls [151]. Similarly, Kjaer et al. [152] reported that δ TE at 300 mg thrice a day did not enhance the efficacy of neoadjuvant breast cancer treatment or reduce the frequency of side effects in a phase II trial involving 80 patients with newly diagnosed breast cancer (NCT02909751). On the contrary, δ TE at daily 400–1600 mg induced apoptosis in dysplastic or malignant pancreatic tissues in a phase I trial including 25 patients for curative surgical resection with presumptive premalignant or malignant neoplasms of exocrine pancreas (NCT00985777) [25]. In a randomized, double-blind, placebo-controlled phase II study, the use of δ TE (300 mg thrice a day) as an adjuvant for FOLFOXIRI (5-fluorouracil, oxaliplatin, and irinotecan) was assessed in patients with metastatic colorectal cancer. It was concluded that δ TE treatment, although did not improve efficacy of FOLFOXIRI, resulted in dose reduction of oxaliplatin, suggesting a possible neuroprotective effect of δ TE [153]. Interestingly, in a phase II trial including 23 patients diagnosed with stage III platinum-resistant ovarian cancer (NCT02399592), treatment with δ TE (300 mg thrice daily) and bevacizumab resulted in 70% disease control [154], which appears to be better than bevacizumab alone [155]. Together, these studies suggest that potential use of δ TE as adjuvant therapies for improving treatment outcomes should be further explored for treating ovarian and pancreatic cancers.

Conclusions and Future Directions

From 1980s to early 2010s, research of vitamin E intervention against PCa was focused on α T. The ATBC trial reported that modest α T supplement (50 mg) decreased PCa death among heavy smokers. This observation encouraged subsequent RCTs including the SELECT, which, however, observed that α T at ≥ 400 IU show no beneficial effects or even increased risk of early-stage PCa incidence among nonsmokers. Interestingly, animal and cell-based studies also failed to show beneficial effects of high doses of α T on PCa. In another word, the lack of PCa-preventive effects of high-dose α T supplement in preclinical studies is in agreement with no beneficial effects observed in RCTs. Therefore, preclinical and clinical data indicate that α T at relatively high doses will not likely prevent early-stage PCa development in nonsmokers but may exert adverse effects via induction of drug-metabolizing enzymes and even pro-oxidant effects. As to moderate supplementation of α T, it is encouraging that α T at 50 mg decreased PCa-associated death in heavy smokers in the ATBC trail, but this beneficial effect should be further assessed. This is because PCa was a secondary end point and there was no pretrial screening of PSA or DRE in the ATBC trial, and therefore, the observed beneficial effects of α T may be accidental. Nevertheless, given that smoking is still relatively prevalent, potential benefit of α T to prevention of clinical PCa among smokers is relevant to public health and deserves further investigation. It is this author's opinion that preclinical research in animal models should be conducted to test the idea that modest α T supplement may prevent PCa under high oxidative

stress conditions such as smoking. On confirmation with relevant preclinical work, the effects of α T on PCa should be further assessed in a RCT where the effect of α T at modest doses (50–100 mg) on clinical PCa (as the primary end point) should be examined among smokers.

Starting from 2002, traditionally ignored vitamin E forms have been researched on their ability to modulate PCa, including γ T, δ T, and TEs (mainly γ TE and δ TE) in preclinical cell and animal studies. In particular, these vitamin E forms show much stronger anti-PCa effects than α T in cell studies, with relative potency concerning antiproliferation and proapoptosis of δ TE, γ TE > δ T > γ T >> α T. Further, γ T, γ TmT, and δ T have been found to be effective for inhibiting relatively early-stage PCa, as indicated in carcinogens-induced and genetically engineered PCa models, whereas display modest effects against late-stage cancer as indicated in PCa cell-implanted xenograft models. Meanwhile, γ TE and δ TE are shown to strongly inhibit development of prostate adenocarcinoma in genetically engineered spontaneously tumor-developing models. For this effect, δ TE appears to be stronger than δ T, the latter being more effective than γ T. Additionally, amber evidence also suggests that γ TE can block implanted PCa cells associated tumor development in xenograft models and is stronger than γ T for this effect. γ TE can also enhance anti-PCa effects of chemotherapeutic drugs in mice. Overall, these anti-PCa effects of γ T, δ TE, γ TE, and δ TE observed in preclinical studies provide evidence supporting the notion that these compounds may be useful for preventing early-stage PCa progression in people at moderate-risk and high-risk of PCa. Considering their good safety, these compounds should be considered in RCT trials for secondary and tertiary (especially γ TE and δ TE) chemoprevention.

Despite promising data supporting chemopreventive and even therapeutic effects of γ T, δ T, γ TE, and δ TE against PCa in preclinical research, future research is needed to further assess their anti-PCa efficacy and elucidate underlying mechanisms. First, among different forms of vitamin E, δ TE appears to show the strongest antiproliferative effect against advanced PCa cells, but there is lack of documentation of the impact of δ TE on PCa tumor development in xenograft models. This is a significant gap because such evidence is essential for recommending the use of δ TE for inhibiting relatively late-stage PCa including CRPC in RCTs. Therefore, the effectiveness of δ TE for blocking PCa progression or recurrence should be assessed in PCa-implanted models including patient-derived xenograft models. Second, potential use of γ TE or δ TE as an adjuvant for improving therapeutic outcomes and possibly offering neuroprotection of chemotherapy or radiation therapy are supported by preclinical research [58,87–90] and some encouraging observations of δ TE as an adjuvant therapy for ovarian and colorectal cancers in RCTs [153,154]. Therefore, the anticancer efficacy of δ TE in combinations with therapeutic agents should also be tested using PCa cell-implanted and patient-derived xenograft models. Third, the gut microbiota have been shown to contribute to endocrine resistance in CRPC by providing an alternative source of androgens [156]. Interestingly, γ T and δ TE/ γ TE as well as δ TE-13'-COOH have been reported to cause favorable changes of gut microbiome in cancer models [157,158] or under proinflammatory conditions [34,159]. In particular, δ TE/ γ TE (8:1) has been found to significantly increase [*Eubacterium*] *coprostanoligenes* and *Parabacteroides goldsteinii* CL02T12C30, which

are known to be involved in the metabolism of cholesterol, the precursor of androgen [158]. It is therefore of importance to assessing potential modulation of gut microbes by these vitamin E forms in PCa models and evaluating the role of modulating gut microbiome in anti-PCa by different vitamin E forms. Finally, γ T, δ T, γ TE, and δ TE are readily metabolized in vivo. Although anticancer effects of their metabolites including CEHCs and 13'-COOHs have been observed in cell-based studies, potential impacts of 13'-COOH on PCa cells have not been assessed [26,68,160]. Therefore, the effects of 13'-COOHs on the growth of PCa cells should be evaluated in vitro and in vivo, and such research will offer mechanistic insights into the role of metabolites in anti-PCa effects by precursor vitamin E forms.
