microRNA associated with hepatocyte injury and systemic inflammation may predict adverse outcomes in cirrhotic patients

As the global prevalence of chronic liver disease continues to rise, the need to determine which patients will develop end-stage liver disease and require liver transplantation is increasingly important. However, current prognostic models perform sub-optimally. We aim to determine microRNA profiles associated with clinical decompensation and mortality/transplantation within 1 year. We examined microRNA expression profiles in plasma samples from patients across the spectrum of cirrhosis (n = 154), acute liver failure (ALF) (n = 22), sepsis (n = 20) and healthy controls (HC) (n = 20). We demonstrated that a microRNA-based model (miR-24 and -27a) associated with systemic inflammation differentiated decompensated cirrhosis states from compensated cirrhosis and HC (AUC 0.77 (95% CI 0.69–0.85)). 6 patients within the compensated cirrhosis group decompensated the subsequent year and their exclusion improved model performance (AUC 0.81 (95% CI 0.71-0.89)). miR-191 (associated with liver injury) predicted risk of mortality across the cohort when acutely decompensated and acute-on-chronic-liver failure patients were included. When they were excluded miR-24 (associated with systemic inflammation) predicted risk of mortality. Our findings demonstrate that microRNA associated with systemic inflammation and liver injury predict adverse outcomes in cirrhosis. miR-24 and -191 require further investigation as prognostic biomarkers and therapeutic targets for patients with liver disease.

Morbidity and mortality from chronic liver disease (CLD) has become an international health crisis. CLD significantly impacts people of working age with alcohol-related liver disease (ARLD) the predominant etiology of patients who develop decompensated cirrhosis within Europe^{1,2}. The transition through the development of cirrhosis to clinically significant portal hypertension and subsequent decompensation is associated with increased morbidity and mortality³. The PREDICT study demonstrated that following acute decompensation (AD), patients followed three distinct clinical pathways, including the development of acute-on-chronic liver failure (ACLF), with each pathway having a significantly different risk of mortality⁴. Whilst there are effective treatments for specific etiologies of liver disease, the only effective treatment for end-stage cirrhosis remains liver transplantation (LT). Accurate prediction of progression through this pathway to poor prognostic outcomes remains elusive.

There has been extensive work undertaken to determine novel biomarkers which predict which patients with cirrhosis are at risk of clinical decompensation. However, to this point, none have outperformed well-established models which include standard clinical and laboratory data and perform most optimally over longer-term follow-up^{5,6}. Following decompensation, conventional prognostic models focus on clinical and biochemical markers of liver failure to predict mortality^{7–9}. With the development of classifications for ACLF and AD, novel models

Tavabie, Vishal C. Patel and Siamak Salehi. ^{See}email: varuna.aluvihare@kcl.ac.uk

which integrate conventional markers of liver and non-liver organ failure, inflammation and patient age have been established which improve prognostication within these specific subgroups of cirrhosis^{10,11}. However, these prognostic models again perform optimally later in the patient's clinical course, limiting their clinical value. There is a need for novel biomarkers that predict decompensation and mortality in patients with cirrhosis earlier in their clinical course.

MicroRNA (miRNA) have long been heralded as potential biomarkers across a range of clinical conditions including CLD¹²⁻¹⁶. However, there has been limited translation into routine clinical practice. This likely reflects a lack of standardized methodology in quantifying miRNA expression as well as the complex pathways that govern miRNA expression. We have previously demonstrated that miRNA expression is time dependent in acute liver failure (ALF)¹⁷. A previous study exploring miRNA expression in patients with cirrhosis following an acute decompensation event showed that grouping patients with similar characteristics likely improves miRNA performance as prognostic biomarkers¹². A standardized methodological approach examining miRNA expression in carefully defined cohorts at set time points may potentially improve the performance of miRNA as clinically tractable biomarkers.

We have previously described a distinct hepatic miRNA signature associated with successful native liver regeneration following auxiliary LT (ALT)¹⁸. This miRNA signature is present in the circulation of patients who recover from ALF and cirrhotic patients who clinically recompensate following direct-acting antiviral therapy (DAA) for hepatitis C (HCV)¹⁹. We have integrated this regeneration-linked miRNA signature within a prognostic model for ALF which outperformed conventional models as opposed to microRNA associated with cell-death and response to cellular injury which did not¹⁷. We hypothesized that circulating miRNA may have utility in predicting clinical decompensated cirrhosis states and those at risk of clinical decompensation. In addition, we investigated whether these miRNA have the potential to be developed as biomarkers to predict 1 year risk of mortality/transplantation for patients with cirrhosis.

Results

Plasma miRNA expression across the spectrum of cirrhosis, ALF, sepsis and HC

Minimal hemolysis was observed across samples (8/216) and there was a stable expression of quality control markers for RNA isolation, RT and PCR efficiency (Supplementary Figs. 1, 2). No samples were excluded from further analysis. All samples expressed the normalizing miRNA (miR-23a, -26a and -103) therefore all samples were included in the study.

Across clinical groups, 18 miRNA were expressed in greater than a third of samples and these were used to perform two-way unsupervised hierarchical clustering (Fig. 1). Whilst the ALF and sepsis clinical cohorts clustered based on miRNA expression, the cirrhosis groups (ACLF/AD/cCLD/dCLD) and HCs did not.

miRNA expression profiles of patients with acute presentations of liver disease and sepsis

Clinical, demographic and laboratory data from patients within ACLF, AD, ALF and sepsis cohorts are shown in Supplementary Table 3. There were several differences between groups; namely patient age (ALF patients youngest and sepsis patients oldest), laboratory biomarkers of infection and antibiotic use (highest in sepsis group although notably 19/20 of the ACLF cohort (11.76% positive bacterial cultures within 72 h) and 15/20 of the AD cohort (5.56% positive bacterial cultures within 72 h) were being treated for infection), biomarkers of liver injury/failure and MELD score (highest in the ALF group) and need for organ support (lowest in the AD group).

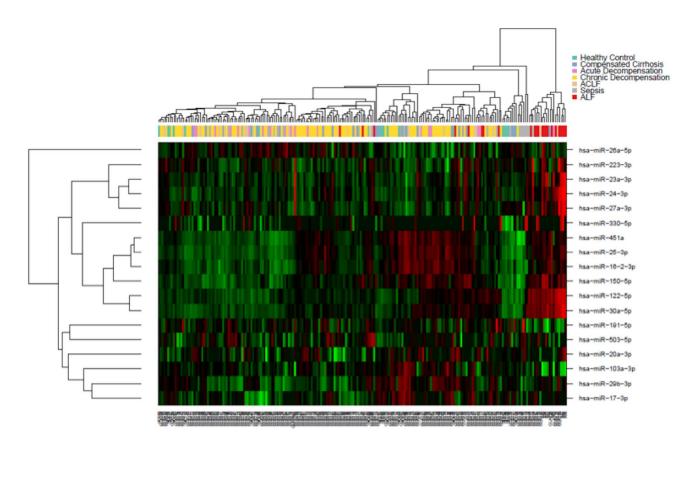

There was significant variation in the expression of the following miRNA; miR-122, -150, -16-2, -191, -24, -25, -26a, -30a and -451a (Supplementary Table 4A). Following conversion of less prevalently expressed miRNA into categorical variables, miR-503 expression was demonstrated to vary significantly across clinical groups (Supplementary Table 4B).

Principle component analysis was utilized to identify clustering of prevalently expressed miRNA to understand expression profiles in AD and ACLF states compared with ALF and sepsis states (Fig. 2). Patients with ALF and sepsis had distinct, divergent expression profiles. Patients with ACLF associated more with the sepsis cohort rather than ALF based on miRNA expression.

miRNA expression profiles of patients across the cirrhosis spectrum

Comparisons of clinical, demographic and laboratory data from patients with ACLF, AD, cCLD, dCLD and HC are shown in Supplementary Table 5. HC individuals were younger than patients within the cirrhosis groups. Active alcohol consumption was highest amongst patients with acute presentations of cirrhosis (ACLF/AD). Markers of systemic inflammation and infection (white cell counts (WCC) and CRP), hepatic synthetic failure (bilirubin, INR, ascites and ammonia), hepatic inflammation (aspartate aminotransferase (AST)) and renal impairment (creatinine) were highest in the ACLF cohort.

Significant variations in expression across patient groups were demonstrated across a number of miRNA. Notably, acute presentations of cirrhosis had opposing expression profiles to the HC and cCLD cohorts, with the most significant being for miR-122, -24 and -30a (Supplementary Table 6A and Supplementary Fig. 3). However, there were opposing expression profiles of certain miRNA across the decompensated CLD groups including; miR-223 (dCLD and ACLF), -23a (dCLD and ACLF/AD), -26a (ACLF and AD) and -103a (AD and ACLF/dCLD) (Supplementary Table 6A and Supplementary Fig. 3). There was significant variation in the detection of miR-503 across the cohorts with the lowest rate of detection in the AD cohort (Supplementary Table 6B).

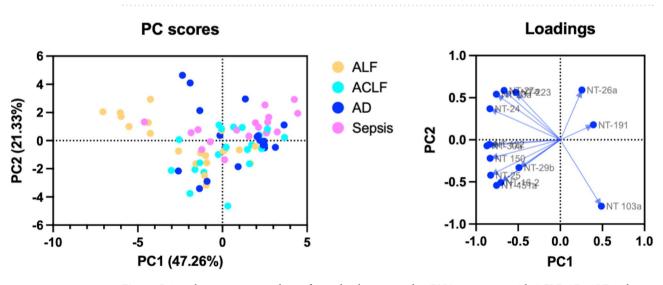

Fig. 1. Heatmap and 2-way hierarchical clustering of miRNA expression across all patient groups. Clustering was performed on all samples including all miRNA expressed in more than a third of samples.

Determining miRNA associated with decompensated CLD states

Decompensated CLD states (ACLF/AD/dCLD) were grouped together and miRNA expression profiles were compared to cCLD/HC cohort (Table 1A + B). Significant differences in miRNA expression between groups were observed for miR-122, -223, -24, -27a, -29b, -30a, -330 and -663. The best performing prevalently expressed miRNA at discriminating patients with decompensated CLD states from those without was miR-27a (AUC 0.67 (95% CI 0.58–0.76)). Conversion of miRNA into categorical variables did not identify further miRNA which discriminated between patient with decompensated states and those without.

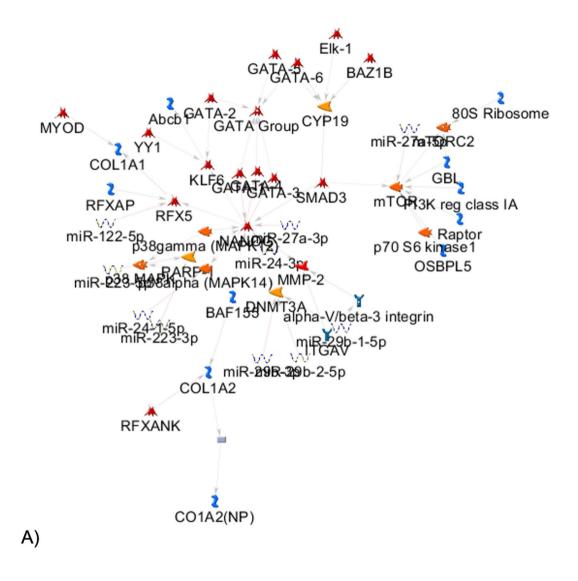

MetaCore[™] pathway analysis was utilized to identify biological pathways regulated by the miRNA which discriminated patients with decompensated CLD states from those without (miR-122, -223, -24, -27a, -29b and -30a). This demonstrated that these miRNA regulate the response to endogenous stimuli, nucleic acid transcription, RNA and macromolecule biosynthesis (Fig. 3), which are key processes in the response to systemic inflammation. Within the network were genes implicated with progression of liver fibrosis/cirrhosis (*MMP-2, GATA* family, *COL1*²⁰⁻²²). *NANOG*, a gene with key roles in promoting stem cell pluripotency and suppressing apoptosis²³⁻²⁵, was central to the network and upregulated.

A Spearman's correlation matrix was utilized to further understand relationships between miRNA and clinical, laboratory and prognostic model data across the cirrhosis cohorts (Fig. 4) with the aim to investigate the

relationship between these miRNA and systemic inflammation. Significant correlations with CP and MELD scores were seen with miR-23a ($r_s = 0.21$ (95% CI 0.05–0.36), $p = 0.01^*$), -24 ($r_s = 0.25$ (95% CI 0.09–0.40), $p = 0.002^*$) and -26a ($r_s = -0.19$ (95% CI -0.34 to -0.02), $p = 0.02^*$). miR-24 was also demonstrated to significantly correlate with markers of inflammation (CRP, $r_s = 0.18$ (95% CI 0.01–0.33), $p = 0.03^*$), portal hypertension (ascites grade, $r_s = 0.23$ (95% CI 0.07–0.38), $p = 0.004^*$) and liver failure (bilirubin ($r_s = 0.19$ (95% CI 0.03–0.35), $p = 0.02^*$), INR ($r_s = 0.20$ (95% CI 0.04–0.35), $p = 0.004^*$) and liver failure (bilirubin ($r_s = 0.19$ (95% CI 0.03–0.35), $p = 0.02^*$) and lactate ($r_s = 0.23$ (95% CI 0.05–0.39), $p = 0.008^*$)). miR-26a demonstrated significant correlations with markers of portal hypertension (platelet count ($r_s = 0.27$ (95% CI 0.11–0.41), $p = 0.001^*$) and HE ($r_s = -0.23$ (95% CI -0.38 to -0.07), $p = 0.004^*$) and inflammation (lymphocyte count ($r_s = 0.19$ (95% CI 0.03–0.34), $p = 0.02^*$)). miR-23a demonstrated significant correlation with CRP ($r_s = 0.20$ (95% CI 0.04–0.36), $p = 0.01^*$). miR-30a demonstrated significant correlations with CP score ($r_s = 0.17$ (95% CI 0.01–0.33), $p = 0.04^*$), inflammation (lymphocyte count ($r_s = -0.21$ (95% CI -0.36 to -0.05), $p = 0.009^*$)) and markers of portal hypertension (platelet count ($r_s = -0.40$ (95% CI -0.53 to -0.26), $p < 0.0001^*$) and ammonia ($r_s = 0.20$ (95% CI 0.02–0.37), $p = 0.02^*$). miR-191 demonstrated significant correlation with markers of inflammation (CRP ($r_s = 0.23$ (95% CI 0.07–0.38), $p = 0.005^*$, lymphocyte ($r_s = -0.22$ (95% CI -0.37 to -0.05), $p = 0.008^*$) and liver failure (lactate ($r_s = 0.22$ (95%

CI 0.04–0.38), $p = 0.01^*$, ammonia ($r_s = -0.21$ (95% CI – 0.37 to – 0.03), $p = 0.02^*$, and ascites grade (rs = 0.19 (95% 0.01–0.33 CI), $p = 0.03^*$).

Multiple logistic regression was utilized to generate a microRNA-based model to discriminate patients with decompensated cirrhosis states from those without (Table 1C, Fig. 5A). This included miR-24 and -27a and generated an AUC of 0.77 (95%CI 0.69–0.85, $p < 0.0001^*$). Given the heterogeneity of the cohorts, sensitivity analyses were performed to ensure that performance was maintained across patient groups. Excluding acute (ACLF/AD; AUC 0.78 (95% CI 0.69–0.86)) and chronic (dCLD; AUC 0.76 (95% CI 0.65–0.86) decompensation patient groups did not impact on model performance (Fig. 5B + C). However, excluding the HC cohort did reduce the model performance (AUC 0.69 (95% CI 0.56–0.81) (Fig. 5D). Further interrogation of the cCLD cohort led to the discovery that 6 patients decompensated within the subsequent year (3 patients with new HE and 3 patients with new ascites) (Table 2). Exclusion of these patients with HC individuals improved sensitivity analysis (AUC 0.74 (95% CI 0.60–0.88)) (Fig. 5E). Excluding these patients from the entire cohort improved overall model performance (AUC 0.81 (95% CI 0.73–0.89)) (Fig. 5F).

Evaluating performance of miRNA in predicting 1 year risk of mortality and/or transplantation in patients with cirrhosis

Across the entire cirrhotic cohort (ACLF/AD/cCLD/dCLD), 46 patients underwent LT (ACLF = 1/20, AD = 1/20. cCLD = 2/20, dCLD = 42/94) and 28 patients died (ACLF = 10/20, AD = 4/20, cCLD = 0/20. dCLD = 14/94) within 1 year of sampling. When mortality and LT were used as a composite end-point, only miR-330 discriminated clinical outcomes and did not remain significant when adjusted for both MELD and CP scores (Table 3A + B). Competing risk analysis was then performed to look for associations of microRNA expression with LT. No microRNA was able to discriminate outcome in this cohort (Table 3C). Performance of MELD and CP scores to discriminate patients who underwent LT was also poor (Supplementary Table 7).

Competing risk analysis was then used to look for associations of microRNA expression and patient mortality (Table 4). On univariable analyses, miR-150 (SHR 1.04 (95% CI 1.00–1.08)) miR-191 (SHR 1.52 (95% CI 1.12–2.05), miR-24 (SHR 1.20 (95% CI 1.08–1.35)) and miR 26a (SHR 0.79 (95% CI 0.63–0.99)) predicted 1 year risk of mortality (Table 4A). On multivariable analyses, only miR-191 remained significant when adjusted for MELD (aSHR 1.85 (95% CI 1.32–2.60)) and CP scores (SHR 1.63 (95% CI 1.19–2.24)) (Table 4B + C). The analysis was then repeated in patients with a diagnosis of ARLD, patients with ascites and the dCLD cohort alone. miR-191 was the only microRNA to predict 1 year mortality which remained significant when adjusted for both MELD and CP scores in the ARLD and ascites cohort (Table 4D + E). However, in the dCLD cohort, miR-191 did not predict risk of mortality at 1 year on univariable analyses. miR-24 did predict risk of mortality at 1 year for patients with dCLD and remained significant when adjusted for MELD (aSHR 1.40 (95% CI 1.04–1.90) and CP scores (aSHR 1.36 (95% CI 1.01–1.82)) (Table 4D + E).

Discussion

To our knowledge, this is the largest study of miRNA expression across the full clinical spectrum of liver failure syndromes. We have demonstrated that miRNA associated with systemic inflammation are more prevalently expressed in patients with decompensated cirrhosis states compared to compensated cirrhosis and HC individuals. These microRNA may be present in patients with compensated cirrhosis prior to clinical decompensation and may predict risk of mortality in dCLD patients. We also demonstrate that miR-191 expression predicts risk of mortality within 1 year across the spectrum of cirrhosis when patients with ACLF and AD are included but does not when they are removed.

We have previously demonstrated the prognostic utility of miR-191 in ALF¹⁷. Whilst we generated a regeneration-linked microRNA model at the early time point and a cell-death related microRNA model at the late time point, it was notable that both miR-191 and -149 were included in both models. We previously have performed MetaCore[™] pathway analysis to understand the processes that miR-191 and -149 were implicated in. This demonstrated that they were associated with responses to cellular injury. In this study we demonstrate that miR-191 correlates with markers of inflammation and liver failure. The association it has with inflammation has been demonstrated in other settings such as ulcerative colitis²⁶. However, the ability of miR-191 to identify patients with liver disease was demonstrated in patients with alcohol use disorders where elevated levels differentiated patients with cirrhosis from those without²⁷). It was notable that within our analysis that miR-191 did not differentiate between decompensated states and compensated/HC and that it was not able to predict risk of mortality at 1 year in the dCLD cohort on its own. We would hypothesize that miR-191 represents an acute marker of hepatocyte injury which is implicated in risk of mortality in acute presentations of liver disease (ACLF, AD and ALF). Further exploration is required to validate these findings and explore the role of it as a therapeutic target in these clinical scenarios.

Systemic inflammation is believed to be the major driver of progression from compensated to decompensated cirrhosis^{28,29}. Here we show that there is a common, shared miRNA signature that defines decompensated cirrhosis states which is associated with critical epigenetic responses to systemic inflammation. Furthermore, we demonstrate that these miRNA correlate with conventional clinical and laboratory surrogate markers of systemic inflammation, portal hypertension and hepatic synthetic failure. A model containing miR-24 and -27a from this system inflammation signature discriminated between decompensated and compensated states. Both of these miRNAs have been demonstrated to have key roles in the regulation of macrophage and monocyte activation which supports this model being associated with systemic inflammation^{30–32}. Sensitivity analyses of the miRNA model discriminating between decompensated and compensated minimal change in model performance when excluding patients dCLD patients or ACLF/AD patients, indicating that the miRNA within this model may reflect systemic inflammation related to underlying liver disease. This is supported by our

Table 2. Clinical characteristics of the 6 cCLD patients who decompensated the year after sampling.

systemic inflammation network including genes (*MMP-2, GATA* family, *COL1*) implicated in the progression of liver fibrosis/cirrhosis. However, excluding patients with cCLD who subsequently decompensate improves overall model performance. Furthermore, a subgroup analysis including only patients from the dCLD cohort demonstrated that miR-24 predicted 1 year risk of mortality and remained significant when adjusted for both MELD and CP score. These results would support the hypothesis that the onset of systemic inflammation may predate clinical decompensation and worsening systemic inflammation is associated with increased risk of adverse clinical outcomes in chronically decompensated patients. There are evolving data which suggest that carvedilol and rifaximin may have protective roles in the prevention of decompensation and mortality in cirrhosis³³⁻³⁶. There has also recently been characterization of 'non-acute' decompensation which is a progressive disorder without acute events associated with significant mortality³⁷. These data combined with our findings may suggest that there is a therapeutic window to prevent the progression of cirrhosis through a compensated state to decompensation and mortality. These miRNA therefore may not only represent potential novel prognostic biomarkers, but also potential therapeutic targets for patients with cirrhosis. Subject to validation, they may be useful tools in the preventing decompensation and mortality, which remain a significant area of unmet clinical need.

We have demonstrated that miRNA expression in ACLF shares more similarity to sepsis than ALF. The importance of bacterial infection has been well described in ACLF and 95% of the ACLF cohort were being treated for infection (although only 11.76% of patients had positive cultures for bacterial infection)³⁸. We have previously demonstrated the importance of regeneration-linked miRNA in determining outcome in ALF¹⁷⁻¹⁹. The difference in miRNA expression profile demonstrated in this study between patients with ACLF and patients with ALF implies reduced prognostic utility of regeneration-linked miRNA in cirrhosis compared to ALF. However, reversal of the underlying disease process that led to decompensation is likely to be relevant prior to recovery of underlying liver function and clinical recompensation. We have previously demonstrated that following DAA therapy for HCV, clinical recompensation is predicted by regeneration-linked miRNA¹⁹. Interleukin-22Fc therapy has also been demonstrated to ameliorate bacterial infection and subsequently upregulate regenerative pathways in an ACLF animal model³⁹. Here, we have demonstrated that the detection of miR-150, which was previously utilized within our regeneration-linked ALF prognostic model¹⁷, is associated with 1 year risk of mortality but does not remain significant when adjusted for MELD or CP score. We also demonstrate that NANOG, a gene with a key role in processes which govern successful regeneration²³⁻²⁵, is upregulated and central within our systemic inflammation network. It remains unclear whether liver regeneration plays a significant role in determining clinical outcomes in all cirrhosis patients following control of the underlying cause of decompensation.

It is notable that the inclusion of patients undergoing LT within 1 year significantly impacted the analysis of the results with 1 year mortality/LT as a composite endpoint. LT in the UK is offered to patients with cirrhosis with a greater than 10% risk of liver related mortality at 1 year which is assessed by the United Kingdom model for End-stage Liver Disease (UKELD score)⁴⁰. As such, whilst patients listed for LT have a higher risk of mortality, this does not mean there is an absolute correlation with the patient cohort that dies within 1 year. This is likely reflected by the suboptimal performance of MELD and CP scores in predicting LT within 1 year in our cohort. As such, competing risk analysis is required to evaluate the impact of this if used as a composite endpoint.

The limitations of this study include the retrospective design. However, samples and data were collected prospectively and investigators were blinded to outcome data when performing miRNA analysis. This study was performed in a single high-volume LT center in a large city in the United Kingdom and outcome, disease

Table 3. One year risk of mortality/LT and competing risk analysis for 1 year risk of LT. (A) One year risk ofmortality/LT and association with microRNA expression. For microRNA with significant HR, C-statistic is calculated.(B) D/ND miR-330 adjusted for MELD (MELD score performance n = 151, C-statistic = 0.69 (95% CI 0.63-0.75)) andCP (CP score performance n = 151, C-statistic = 0.69 (95% CI 0.63-0.75)). (C) Competing risk analysis for 1 year riskof LT. D/ND=microRNA converted into categorical variable and marked as detected = 1 or not detected = 0.

etiology and severity data likely reflects this. Future multicentered prospective work should be conducted at specialist and non-specialist hepatology centers across a broad geographical area. Formal mechanistic work is required to investigate the role of these miRNA in; the development of liver cirrhosis and portal hypertension, response to pharmacotherapy in cirrhosis, and to understand if modulation of miRNA expression can impact on patient clinical trajectory through different cirrhosis states. This may allow for the development of miRNA-based therapeutics to manage cirrhosis. Finally, the findings described in this study require validation in an external cohort. An adequately powered prospective study, with sufficient longitudinal follow up to allow for detailed time-to-event analyses as well as multiple sampling time points, is also required to evaluate the performance of these miRNA in predicting clinical decompensation amongst patients with cCLD. Understanding the relationship these microRNA have with the development of infection is essential and conventional tests may not adequately detect infection in cirrhotic patients. The field of molecular diagnostics for infection is rapidly evolving and these novel technologies could be utilized to better understand this association⁴¹ However, this remains a large-scale translational study which included patients from across the spectrum of cirrhosis as well as a septic non-CLD, ALF and HC cohorts. The miRNA panel utilized was based on our previous study in dCLD¹⁹ and we ensured quality control for each step of miRNA analysis. Therefore, our findings are robust and warrant further investigation.

In conclusion, we identify a common miRNA signature associated with systemic inflammation which discriminates patients with decompensated cirrhosis from those without. This signature may have utility in identifying patients with compensated cirrhosis at the highest risk of clinical decompensation as well as predicting mortality in patients with non-acute decompensation. We demonstrated that miR-191 predicts mortality across the cirrhotic cohort when patients with AD and ACLF are included but not when they are excluded. miR-191 was previously included in both our cell-death and regeneration linked prognostic models in ALF and is associated with hepatocyte injury. This may suggest that miR-191 represents a prognostic biomarker associated with poor clinical outcomes across acute presentations of liver disease. Biomarkers associated with systemic inflammation and hepatocyte injury may improve prognostication of patients with cirrhosis.

Materials and methods Study design

This study was designed as a cohort study of prospectively collected data and biological samples from patients enrolled in the 'Gut-liver axis in liver disease and liver transplantation' (GLA) and 'Immunometabolism in sepsis, systemic inflammation and liver failure syndromes' (IMET) studies based at King's College Hospital (United Kingdom) between 2014 and 2021. Patients were categorized into the following clinical groups; ACLF, AD, decompensated cirrhosis (dCLD), compensated cirrhosis (cCLD), HC, ALF and sepsis (definitions/inclusion criteria in supplementary Table 1). Patients were excluded if; they were younger than 18 years old, if they had an underlying diagnosis of malignancy (liver or non-liver in origin), if they had previously undergone any organ transplantation, if they had an active viraemia secondary to hepatitis B or C, if they were taking immunosuppression or if they had been previously sampled. Patients with acute presentations (ACLF, AD, ALF and sepsis) were all sampled within 72 h of admission. Non-acute presentations (cCLD) and HC) were sampled in outpatient or in elective clinical settings prior to any elective clinical intervention.

Consecutively enrolled patients fulfilling inclusion and exclusion criteria from the GLA study were included as follows; 19 ACLF, 20 AD, 94 dCLD, 20 cCLD, 20 HC, 14 ALF and 20 sepsis patients. Patients from the IMET study were randomly selected to ensure that each clinical group had a minimum of 20 patients and included 1 ACLF and 8 ALF patients. Total patient number was 216 which included; 20 ACLF, 20 AD, 94 dCLD, 20 cCLD, 20 HC, 22 ALF and 20 sepsis patients. Patients were further grouped by; decompensated states (ACLF, AD and dCLD, n = 134) and compensated/healthy states (cCLD and HC, n = 40). One year mortality/LT was used as a composite endpoint for patients with cirrhosis (ACLF, AD, cCLD and dCLD) with competing risk analysis subsequently performed to understand associations with LT and death separately. Sensitivity analysis was performed for patients with cirrhosis 1 year risk of mortality for; patients with dCLD, patients with alcohol related liver disease (ARLD) and patients with ascites.

This study was approved by the London East Ethics Committee ethics committee (12/LO/1417 and 19/ NW/0750) and the King's College Hospital Research and Innovation Committee, and has been conducted according to the principles expressed in the 1975 Declaration of Helsinki. Patients provided written informed consent; if patients were unable to provide informed consent due to incapacity, written informed assent was provided by the patients next of kin. Reporting of the analysis of this study complies to the STROBE Guidelines for reporting of cohort studies⁴². All authors had access to the study data and reviewed and approved the final manuscript.

Clinical data

Demographic, clinical and laboratory data were recorded prospectively simultaneous to blood sampling as part of enrolment to GLA and IMET studies. Data assessed in this study include; laboratory (full blood count, c-reactive protein (CRP), electrolytes, creatinine, liver function tests, albumin, INR, ammonia, lactate and arterial pH), ascites grade (as per Child–Pugh (CP) score^{7,8}), hepatic encephalopathy (HE) grade (as per West Haven criteria⁴³) and requirement for organ support (mechanical ventilation, vasopressors and renal replacement therapy). Infection was characterized by treatment with antibiotics and a positive culture within 72 h of sampling. Prognostic scores including CP score^{7,8} and MELD score⁹ were calculated from these data.

miRNA analysis

RNA extraction

Plasma samples were thawed on ice and centrifuged at $3000 \times g$ for 5 min in a 4 °C microcentrifuge. An aliquot of 200μ L per sample was transferred to a FluidX tube and 60μ L of lysis solution biofluids containing 1μ g

Table 4. Evaluation of microRNA performance in predicting 1 year risk of mortality. (A) Competing risk analysis for 1 year risk of mortality. (B) MELD adjustment of prevalently expressed microRNA which discriminated 1 year risk of mortality. Performance of MELD adjusted miR-191; n = 148, Wald Chi² = 26.31, $p < 0.001^*$. (C) CP adjustment of prevalently expressed microRNA which discriminated 1 year risk of mortality. Performance of CP adjusted miR-191; n = 148, Wald Chi² = 53.69, $p < 0.001^*$. (D) microRNA which discriminated outcome on sensitivity analyses and remained significant following adjustment for MELD. (E) microRNA which discriminated outcome on sensitivity analyses and remained significant following adjustment for OP. D/ND = microRNA converted into categorical variable and marked as detected = 1 or not detected = 0. See Supplementary Tables 8–10 for model performance.

carrier-RNA and RNA spike-in temperature mixture were added. Each sample was then mixed for 1 min and incubated for 7 min at room temperature. Following this, 20μ L of protein precipitation solution biofluids were added to each sample. Total RNA was extracted from plasma using the miRCURY[™] RNA isolation kit—biofluids (QIAGEN, Hilden, Germany) using according to the manufacturer's protocol (high-throughput bead based protocol v.1) into an automated 96 well format⁴⁴. The purified total RNA was eluted to a final volume of 50µL.

miRNA real-time quantitative PCR

20µL of RNA was reverse transcribed using the miRCURY[™] LNA RT kit (QIAGEN, Hilden Germany). Complementary DNA (cDNA) was diluted 50× and assayed in 10µL polymerase-chain reactions (PCR) according to the manufacturer's protocol⁴⁴. 21 miRNAs were selected for analysis based on our previous study findings^{17–19}, review of the literature for miRNA associated with outcome in CLD^{12,16} and to allow for normalization (see supplementary Table 2). Also included within this panel were; an RNA spike in (UniSp4) to ensure RNA isolation efficiency, a cDNA control marker (UniSp6) to assess reverse transcription (RT) and a DNA spike-in (UniSp3) to assess PCR efficiency. Each miRNA was assayed once by quantitative PCR (qPCR) on the miRNA Ready-to-Use PCR Custom Panel (Qiagen, Hilden Germany) using the miRCURY[™] LNA SYBR Green master mix. Negative controls excluding the template from the RT reaction were performed and profiled in comparison to the samples. Amplification was performed in a LightCycler* 480 Real-Time PCR System (Roche, Basel, Switzerland) in 384 well plates. Amplification curves were analyzed using the Roche LC software v 1.5 (www.lifescience.roche.com/ global/en/products/product-category/lightcycler.html, Roche, Basel, Switzerland), both for determination of quantification cycle (Cq) (by the second derivative method) and melting curve analysis.

Assessment of hemolysis

Two miRNAs were used to perform this: miRNA-451 which is expressed in red blood cells, and miRNA-23a which is relatively stable in serum and plasma but not affected by hemolysis⁴⁵. The ratio between these two miRNAs correlates with the degree of hemolysis. In our experience, samples with ratios above seven will have an increased risk of being affected by hemolysis. Samples with lower ratios are generally not affected by hemolysis. These values refer to human samples and may vary with species and diseases studied.

miRNA data analysis

The amplification efficiency was calculated using algorithms similar to the LinReg software. All assays were inspected for distinct melting curves the Tm was checked to be within known specifications for the assay. To be deemed as detected, assays must be three Cq less than the negative control and have a Cq less than 37. Assays were deemed to be not detected within a sample if these criteria were not met.

Normalized Cq (dCq) values were generated subtracting the Cq of the assay of interest from the mean of the Cq of the normalizing miRNA developed from our previous work (miR-23a, -26a, -103)¹⁷. A positive dCq reflects a more abundantly expressed miRNA whereas a negative dCq reflects a less abundantly expressed miRNA. Samples where any of the normalizing miRNA (miR-23a, -26a and -103) were not detected were excluded from further analysis.

Statistical analysis

Comparisons were made between; acute presentation clinical groups (ACLF/AD/ALF/sepsis), decompensated (ACLF/AD/dCLD) and compensated/healthy clinical states, and between cirrhosis 1 year survivors and 1 year mortality/LT (ACLD/AD/cCLD/dCLD). Continuous demographic, clinical and laboratory variables were analyzed for normality using the D'Agostino and Pearson tests. Normally distributed data were analyzed with *t* tests (2 groups) or ANOVA (3 + groups) with results reported as mean (standard deviation (SD)). Non-normally distributed data were analyzed using Mann Whitney U tests (2 groups) or Kruskall-Wallis test (3 + groups) with results reported as median (interquartile range (IQR)). Categorical data were analyzed by Fisher's exact tests (2 groups) or Chi-square test (3 + groups) and results reported as number (%).

Individual dCq values for each miRNA in each sample were utilized to demonstrate miRNA expression. These underwent a natural logarithmic (ln) transformation in a formula developed for this analysis to transform to a normal distribution. Given that dCq values were negative (demonstrating less abundant expression within a sample), 20 was added to the dCq value prior to ln transformation. 20 was chosen to ensure that no dCq values remained negative and all were greater than one. As the majority of dCq values were closer to the mean of the controls than 20 prior to the ln transformation leading to small differences being potentially significance, this value was subsequently multiplied by 100 to increase the standard deviation. Therefore the formula for transformation was $100 \times \ln(20 + dCq)$ of miRNA of interest).

Two-way unsupervised hierarchical clustering of miRNA expression of samples from across the entire study was performed. miRNA were excluded from this analysis if not present in greater than a third of samples. Spear-man's rank correlation was used to correlate miRNA data with clinical/laboratory variables. When comparing miRNA data in decompensated to compensated/healthy clinical states, receiver-operating characteristic curve analysis was performed if a *p* value < 0.05 was achieved. This was reported as area under the curve (AUC) (95% confidence interval (CI)). When understanding the association of microRNA with 1 year risk of mortality/LT, univariable Cox regression was utilized with a C-Statistic (95% CI) generated if a significant result was achieved. To increase the utility of less prevalently expressed miRNA, those detected in less than 85% of samples were treated as categorical variables (detected (D) = 1, non-detected (ND) = 0) and analyzed as described above.

Prevalently expressed miRNA (expressed in > 85% of samples) data were scaled and principle component analysis was used to evaluate expression across acute presentations (ACLF/AD/ALF/sepsis). Scaling of prevalently

expressed miRNA data (>85% of samples) was performed using the following equation prior to principle component analysis;

Scaled value = $\frac{\text{value} - \text{mean of variable}}{\text{variable standard deviation}}$.

Multiple logistic regression was used to develop miRNA-based models to predict decompensated cirrhosis clinical states. Multivariable Cox regression was utilized to understand the association of microRNA with 1 year mortality/LT following adjustment for liver disease severity as per CP and MELD score. Competing risk analysis was subsequently undertaken to specifically understand the risks of LT or death. miRNA were converted into categorical data if not present in more than 85% of samples. If a significant result was achieved with a microRNA expressed in less than 50% of samples, this was not included in multivariable analyses.

For the decompensated cirrhosis state model, variables with a *p* value of < 0.2 were included in each model at each time point and backwards elimination was performed. An r^2 threshold with other variables within the model was set at < 0.50 to reduce co-linearity. Goodness of fit was assessed using Hosmer Lemeshow (HL) test and pseudo r^2 values for multiple logistic regression analyses. Goodness of fit was assessed using log-likelihood ratios for multivariable Cox regression analyses. Results for multiple logistic regression analyses were recorded as adjusted odds ratios (aOR) with 95% CI and *p* value s. For Cox regression analyses, data were recorded as hazard ratio (HR) with 95% CI. Results from competing risk regression (based on Fine and Gray's proportional subhazards model) were presented as subhazard ratio (SHR) with 95% CI with Walds Chi² results. Sensitivity analyses were performed to assess performance of the decompensated cirrhosis model by simultaneously removing AD/ACLF, dCLD and HC patients. Sensitivity analyses were also performed to assess performance of microRNA in discriminating 1 year outcome in patients with ARLD, ascites and dCLD only. Complete case analysis was used, excluding individuals with missing data.

MetaCore^{∞} pathway analysis V6.29 (www.portal.genego.com, GeneGo Inc, Michigan, USA) was used to identify biological processes associated with miRNA associated with decompensated cirrhosis states. The Analyze Networks algorithm was used to demonstrate biological processes associated with miRNA signatures developed. This uses a library of greater than 24,000 human genes in networks to predict pathways likely to be associated with inputted data⁴⁶. The algorithm generates and ranks biological networks based on:- 1) the relative enrichment of the network with the uploaded data (miRNA) and 2) the relative saturation of these networks with canonical pathways. This generates a Z score based on the statistical likelihood that these processes are associated with the given data (the higher the Z score, the greater likelihood of relevance). Following this, results were excluded if they did not include all of the given miRNA of interest and the processes remaining with the highest Z score were reported.

Correction for multiple comparisons was performed using the Benjamini–Hochberg procedure with a false discovery rate (FDR) set at 0.10⁴⁷. Competing risk analysis was performed using Stata V17.0 (www.stata.com, StataCorp LLC, Texas, USA). All other analyses were performed using Prism V10.2.3 (www.graphpad.com/featu res, GraphPad, San Diego, USA).
