Loss-of-function mutations in *CLN3* cause juvenile Batten disease, featuring neurodegeneration and early-stage neuroinflammation. How loss of CLN3 function leads to early neuroinflammation is not yet understood. Here, we have comprehensively studied microglia from *Cln3*<sup>Δex7/8</sup> mice, a genetically accurate disease model. Loss of CLN3 function in microglia leads to lysosomal storage material accumulation and abnormal morphology of subcellular organelles. Moreover, pathological proteomic signatures are indicative of defects in lysosomal function and abnormal lipid metabolism. Consistent with these findings, CLN3-deficient microglia are unable to efficiently turnover myelin and metabolize the associated lipids, showing defects in lipid droplet formation and cholesterol accumulation. Accordingly, we also observe impaired myelin integrity in aged *Cln3*<sup>Δex7/8</sup> mouse brain. Autophagy inducers and cholesterol-lowering drugs correct the observed microglial phenotypes. Taken together, these data implicate a cell-autonomous defect in CLN3-deficient microglia that impacts their ability to support neuronal cell health, suggesting microglial targeted therapies should be considered for CLN3 disease.

The neuronal ceroid lipofuscinoses (NCLs) are a group of rare inherited lysosomal disorders with overlapping clinical and pathological features, including seizures, progressive motor and cognitive decline and accumulation of autofluorescent material in the lysosome<sup>1</sup>. The NCLs are caused by mutations in one of 13 distinct genes (*CLN1–CLN8*, *CLN10–CLN14*), whose proteins have different characteristics, including subcellular localization and function<sup>1,2</sup>. Despite the diversity of NCL proteins, their loss of function similarly causes aberrant lysosomal function, lysosomal accumulation of electron-dense autofluorescent storage material (primarily comprised of subunit c of the mitochondrial ATP synthase, saposins, and phospholipids), and cell death<sup>3,4</sup>. NCL affects all ages and ethnicities, and the NCL subtypes are categorized with respect to the gene that causes the disorder<sup>5</sup>. Autosomal recessive *CLN3* mutations cause CLN3 disease (also known as juvenile NCL or Batten disease), which is the most common form of neurodegeneration in children worldwide<sup>1</sup>. Patients first develop vision loss, typically between 4

and 10 years of age, which is followed by onset of seizures, loss of motor and cognitive function, and premature death, typically by the mid-twenties<sup>3,4</sup>. Unfortunately, there are no effective treatments for this devastating disorder.

Although the primary function of CLN3 is still unknown, numerous studies revealed that this endo/lysosomal transmembrane protein has roles associated with endocytic trafficking, autophagy, cytoskeletal organization, lysosomal pH homeostasis, lipid metabolism, and calcium signaling<sup>6–20</sup>. While CLN3 disease is primarily a neurodegenerative disease, recent studies have demonstrated that peripheral organs are also clinically impacted at later disease stages<sup>21</sup>. Despite the ubiquitous expression of *CLN3*<sup>22,23</sup>, expression levels vary in different tissues and cell populations, suggesting the biological role of CLN3 may differ in different cell types<sup>22,24</sup>.

Neuroinflammation has been documented at early disease stages in CLN3 disease mouse models. For example, astrocyte activation was

<sup>1</sup>Center for Genomic Medicine, Massachusetts General Hospital Research Institute, Boston, MA, USA. <sup>2</sup>Department of Neurology, Massachusetts General Hospital Research Institute, Boston, MA, USA. <sup>3</sup>Department of Neurology, Harvard Medical School, Boston, MA, USA. <sup>4</sup>Medical and Population Genetics Program, the Broad Institute of M.I.T. and Harvard, Cambridge, MA, USA. <sup>5</sup>Institute of Neuronal Cell Biology, Technical University Munich, Munich, Germany. <sup>6</sup>German Center for Neurodegenerative Diseases (DZNE) Munich, Munich, Germany. <sup>7</sup>Neuroproteomics, School of Medicine, Klinikum rechts der Isar, Technical University of Munich, Munich, Germany. <sup>8</sup>Munich Cluster for Systems Neurology (SyNergy), Munich, Germany. <sup>9</sup>Department of Psychiatry, Massachusetts General Hospital, Boston, MA, USA. <sup>10</sup>Department of Psychiatry, Harvard Medical School, Boston, MA, USA. ✉e-mail: [scotman@mgh.harvard.edu](mailto:scotman@mgh.harvard.edu)

observed already in 1–3-month-old homozygous *Cln3*<sup>Δex7/8</sup> mice, whereas neuronal loss was not obvious until later ages (12–18 months)<sup>25,26</sup>. Moreover, in vitro studies revealed the neurotoxic effects of CLN3-deficient primary microglia on neuronal growth in neuron-glia co-culture models<sup>27–29</sup>. Constitutive activity of caspase-1 and concomitant inflammatory activation were also demonstrated in CLN3-deficient microglia, with increased levels of pro-inflammatory cytokines, including TNFα, IL-1β or IL-1α, following exposure to CLN3 disease-specific pathophysiological stimuli, such as ceramide or neuronal lysate<sup>28</sup>. Taken together, these studies suggest neuroinflammation likely plays an important role early in the CLN3 disease process. Indeed, neuroinflammation has emerged as a candidate therapeutic target, with several recent studies investigating the impact of dampening glial activation or T cell infiltration on CLN3 neuropathogenesis with promising results<sup>27,29–32</sup>. However, the mechanism by which neuroinflammation impacts disease onset and progression, especially how microglia play a role, is poorly understood. Establishing a clear role for loss of function mechanisms in CLN3-dependent neurodegeneration and a mechanistic connection to chronic inflammation has high potential to aid in developing novel therapeutic strategies in CLN3 disease. Here, we have established a model system to study CLN3-deficient microglia using acutely isolated microglia from homozygous *Cln3*<sup>Δex7/8</sup> mice, which were engineered to recapitulate the most common CLN3 disease-associated mutation<sup>33,34</sup>. Herein, we confirm a pro-inflammatory state and describe newly discovered molecular and functional changes in CLN3-deficient microglia that collectively point towards cell-autonomous defects in microglial function that likely impact their ability to support neuronal cell health in CLN3 disease.

## Results

### *Cln3*<sup>Δex7/8/Δex7/8</sup> mouse microglia exhibit characteristic pathological features of CLN3 disease

To study CLN3-deficient microglia, we used a MACS approach to establish highly enriched microglial fractions from adult homozygous *Cln3*<sup>Δex7/8</sup> mouse brain for downstream primary culture and morphological and biochemical analysis<sup>33</sup> (Supplementary Fig. 1a). The hallmark pathology of CLN3 disease is electron-dense autofluorescent ceroid lipopigment accumulation inside lysosomes<sup>1</sup>. Thus, we first isolated microglia from homozygous *Cln3*<sup>Δex7/8</sup> mice and wild-type littermates at timepoints between 3 and 20 months of age, which were then evaluated for the relative burden of storage material. As early as 3 months of age, isolated microglia from homozygous *Cln3*<sup>Δex7/8</sup> mice had significantly more autofluorescent storage material than that observed in wild-type microglia (Fig. 1a; yellow signal). With increasing age, the amount of autofluorescent material increased in both wild-type and homozygous *Cln3*<sup>Δex7/8</sup> microglia, but this was more dramatic in the homozygous *Cln3*<sup>Δex7/8</sup> microglia (Fig. 1a). Subunit c of the mitochondrial ATP synthase (hereafter referred to as “subunit c”) is the main accumulated protein inside CLN3-deficient lysosomes<sup>3,4</sup>, and indeed, the storage material in homozygous *Cln3*<sup>Δex7/8</sup> mouse microglia was immunopositive for subunit c. As shown in Fig. 1b, the relative burden of subunit c-positive storage material substantially increased with age, such that by 18 months of age, large subunit c-positive deposits were detected in swollen Lamp1-positive vesicles. These findings were consistent with a previous study in which a subpopulation of microglia was shown to accumulate autofluorescent lysosomal storage material in aging wild-type mice, and this population of microglia from homozygous *Cln3*<sup>Δex7/8</sup> mice accumulated dramatically more autofluorescent material compared to that observed in age-matched wild-type littermate microglia<sup>35</sup>.

To examine the ultrastructure of the lysosomal storage material in the homozygous *Cln3*<sup>Δex7/8</sup> mouse microglia, we also performed TEM on isolated microglia from 12-month-old mice. As shown in Fig. 1, the cytoplasm of the homozygous *Cln3*<sup>Δex7/8</sup> microglia was filled with electron-dense, membranous storage bodies, which at higher power magnification exhibited a multilamellar fingerprint-like profile, consistent with the classical NCL-type storage material that is seen in CLN3 disease (Fig. 1c, d)<sup>1</sup>. By comparison, only occasional membranous structures were observed in the cytoplasm of wild-type microglia, which also frequently contained electron-

lucent lipid storage bodies similar to those previously described in aged autofluorescent-positive microglia<sup>35</sup>. However, interestingly, these lipid storage bodies were virtually absent in the microglia from homozygous *Cln3*<sup>Δex7/8</sup> mice (Fig. 1e).

It has been shown in neurons and in lower organism models that, in addition to endolysosomal abnormalities, other organelle systems are also impacted by the loss of CLN3 function<sup>6,15,36,37</sup>. However, to the best of our knowledge, this has not been examined in microglia. Therefore, we next wanted to examine late endosomes/lysosomes more carefully and survey the membrane organelles in microglia isolated from homozygous *Cln3*<sup>Δex7/8</sup> mice. To accomplish this, we probed the isolated microglia from homozygous *Cln3*<sup>Δex7/8</sup> and wild-type littermate mice with additional markers for endolysosomes, endoplasmic reticulum, Golgi apparatus, and mitochondria (lysosome-associated membrane protein 2a ‘Lamp 2a’, LysoTracker™, PDI, GM130, Grp75, respectively). Consistent with our observations using Lamp 1 antibody (Fig. 1b), Lamp 2a immunostaining highlighted a significantly expanded lysosomal network in homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type controls. The overall cellular Lamp 2a signal intensity was higher and the diameter of the Lamp 2a structures was larger in the homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type controls (Fig. 2a, e, f). Further staining using LysoTracker™, a pH-sensitive lysosomotropic dye, supported these observations, where LysoTracker™ stained vesicles were reduced in number in the homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type (Fig. 2b, g). Notably, the relative intensity of LysoTracker™ signal in the stained vesicles was also reduced in the homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type (Fig. 2h). Although we did not directly measure the lysosomal pH of CLN3-deficient microglia in the present study, we note that altered lysosomal pH has been reported in several other cell models of CLN3 disease<sup>14–16</sup>. However, LysoTracker™ staining differences may alternatively reflect differences in the permeability of the lysosomal membrane or in dye uptake/diffusion.

In addition to the lysosomal abnormalities observed in homozygous *Cln3*<sup>Δex7/8</sup> microglia, we also observed altered morphology of the mitochondrial network and the Golgi apparatus (Fig. 2c, d, i–k). More specifically, the mitochondrial network appeared more fragmented in homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type (Fig. 2i, j), and the Golgi was less compact and more spread away from the nucleus in the homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type (Fig. 2k). No obvious morphological differences were observed in the ER, as highlighted by PDI immunostaining (Supplementary Fig. 2).

### *Cln3*<sup>Δex7/8/Δex7/8</sup> mouse microglia harbor a significantly altered lysosomal proteome

To gain further unbiased insights into the impact of CLN3 deficiency on microglia, we prepared acutely isolated microglia samples from 3-month-old and 12-month-old homozygous *Cln3*<sup>Δex7/8/Δex7/8</sup> mice and littermate controls (wild-type or heterozygous littermates), which were then subjected to proteomics analysis by liquid chromatography/mass spectrometry (LC/MS). Publicly available RNA sequencing data indicated that the *Cln3* expression level in mouse brain is relatively higher in microglia compared to other cell types, including neurons, oligodendrocytes, and astrocytes<sup>38</sup>. Notably, CLN3-specific peptides were detected by LC/MS in both 3-month-old and 12-month-old control microglial samples, and CLN3 was also detected by immunoblot analysis in microglia-enriched samples from wild-type mice, more than in the microglia-depleted fractions from wild-type mice containing primarily neurons and astrocytes, consistent with the RNAseq data (Supplementary Data 1; Supplementary Fig. 1). To the contrary, no CLN3 peptides were detected by LC/MS in the homozygous *Cln3*<sup>Δex7/8/Δex7/8</sup> microglial samples (Supplementary Data 1).

As depicted by the volcano plots in Fig. 3, our proteomics analysis revealed prominent upregulation of lysosomal proteins already at 3 months of age (Fig. 3a), and this was exacerbated further with age, with both a greater degree of change and a greater number of lysosomal proteins with increased abundance at 12 months of age in homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to control microglia (Fig. 3b). Moreover, multiple components of the

**Fig. 1 | CLN3-deficient microglia accumulate high amounts of storage material.** **a** Representative fluorescent images of cultured microglia from 3- and 20-month-old (mo) *Cln3*<sup>Δex7/8/Δex7/8</sup> mice and wild-type (*Cln3*<sup>+/+</sup>) littermates. Microglia from aged mice show broad-spectrum autofluorescence (obtained using excitation wavelengths of 488 and 555), which is more abundant in the *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia. Scale bar = 25 μm. **b** Representative micrographs of cultured primary isolated microglia from 3-, 12-, and 18-month-old homozygous *Cln3*<sup>Δex7/8</sup> mice and from 18-month-old wild-type littermate mice for comparison. Microglia were

immunostained with Lamp1 (red) and subunit c antibodies (green). Scale bar = 20 μm. **c** Transmission electron microscopy (TEM) images of acutely isolated microglia from *Cln3*<sup>Δex7/8/Δex7/8</sup> mice and littermate wild-type controls at the age of 12 months. Scale bars = 800 nm. **d**, **e** Bar graphs showing the quantification of storage material (asterisks) and lipid storage bodies (arrowheads) from TEM images. *N* = 114 cells/genotype, from 3 mice per genotype (38 cells/mouse). Student's *t*-test, \*\*\*\**P* ≤ 0.0001.

**Fig. 2 | Altered organellar morphology in CLN3-deficient microglia.** Cultured microglia from 6-month-old mice were stained with lysosomal markers, Lamp2a (red) (a) or LysoTracker™ (b), mitochondrial marker, Grp75 (white) (c), or Golgi marker, GM130 (white) (d). Quantification of morphological changes is shown in the bar graphs (e–k). GM130 compactness determination using CellProfiler (k) assigns circular objects a compactness value of 1 and irregular objects, or objects

with holes, compactness values greater than 1, such that a higher value indicates reduced compactness. *N* = 300 cells/genotype (3 mice/genotype from 3 independent experiments and 100 cells/mouse). Unpaired Student’s *t*-test with a two-tailed distribution was used to compare the two groups. Scale bars = 25 μm. Data are shown as mean ± s.d.; \*\**P* ≤ 0.01, \*\*\**P* ≤ 0.001, \*\*\*\**P* ≤ 0.0001 Student’s *t*-test.

mTOR pathway were also upregulated at both 3 and 12 months of age (Fig. 3a, b), including the mTORC1 signaling complex (mTOR, Raptor, Lamtor1, 2, 3, and 5, and Mlst8); mTORC1 is a major signaling hub associated with the lysosome and metabolic regulation<sup>39</sup>. The two most dramatically changed proteins, which were both increased ~10-fold or more in homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to control microglia at both the 3- and 12-month timepoints, were likely novel lysosomal membrane transporters, PTTG1IP and TTYH3 (Fig. 3a, Supplementary Data 1)<sup>40</sup>. Among the lysosomal proteins upregulated were Lamp 1 and Lamp 2, consistent with our immunostaining studies and prior reports (Fig. 2, 35), and further validated by immunoblot (Fig. 3c, Supplementary Fig. 3a).

We next performed a Gene Ontology (GO) analysis on the 12 months of age proteomic datasets to gain more comprehensive insights into the pathways affected by loss of CLN3 function in microglia. Not surprisingly, the lysosome/lytic vacuole was the most prominently changed cellular component, with the intermediate filament cytoskeleton next most prominent (Fig. 3d). GO biological processes that were significantly altered in homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type microglia were mRNA processing, WNT Signaling, Transcription, Cytoskeleton Organization, Chromatin Organization, Cell Motility/

Migration, mRNA Cleavage, Tissue Morphogenesis, and Sphingolipid, Glycolipid Metabolism, revealing numerous interesting pathways for further study (Fig. 3d).

In addition to the GO biological process analysis revealing enrichment in the “Sphingolipid, Glycolipid Metabolism” pathway, we also noted a number of individual lipid-related proteins with significantly altered levels in the early and later time points (3 and 12 months of age, respectively). Examples include proteins linked to glutathione metabolism [glutathione S-transferase omega 1 (GSTO1)], myelin-associated oligodendrocyte basic protein (MOBP), myelin proteolipid protein 1 (PLP), apolipoprotein E (APOE), prosaposin (PSAP), and low-density lipoprotein receptor-related protein 1 (LRP1), which is important in lipoprotein metabolism and cell motility<sup>41</sup>. Finally, consistent with prior reports, homozygous *Cln3*<sup>Δex7/8</sup> microglia showed elevated levels of multiple inflammatory markers, including apolipoprotein E (APOE), integrin alpha-X (ITGAX), CD68, vimentin, galectin 3 (LGALS3) (Supplementary Data 1, Supplementary Fig. 3a, b, Fig. 3c). However, these were less prominent changes than what was seen for lysosomal proteins, and mostly these were only significantly upregulated at the 12-month timepoint. Validation of changes for a selected set of proteins identified in the proteomics studies (LAMP2A, APOE, LRP1,

PLP, LAMP1, galectin 3) was performed on additional microglial samples (Fig. 3c and Supplementary Fig. 3a, b).

To follow up on the GO analysis results, we tested the motility of CLN3-deficient microglia (GO Biological Process: Cell Motility/Migration) and examined glycosphingolipids in CLN3-deficient microglia (GO Biological Process: Sphingolipid, Glycolipid Metabolism). Notably, prior

studies reported on cytoskeleton and motility defects and alterations in the sphingolipid degradation pathway in other cell types with CLN3-deficiency<sup>42–46</sup>. Consistent with these observations, motility of the cultured microglia isolated from homozygous *Cln3*<sup>Δex7/8</sup> mice, measured using live cell time-lapse imaging, was significantly reduced over a 5 h period, as compared to wild-type microglia (Fig. 3e). Glycosphingolipid alterations

**Fig. 3 | Proteomic analysis of homozygous *Cln3*<sup>Δex7/8</sup> microglia reveals early lysosomal changes.** Relative levels of detected proteins for homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to littermate heterozygous and wild-type control microglia (CON) are depicted in the volcano plots from 3-month (a) and 12-month-old mice (b). Open red dots indicate proteins with a significant change in abundance [greater than false discovery rate (FDR, hyperbolic curve) threshold], while open blue dots represent proteins that were detected but did not significantly differ between *Cln3*<sup>Δex7/8/Δex7/8</sup> and controls. Lysosomal proteins are depicted by solid orange dots, with significant lysosomal protein dots being bounded by a red border and non-significant lysosomal proteins being bounded by a blue border c.) Representative immunoblots are shown for the validation of the indicated protein changes in the microglial (CD11b+) fractions from wild-type (+/+) and homozygous *Cln3*<sup>Δex7/8</sup> (Δex7/8/Δex7/8) microglia and relevant molecular weight markers are shown. Bar graphs show the quantification of immunoblots using ImageJ (*N* = 3 biological replicate samples/genotype). Data are shown as mean ± s.d.; \**P* ≤ 0.05, \*\**P* ≤ 0.01 Student's *t*-test. d GO analysis results for 'Cellular component' (top) and 'Biological process' (bottom). e Graphs represent the results of a representative migration assay

on microglia isolated from homozygous *Cln3*<sup>Δex7/8</sup> and wild-type control mice. Real-time imaging was performed every 15 min for 5 h to generate the migration plots, with each track from an individual cell aligned at the starting point. Axis units in μm from the starting point. Quantification of migration velocity (μm/min) over 5 h was performed using ImageJ and Ibidi's Chemotaxis and Migration Tool plugin. *N* = 37 cells for wild-type and *N* = 45 cells for homozygous *Cln3*<sup>Δex7/8</sup> microglia. Data are shown as mean ± s.d.; \*\*\**P* ≤ 0.0001 Student's *t*-test. f Cultured microglia from 9-month-old wild-type (+/+) or homozygous *Cln3*<sup>Δex7/8</sup> (Δex7/8/Δex7/8) mice were stained with ganglioside markers, GM1 (red, left panels) or GM3 (red, right panels). Quantification of mean GM1 intensity per cell (left) and mean GM3 intensity per cell (right) are shown in the bar graphs. 250 cells/genotype were analyzed. Data are shown as mean ± s.d.; \*\**P* ≤ 0.01, \*\*\**P* ≤ 0.001, Two-way ANOVA followed by Sidac's multiple comparison test. Scale bar = 25 μm. Heatmap represents relative levels of sphingolipid degradation pathway proteins where the color scale depicts relative abundance in 3 month (3 m) or 6 month (6 m) homozygous *Cln3*<sup>Δex7/8</sup> microglia samples compared to control. "X" = not detected.

were also detected, with reduced GM1 ganglioside and elevated GM3 ganglioside immunostaining seen in the cultured homozygous *Cln3*<sup>Δex7/8</sup> microglia, as compared to wild-type microglia (Fig. 3f). These changes were consistent with the prior published reports detecting glycosphingolipid changes in CLN3-deficient cells using LC/MS<sup>44,45</sup>.

### Abnormal myelin turnover and cholesterol accumulation in *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia

As reported above, levels of several myelin-component and myelin-related proteins were altered in the *Cln3*<sup>Δex7/8/Δex7/8</sup> mouse microglial proteomes, including PLP, MOBP, and LRP1 (an essential receptor for microglial myelin phagocytosis<sup>47</sup>) (Supplementary Data 1). We therefore next sought to evaluate myelin phagocytosis and turnover in CLN3-deficient microglia to test whether the proteomic signatures observed were accompanied by functional changes.

Myelin is an important insulating component for neurons that facilitates the transduction of electrical impulses. During developmental remodeling and throughout aging, myelin is taken up by microglia via phagocytosis, where it is trafficked to the lysosome for degradation by proteases and lysosomal lipases. The cholesterol component of myelin cannot be degraded by lysosomal enzymes and instead is exported from the lysosome for extracellular release, or it is transported to the ER where it is esterified and stored in lipid droplets (LD) as cholesterol esters. Cholesterol esters can then be used by the cell as energy fuel<sup>48</sup>. These pathways for handling free cholesterol are critical for cellular health since accumulated cholesterol is toxic to the cell<sup>49</sup>.

To first study myelin uptake in homozygous *Cln3*<sup>Δex7/8</sup> microglia, we incubated green fluorescent-labeled myelin with isolated microglia and analyzed its uptake by fluorescent microscopy. As shown in Fig. 4a, the labeled myelin was readily taken up by both the wild-type and homozygous *Cln3*<sup>Δex7/8</sup> microglia, although a comparison of the relative green fluorescent intensities revealed reduced signal in the homozygous *Cln3*<sup>Δex7/8</sup> microglia compared to wild-type on both the per vesicle and per cell level, suggesting a slight reduction in the phagocytosis of the labeled myelin (Fig. 4a).

Next, to examine the turnover of the labeled myelin, we washed the cultured microglia post-myelin uptake and subsequently incubated the cells in regular media for another 48 or 72 h. Green-fluorescent signal was similar in the wild-type and *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia at the 48 h timepoint, although the green fluorescence took on a more punctate appearance versus the more diffuse signal seen immediately following the myelin uptake, likely reflecting the degradation process (Fig. 4b, Supplementary Fig. 4b). By 72 h post-green-fluorescent-myelin washout, very little green signal was observed in the wild-type cells, indicating these cells had almost completely degraded the myelin. To the contrary, significant green punctate signal was still observed in the *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia at 72 hours post-green-fluorescent-myelin washout, indicating these cells were significantly less efficient in the

degradation of the phagocytosed green fluorescent-myelin compared to wild-type microglia (Fig. 4b).

We next studied LD formation following myelin phagocytosis. To do so, we fed the cells unlabeled myelin for 6 h, which was followed by a washout and regular media incubation for an additional 48 h. LDs were then labeled with LipiDyeII. At 48 h post-myelin washout, wild-type cells displayed nicely rounded spherical LDs that were strongly LipiDyeII positive (Fig. 4c). To the contrary, *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia displayed very few LDs labeled with LipiDyeII, with only a few cells harboring small LipiDyeII-positive LDs (Fig. 4c).

The recycling of cholesterol is an important process following myelin uptake, and given the observation that APOE, a key cholesterol handling protein, was significantly elevated in the homozygous *Cln3*<sup>Δex7/8</sup> microglial proteome, we followed cholesterol handling by Filipin staining throughout the myelin uptake assay. Even prior to challenge by myelin uptake, we identified significant accumulation of cholesterol in the cultured homozygous *Cln3*<sup>Δex7/8</sup> microglia, as revealed by Filipin staining, which localized to vesicles surrounded by Lamp2a, suggesting the accumulated cholesterol localized to lysosomes (Fig. 4d, f, Supplementary Fig. 5a). Following the 6-hour myelin incubation, Filipin staining was robustly increased in both wild-type and *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia (Fig. 4d, e). At 48 h post-myelin washout we observed a major reduction in the level of Filipin stain in wild-type cells and nearly complete loss of Filipin stain by 72 h (Fig. 4d, e). By contrast, *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia still showed significantly elevated Filipin at 48 h and 72 h post-myelin washout, even over the basal level observed, (Fig. 4d, e). Notably, ganglioside levels also significantly differed following myelin washout (Supplementary Fig. 5b). Altogether, these data suggest that CLN3-deficient microglia are defective in the efficient turnover of myelin and the handling of its associated lipids.

### Autophagy inducers and cholesterol-lowering drugs rescue the myelin turnover defects in *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia

We have previously identified compounds that promote autophagy-lysosomal function in CLN3-deficient cells, which notably also included several FDA-approved cholesterol-lowering drugs, including statins, which are inhibitors of isoprenoid (e.g. cholesterol) biosynthesis<sup>50</sup>. We next tested whether the compounds promoting autophagy-lysosomal function and/or the cholesterol-lowering drugs had any significant impact on the ability of *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia to efficiently degrade phagocytosed myelin and handle the myelin-associated cholesterol. For this, Lovastatin, the most effective cholesterol-lowering drug from prior studies<sup>50</sup>, Verapamil (an mTOR-independent autophagy inducer), and ML-SA5 [a TRPML-1 agonist that promotes TFEB activation and autophagy-lysosomal function in CLN3 disease models<sup>51</sup>, Supplementary Fig. 6] were tested. Microglia from wild-type and *Cln3*<sup>Δex7/8/Δex7/8</sup> mice were fed unlabeled myelin for 6 h, followed by a thorough washout and subsequent incubation in regular media for an additional 48 h. In the final 24 h of the 48 h incubation period, we

introduced ML-SA5, Verapamil, or Lovastatin (or DMSO vehicle control) to assess their potential in correcting the LD formation phenotype, using LipiDyeII to visualize LD formation. As seen in our prior experiments, CLN3-deficient microglia (Fig. 5b) produced fewer LDs than wild-type microglia (Fig. 5a, p). Interestingly, all three drugs tested partially rescued the reduced LD formation (Fig. 5c, d, e, p), with ML-SA5 being the most

efficacious. We next performed the same assay but, this time, stained with Filipin to see the effect of drug treatments on cholesterol levels. The cholesterol-reducing drug, Lovastatin, was the most effective in reducing cholesterol in *Cln3*<sup>Δex7/8/Δex7/8</sup> mutant microglia (Fig. 5j) to a level seen in wild-type cells (Fig. 5f, r), but ML-SA5 also showed a significant reduction in accumulated cholesterol in the *Cln3*<sup>Δex7/8/Δex7/8</sup> mutant microglia post myelin

**Fig. 4 | Myelin turnover is disrupted in CLN3-deficient microglia.**

Data are shown as mean  $\pm$  s.d.;  $***P \leq 0.0001$ , Student's *t*-test. **b** Representative micrographs of green-fluorescent myelin degradation at 48 and 72 h for wild-type and homozygous *Cln3*<sup>Δex7/8</sup> microglia. Myelin (green), Iba-1 (red), DAPI= nuclei (blue). See Supplementary Fig. 4b for low-power images. Quantification of green fluorescent-myelin at 72 h ( $N = 203$  cells, wild-type;  $N = 248$  cells, *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia, from 3 independent

experiments). Each dot represents one cell. Data are shown as mean  $\pm$  s.d.;  $***P \leq 0.0001$ , Student's *t*-test. See Supplementary Fig. 4b for the quantification of green fluorescent-myelin at 48 h. **c** Representative micrographs of lipid droplets labeled with LipiDyeII following unlabeled myelin uptake and 48 h post myelin washout. Bar graph shows quantification of lipid droplet number per cell ( $N = 297$  cells, wild-type;  $N = 316$  cells, *Cln3*<sup>Δex7/8/Δex7/8</sup>). **d** Representative micrographs following Filipin staining during myelin uptake and turnover. Basal panels show Filipin staining prior to myelin uptake. PDI (green), Iba-1 (red), and Filipin (blue). **e** Bar graph shows quantification of Filipin intensity per cell. ( $N = 134$  cells, wild-type;  $N = 150$  cells, *Cln3*<sup>Δex7/8/Δex7/8</sup>, from 3 independent experiments). Data are shown as mean  $\pm$  s.d.; ns: non-significant,  $**P \leq 0.01$ ,  $***P \leq 0.0001$ , Two-way ANOVA followed by Sidac's multiple comparison test. **f** Zoomed in representative images from unchallenged (i.e. no myelin phagocytosis) 6-month-old wild-type and *Cln3*<sup>Δex7/8</sup> mice microglia co-stained with Filipin (blue) and lysosomal marker Lamp2a (red). See Supplementary Fig. 5a for low-power images. Scale bars = 25  $\mu$ m.

uptake/washout (Fig. 5h, r). We also tested these drugs for their ability to clear the autofluorescent storage material (Fig. 5k–o). Following a 24-hour incubation using doses previously determined to be effective in a neuronal model system<sup>50</sup>, all three drugs significantly reduced the relative abundance of autofluorescent storage material, with ML-SA5 again being the most efficacious (Fig. 5s).

**Impaired myelin integrity in aged *Cln3*<sup>Δex7/8/Δex7/8</sup> mouse brain**

The critical role of microglia in clearing myelin debris after acute demyelinating injury to facilitate remyelination has been well-established<sup>49</sup>. Removal of aberrant myelin in development and aging is also mediated by microglial uptake and lysosomal degradation<sup>52–54</sup>. Notably, thinning of the corpus callosum and degeneration of optic nerves, major white matter tracts that primarily consist of myelinated nerve fibers, was previously reported in CLN3 disease patients and *Cln3* mice<sup>55–57</sup>. Given these prior reports and the intriguing observations from our proteomics and myelin turnover studies, we hypothesized that CLN3 deficiency may impact myelin formation or maintenance, which would lead to a reduction in myelin integrity in the aging CLN3-deficient brain. We therefore immunostained brain sections from aged wild-type and homozygous *Cln3*<sup>Δex7/8/Δex7/8</sup> mice with the compact myelin markers MBP and PLP. Both markers showed significantly reduced signal in 20-month-old *Cln3*<sup>Δex7/8/Δex7/8</sup> mouse brain sections compared to wild-type mice (Fig. 6a–e, Supplementary Fig. 7). Moreover, TEM analysis of optic nerves from 18-month-old *Cln3*<sup>Δex7/8/Δex7/8</sup> mice revealed an increased frequency of several aberrations in myelinated fiber integrity compared to wild-type mice (Fig. 6f–h). In addition to previously described hallmarks of axonal damage and degeneration<sup>31</sup>, we detected an accumulation of fibers with myelin infoldings, outfoldings, redundant or fragmented myelin, as well as myelin vacuoles (Fig. 6g). Quantification of fibers with these myelin aberrations showed a significant increase in *Cln3*<sup>Δex7/8/Δex7/8</sup> compared to wild-type mice, while amyelinated or thinly myelinated fibers were not changed in frequency (Fig. 6h). Occasionally, we detected microglia with an accumulation of lysosomal storage material in optic nerves of *Cln3*<sup>Δex7/8/Δex7/8</sup> mice, indicating decreased clearance function related to myelin degradation<sup>54</sup>. These observations lend support to our functional data that loss of CLN3 in microglia leads to altered myelin turnover in a manner that likely impacts neuronal cell health and function, particularly in the aging brain.

**Discussion**

Microglia are the primary immune cells of the central nervous system (CNS) and have fundamental neuroprotective and tissue homeostatic functions through sensing the neuronal microenvironment. They protect the brain via phagocytosis and cytokine release to remove debris/pathogens and protect against infection. In response to an imbalance of microglial functions, they may become reactive and drive neuroinflammatory processes<sup>58</sup>. Microglia also play a critical role in synaptic development and remodeling and in the response to neuronal injury through their ability to turnover synapse and myelin components<sup>59</sup>. Notably, neuroinflammation and synaptic alterations

have been reported in models of CLN3 disease and other forms of NCL<sup>8,28,30,32,60–63</sup>. Consistent with findings in those prior studies, our research on microglia from a genetically accurate mouse model of CLN3 disease, *Cln3*<sup>Δex7/8</sup> mice, presented in this study, also highlights evidence of elevated neuroinflammation. In addition, we have now significantly expanded upon the cell biological processes affected by the loss of CLN3 function in microglia, which likely have a significant impact on the degenerative disease process observed in CLN3 disease.

Changes in the lysosomal, Golgi and mitochondria subcellular organelles have previously been documented in neurons and other cell types upon loss of CLN3 function<sup>6,15,36,37</sup>. In the current study, we have similarly observed significant changes in these membrane organelles in microglia isolated from homozygous *Cln3*<sup>Δex7/8</sup> mice. Moreover, consistent with the primary localization of the CLN3 protein to the endolysosome, unbiased proteomics studies revealed a dramatic impact of loss of CLN3 function on the lysosomal proteome. The two proteins with the greatest change in homozygous *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia, at both time points analyzed, were PTTG1IP and TTYH3, which were both previously identified as likely novel lysosomal membrane transporters by biochemical studies and by their colocalization with lysosomal markers when overexpressed as tagged proteins<sup>40</sup>. TTYH3 is predicted to be a calcium-activated chloride channel and PTTG1IP is an integral membrane protein that was also shown to be induced by TFEB, the master regulator of lysosomal biogenesis<sup>64,65</sup>. Unfortunately, there are no validated antibodies available that recognize these proteins, hampering our ability to readily follow up on these findings; however, this is of high importance for future work to better understand the potential role of these two proteins in CLN3 protein function and CLN3 disease pathophysiology. Accompanying these changes in the lysosomal proteome were changes in levels of the mTORC1 signaling complex, a major signaling hub associated with the lysosome and metabolic regulation<sup>39</sup>. Prior reports of altered mTORC1 signaling in CLN3-deficiency models support these findings<sup>10,12,66</sup>.

In addition to the lysosomal proteomic signature detected in CLN3-deficient microglia, other pathways were also highlighted that prompted our follow-up functional studies. These included changes in cytoskeletal proteins and cell motility/migration pathways, sphingolipid/glycolipid metabolism pathways, as well as in myelin component and myelin-associated proteins and lipid-related proteins. Microglia are highly dependent on their ability to migrate towards sites of infection and injury and on their ability to phagocytose damaged or foreign debris/pathogens to neutralize these danger signals. Herein, we found that CLN3-deficient microglia were unable to perform either of these processes in an efficient manner, strongly suggesting CLN3-deficient microglia cannot serve their normal neuroprotective role. In addition to reducing microglial motility, CLN3-deficiency also led to abnormalities in the phagocytic uptake and turnover of myelin. More specifically, myelin uptake was slightly reduced while its degradation was delayed in the CLN3-deficient microglia. Interestingly, defects in phagocytosis have also been implicated in other CLN3 deficiency model systems<sup>67,68</sup>. In a recent study by Tang et al., CLN3-deficient retinal pigment

**Fig. 5 | Correction of storage material and myelin turnover defects in CLN3-deficient microglia using small molecules targeting autophagy/lysosomal function and cholesterol. a–j** Representative micrographs of wild-type and *Cln3 $\Delta$ ex7/8/ $\Delta$ ex7/8* microglia, treated with small molecules or DMSO vehicle, as indicated, and subsequently labeled with LipiDyeII or Filipin, 48 h post-myelin washout. **k–o** For autofluorescence, microglia were unchallenged (no myelin) and unlabeled. Scale bars = 25  $\mu$ m. **p** Bar graph shows quantification of lipid droplet number ( $N = 200$

cells/genotype or treatment, from 3 independent experiments). **r** Bar graph shows quantification of average Filipin intensity (Mean intensities of 240 cells/genotype or treatment, from 3 independent experiments). **s** Bar graphs show quantification of average autofluorescence intensity (Mean intensities of 180 cells/genotype or treatment, from 3 independent experiments). Data are shown as mean  $\pm$  s.d.; ns: non-significant,  $*P \leq 0.05$ ,  $**P \leq 0.01$ ,  $***P \leq 0.001$ ,  $****P \leq 0.0001$ , One-way ANOVA followed by Tukey’s multiple comparisons test was used.

**Fig. 6 | Impaired myelin integrity in *Cln3*<sup>Δex7/8/Δex7/8</sup> mice.** Representative brain sections from 20-month-old wild-type (**a**, **b**) and *Cln3*<sup>Δex7/8/Δex7/8</sup> (**c**, **d**) mice immunostained for myelin using anti-MBP (red) antibody. Hoechst nuclear counterstaining is shown in blue. Scale bar = 500 μm. The bar graph represents the average of mean MBP intensities (**e**). *N* = 9 brain sections (3 mice per genotype, 3 brain sections per mouse, matched to represent comparable brain regions for control and *Cln3*<sup>Δex7/8/Δex7/8</sup>). Data are represented as mean ± standard error of the mean (SEM); \*\*\*\**P* ≤ 0.0001, Student's *t*-test. **f** Representative electron micrographs of transverse sections through the optic nerves from 18-months-old wild-type and *Cln3*-deficient mice. Scale bar = 2 μm. **g** Representative examples of distinct structural aberrations in

myelin sheaths of *Cln3*-deficient mice. Myelin infoldings or outfoldings (arrowheads), redundant myelin (arrows), myelin fragments (hashtags), and myelin vacuoles (circles) are frequent. Occasionally, microglial cells (MG, green pseudocolor) containing lysosomal storage material (asterisks) can be detected. **h** Quantification of fibers with cumulative myelin aberrations (top) and amyelinated or thinly myelinated fibers (bottom) in the optic nerves from 18-months-old wild-type and *Cln3*-deficient mice (*n* = 5 mice per group, two-sided unpaired *t* test. top: *t* = 10.35, d.f. = 8, bottom: *t* = 10.35, d.f. = 8). Data are presented as the mean ± s.d.

epithelial cells (RPE) were less efficient in their ability to bind and take up photoreceptor outer segments (POS)<sup>68</sup>. Together, these studies support a broader role for CLN3 in the phagocytic turnover of cellular debris, supporting the need for further investigation of phagocytic processes in CLN3 disease pathophysiology.

CLN3-deficient microglia were unable to efficiently store and clear lipids following myelin uptake, including cholesterol, strongly implicating lipid handling as a major defective pathway upon loss of CLN3 function.

Consistent with these findings, a recent study of CLN3 patient brain showed a dramatic lysosomal accumulation of cholesterol compared to age-matched controls<sup>69</sup>, and CLN3 was previously implicated as a genetic regulator of LD formation<sup>70</sup>. Another recent study implicated CLN3 in phospholipid catabolism. Using an elegant lysosomal enrichment technique, coupled with untargeted metabolite profiling of CLN3-deficient lysosomes, Laqtom et al. identified a unique and robust lysosomal accumulation of glycerophosphodiester (GPDs) in the absence of CLN3, together with an

increase in lysophospholipids, the metabolite upstream of GPDs in the phospholipid catabolism pathway<sup>21</sup>. As a result of these findings and further CLN3 complementation and transport assays in cell culture, Laqtom et al. hypothesized CLN3 is required for the efflux of GPDs from the lysosome, a key process at the final stages of phospholipid catabolism<sup>21</sup>.

Given the importance of lipids and lipoprotein metabolism to microglial function<sup>48</sup>, these cells may be especially vulnerable to the loss of CLN3 function and its impact on phospholipid catabolism and cholesterol handling. Lipids serve as essential building blocks for cells and are an important energy source for microglia<sup>48</sup>, but they also have the potential to act as pro-inflammatory stimuli. Excessive cellular accumulation of lipids can lead to toxicity and trigger apoptosis, emphasizing the delicate balance required for maintaining cellular health<sup>71,72</sup>. Although we have not specifically tested the impact of defective lipid handling and phospholipid catabolism on the survival of CLN3-deficient microglia in this study, a prior study showed a significant decrease specifically in the numbers of surviving autofluorescent-positive microglia following acute isolation from *Cln3*<sup>Δex7/8</sup> mice at 9 and 18 months of age, which was accompanied by elevated apoptosis markers, suggesting accumulation of toxic lipid species and/or an altered metabolic capacity may predispose CLN3-deficient microglia to cell death<sup>35</sup>.

In summary, the high level of *CLN3* expression in microglia, together with the early onset of lysosomal storage, disrupted lipid metabolism, and inflammatory signatures in *Cln3*<sup>Δex7/8/Δex7/8</sup> microglia suggests that CLN3 exerts a cell-autonomous function in microglia and that microglial pathology is not solely triggered by a neurodegenerative environment. Moreover, deficient microglial function likely contributes to and/or exacerbates the dysfunction of other cell types in CLN3 disease given the importance of cell-cell interactions in the brain microenvironment. Interestingly, a comprehensive investigation into microglia from a mouse model of another neurodegenerative lysosomal storage disorder, Nieman-Pick Type C disease (NPC), caused by *NPC1* deficiency (*Npc1*<sup>-/-</sup>)<sup>73</sup>, identified defects in myelin turnover and an inflammatory signature that were similar to what has been described here for homozygous *Cln3*<sup>Δex7/8</sup> mouse microglia. However, in the case of *Npc1*<sup>-/-</sup> mouse microglia, phagocytic uptake was enhanced and lysosomal degradation was preserved, yet myelin turnover and lipid handling, particularly of cholesterol, were impaired<sup>33</sup>. Indeed, in an Ingenuity Pathways Analysis (IPA) comparison of the proteomic signatures in *Cln3*<sup>Δex7/8/Δex7/8</sup> and *Npc1*<sup>-/-</sup> microglia<sup>33</sup>, there are clear similarities in the impacted canonical signature pathways and upstream activators, including in CLEAR Signaling and Sphingolipid Metabolism pathways (Supplementary Figs. 8 and 9, Supplementary Data 2). Comparison with IPA analysis of microglial proteomic signatures from the APPPS1 mouse model of Alzheimer's disease (AD) pathology<sup>74,75</sup> also showed some overlap with the CLN3 and NPC signatures, albeit to a lesser degree than the two lysosomal storage diseases (Supplementary Figs. 8 and 9, Supplementary Data 2). Microglial lipid metabolism has also been highlighted as an important pathway in AD and other neurodegenerative diseases including multiple sclerosis and amyotrophic lateral sclerosis (ALS)<sup>48,76</sup>. Therefore, further studies to expand our understanding of CLN3 and microglial function will provide critical new insights into the role of these cells in CLN3 disease and other neurodegenerative diseases, which will be fundamental for the development of novel therapies in the future.

## Materials and methods

### Antibodies

The following antibodies were used: anti- Iba-1 [Western blot (WB): 1:1000, Wako 016-20001], anti- Iba-1 [immunofluorescence (IF): 1:500, Wako 019-19741], anti-Tuj-1 (WB: 1:1000, BioLegend MMS-435P), anti- GFAP (WB: 1:1000, Cell Signalling 3670S), anti-mCln3p (WB: 1:1000,<sup>10</sup>), anti- Apoe (WB/IF: 1:250, Invitrogen 16H22L18), anti- PLP [WB: 1:1000, immunohistochemistry (IHC): 1:300, Abcam ab28486], anti- MBP (IHC: 1:1000, Sigma Aldrich SMI-99), anti- actin (WB: 1:1000, Santa Cruz Biotech sc-81178), anti- subunit c (IF: 1:300, Abcam ab181243 (ATP Synthase C [EPR13907]) and<sup>11</sup>), anti- Lamp1 (WB: 1:1000, IF: 1:100, Santa Cruz Biotech

sc-19992), anti- Lamp2a (WB: 1:1000, IF: 1:500, Abcam ab18528), anti- GM130 (IF: 1:100, BD Transduction 610822), anti- GRP175 (IF: 1:100, Stressgen SPS-825), anti- LRP1 (WB: 1:50000, Abcam ab92544), anti- Galectin 3 (WB: 1:500, Santa Cruz Biotech sc-32790), anti- PDI (IF: 1:100, StressGen SPA-891), anti- Ganglioside GM1 (IF: 1:50, Abcam ab23943). Anti-Ganglioside GM2 (IF: 1:100) and anti-Ganglioside GM3 (IF: 1:50) were generous gifts from Dr. Kostantin Dobrenis, Albert Einstein College of Medicine. Secondary antibody goat anti-rat AlexaFluor 568 (1:800, Thermo Fisher Scientific Inc), secondary antibody donkey anti-rabbit AlexaFluor 488 (1:500, Thermo Fisher Scientific Inc) or 555 (1:800, Thermo Fisher Scientific Inc), secondary antibody donkey anti-mouse Alexa Fluor 488 (1:500, Thermo Fisher Scientific Inc) or 555 (1:800, Thermo Fisher Scientific Inc).

### Reagents

The following compounds were used in this study. ML-SA5 (10 μM) (Cat no: AOB11116 (Aobious INC)), Verapamil (10 μM) (Cat no: CAS 152-11-4 (Santa Cruz)), Lovastatin (10 μM) (Cat no: S2061 (Selleck Chemicals)), LipiDyeII (1 μM) (DiagnoCine FNK-FDV-0027), Filipin III (Sigma-Aldrich SAE0087), LysoTracker™ Deep Red (Invitrogen L12492), True-Black® Lipofuscin Autofluorescence Quencher (Biotium), ProLong™ Gold Antifade Mountant with DNA Stain DAPI (Invitrogen P36931), Tissue-Tek® O.C.T. Compound, ProLong™ Gold Antifade Mountant (P36930), PKH67 Green Fluorescent Cell Linker Kit for General Cell Membrane Labeling (Sigma-Aldrich Cat no: PKH67GL).

### Mice

*Cln3*<sup>Δex7/8</sup> mice have been previously described and are publicly available at The Jackson Laboratory (Strain #: 017895)<sup>34</sup>. *Cln3*<sup>Δex7/8</sup> mice were maintained on a C57BL/6 J congenic background (>20 generations) in the AAALAC-accredited rodent facility at MGH. Heterozygous matings were set up to generate wild-type, heterozygous, and homozygous littermate experimental animals (males and females), which were aged to the indicated time points for microglia isolation or tissue collection for histology. Mice were euthanized by inhalation of CO<sub>2</sub>-bottled gas, in accordance with current guidelines from the American Veterinary Medical Association. Mice collected for Histology studies were transcardially perfused, as described below. All procedures used for this study were reviewed and received ethical approval by the Subcommittee on Research Animal Care at MGH to ensure compliance with government regulations and animal welfare guidelines (Protocol # 2008N000013). We have complied with all relevant ethical regulations for animal use.

### Histology

Mice (*N* = 3, 20-month old mice per genotype) were transcardially perfused with 4% PFA/0.1 M PBS, followed by brain dissection and six hours post-fixation with 4% PFA/0.1 M PBS at 4 °C. Brain hemispheres were placed into a scintillation vial and filled with 10% sucrose/ 1X PBS. After 24 h (24 h), the sunken tissues at the bottom of the vial were transferred to 20% sucrose/ 1X PBS. The next day, tissues were transferred to 30% sucrose/ 1X PBS. After 24 h, the sunken tissues at the bottom of the vial were frozen in O.C.T. A Leica CM3050 S Cryostat was used to make 40 μm coronal brain sections collected in cryoprotectant solution (25% Ethylene Glycol/ 25% Glycerol/ 50% 1X PBS). Free-floating brain sections were processed for antigen retrieval in 1 mM sodium citrate buffer and microwaving for 10 min (min) at 10% power level. Brain sections were then blocked for 1 h in 1X PBS/ 0.1% Triton X-100/ 1% Glycine/ 2% Bovine Serum Albumin (BSA)/ 10% Normal Horse Serum (NHS). Next, sections were incubated for two days at 4 °C with primary antibody diluted in 1X PBS/ 2% BSA/ 10% NHS. After washing three times with 1X PBS/ 0.05% Tween 20, corresponding secondary antibodies were diluted in 1X PBS/ 2% BSA/ 10% NHS and incubated for 2 h at room temperature (RT). Following secondary antibody incubation, sections were washed three times with 1X PBS/ 0.05% Tween 20 and incubated with Hoechst (1:10,000) for 10 min. Finally, sections were washed three more times in 1X PBS and subsequently mounted onto microscope slides in a bath

of 1X PBS and allowed to dry overnight (O/N). Slides with the mounted sections were then coverslipped with mounting media and stored at 4 °C in the dark until imaging. Imaging was performed on a Zeiss Celldiscoverer 7 microscope using a 20× / 0.95 Autocorr Objective.

### Primary microglia

Cerebellum, olfactory bulb, and brain stem were removed from dissected mouse brains. Meninges was dissected away from the remaining cerebrum in ice-cold HBSS under a dissection microscope. The cerebrum was then cut into 16 pieces and dissociated using the Neural Tissue Dissociation Kit (P) (Miltenyi Biotec), according to the manufacturer's protocol. Microglial cells were isolated away from the rest of the cells in the suspension by incubation with CD11b microbeads (Miltenyi Biotec), which were then pulled down using a magnetic-activated cell sorting (MACS) separation LS column (Miltenyi Biotec). Samples prepared for mass spectrometry or biochemical analysis (e.g. immunoblotting) were further washed twice with PBS and frozen for subsequent analysis without culturing. The purity of the microglial fraction was confirmed by immunoblot with cell-type specific antibody markers (e.g. Iba1, microglia; Tuj1, neurons; GFAP, astrocytes). For cell culture experiments, isolated microglia were resuspended in microglial culture medium [DMEM/F12 (Gibco), 5% fetal bovine serum (FBS, Sigma Aldrich), 1% PenStrep (Gibco), and 10 ng/ml GM-CSF (R&D System)] and plated onto 12 mm glass coverslips. 50 µl, containing  $8 \times 10^4$  cells, was plated onto each coverslip placed inside of a well of a 24-well tissue culture plate. Cells were then left to attach for 30' at 37 °C, 5% CO<sub>2</sub>. After the 30 min incubation, 450 µl of culture media were added to each well containing the coverslips. The following day, media was exchanged for fresh media, and the cells were incubated for a further five days at 37 °C, 5% CO<sub>2</sub>. After day five, cultured microglia were further processed for immunostaining, or labeling with LipiDyeII [1 µM overnight (O/N) incubation at 37 °C, 5% CO<sub>2</sub>] or Lysotracker (500 nM for 30 min). For fixation, cells were washed three times with 1X PBS and fixed with 4% PFA for 15 min at RT. Alternatively, cells were fixed with ice-cold methanol: acetone (1:1) at -20 °C for GRP75 and LAMP 1 immunostaining.

### Immunostaining

Fixed coverslips were further processed for immunostaining by first blocking and permeabilizing with 0.05% Triton X-100 in 10% NGS/PBS. To quench autofluorescence, coverslips were then treated with 1X TrueBlack solution for 30 s, followed by three washes with 1X PBS. Coverslips were then incubated with primary antibody diluted in 10% NGS/PBS O/N at 4 °C. After the O/N incubation, coverslips were washed three times in 1X PBS, followed by a 1 h RT incubation with secondary antibody diluted in 10% NGS/PBS (and where indicated, 100 µg/ml Filipin dye for cholesterol staining was also added to the secondary diluted antibody solution). For LAMP 2 A staining, 1% BSA/ 2% NHS/ 0.05% Saponin/ 1X PBS was used for blocking and antibody dilutions. Cells were washed and mounted with or without DAPI using Prolong Gold anti-fade mounting media, according to manufacturer guidelines. Samples were imaged on a Zeiss Epifluorescent Microscope equipped for digital capture of fluorescent images.

### Sample preparation for mass spectrometry

The microglial proteome of *Cln3*<sup>Δex7/8/Δex7/8</sup> mice was compared with those of littermate control heterozygous (*Cln3*<sup>Δex7/8/+</sup>) or wildtype (*Cln3*<sup>+/+</sup>) mice at 3 (*Cln3*<sup>Δex7/8/Δex7/8</sup> *n* = 5 vs controls *n* = 7) and 12 months (*Cln3*<sup>Δex7/8/Δex7/8</sup> *n* = 4 vs controls *n* = 5) of age. Microglia were acutely isolated using MACS with CD11b microbeads (Miltenyi Biotec) as above and as previously described<sup>33</sup>. Sample preparation and mass spectrometric measurements using data independent acquisition were performed as previously described<sup>75</sup>. Data analysis was performed with Spectronaut 12.0.20491.14.21367 using a microglia spectral library generated in Sebastian Monasor et al.<sup>75</sup>. Briefly, peptide and protein FDR were set to 1%. Protein label free quantification (LFQ) required at least two peptides. The statistical data analysis was performed in Perseus version 1.6.15.0<sup>77</sup>. Protein LFQ intensities were log2 transformed and two-sided Student's T-tests were performed between

*Cln3*<sup>Δex7/8/Δex7/8</sup> and controls at 3 and 12 months to evaluate the significance of protein abundance changes. Only proteins with at least three valid values per group were considered for statistical testing. Additionally, a permutation-based FDR was used for multiple hypothesis correction<sup>78</sup> (*p* = 0.05, *s*<sub>0</sub> = 0.1).

The gene ontology enrichment for cellular component (GOTERM\_CC\_FAT) and biological process (GOTERM\_BP\_FAT) were carried out with the webtool DAVID<sup>79</sup>. Proteins with an absolute log2 fold change larger than 0.5 and a *p*-value less than 0.05 were used as a target list and were compared with the list of all relatively quantified proteins as background.

### Immunoblot analysis

Acutely isolated microglia were lysed in lysis buffer (50 mM Tris, 150 mM NaCl, 0.2% Triton X-100) containing protease inhibitors (cOmplete Mini, Sigma Aldrich). Cells were completely lysed by passing the lysates through a 25 G needle ten times followed by incubation on ice for 10 min. Lysates were then cleared by centrifugation at maximum speed in a Microfuge® 18 (Beckman) inside a 4 °C cold room. Supernatants were collected and lysate protein content was quantified using a Pierce™ BCA Protein Assay Kit according to the manufacturer's protocol. 10–20 µg of total protein per sample was separated on a bis-tris acrylamide gel, followed by Western transfer and immunoblotting on nitrocellulose membrane (Bio-Rad). Immunoblots were developed using horseradish peroxidase-conjugated secondary antibodies (GE Healthcare) and the Western Lightning® Plus-ECL reagent (Perkin Elmer). Actin was used as a loading control. Developed immunoblots were imaged using an iBright FL1500 Imaging system (ThermoFisher) or on X-ray films. Immunoblot densitometry (*n* ≥ 3 replicate samples) was performed using the gel analyzer tool in ImageJ (NIH).

### Crude myelin preparation and phagocytic assays

Dissected three-month-old wildtype mouse brains were sonicated in 10 mM HEPES/ 5 mM EDTA/ 0.3 M Sucrose/ Protease inhibitors buffer. A sucrose gradient was prepared in ultracentrifuge tubes with 0.85 M sucrose (pH 7.4) on the bottom and 0.32 M sucrose (pH 7.4) on top. The brain homogenate was added to the sucrose gradient and centrifuged at 75,000 *g* for 30 min with a SW41 Ti rotor. The myelin fraction from the interface was collected in a new ultracentrifuge tube, and osmotic shock was applied with ultra-pure water by centrifuging the tubes at 75,000 *g* for 15 min three times. The yield of myelin was quantified by BCA assay, and some of the myelin was labelled with the green-fluorescent cell linker kit (PKH67 labeling kit, Sigma), according to manufacturer's specifications.

For myelin phagocytosis, unlabeled or green fluorescent labeled myelin was resuspended with a 27 G needle in microglial medium. Primary microglia were then incubated with 10 µg/ml of the resuspended myelin; for monitoring myelin uptake, cells were incubated with green fluorescent myelin for 2 h in a 37 °C incubator<sup>33</sup>, followed by three 1X PBS washes, and fixation with 4%PFA at RT for 15 min at the indicated timepoints. Myelin (green) phagocytosis inside phagocytic Lamp2a-positive vesicles (red) was monitored by fluorescent microscopy. For unlabeled myelin turnover studies, microglia were incubated with 10 µg/ml of the resuspended myelin for 6 h at 37 °C, 5% CO<sub>2</sub>. Myelin containing media was then removed, cells were washed three times with 1X PBS, and fresh microglial medium was added. Further incubation for the indicated times was followed by fixation and further processing for labeling and imaging studies. For microglia rescue experiments, after unlabeled myelin washout, microglia were incubated for an additional 48 h, and for the last 24 h, small molecule compounds (10 µM concentration) were added (with or without LipiDyeII (1 µM), as indicated). At the end of 48 h, cells were fixed with 4% PFA at RT for 15 min and further processed for immunostaining. ML-SA5 was confirmed to have activity on the autophagy marker, LC3 by immunoblot analysis of LC3-II levels (Supplementary Fig. 6).

### Transmission electron microscopy (TEM) of isolated microglia

Microglial cells were isolated as described above, the only exception being that the flow through from the MACS separation LS column was again loaded on

the MACS separation MS column (Miltenyi Biotec) to ensure highest purity of the microglial fraction for TEM imaging. Brains from three 12-month-old mice/genotype were collected for three independent microglial preps/genotype for the TEM studies ( $N = 3/\text{genotype}$ ). The microglia pellets were collected and resuspended (1 h at RT with gentle rotation) in 4% glutaraldehyde in cacodylate buffer. Fixed isolated cell suspensions were stored at 4 °C until they were ready to be processed and sectioned for imaging.

Fixed isolated cell suspensions were centrifuged (3500 rpm for 20 min @ 4 °C) to re-form a pellet aggregate, which was then resuspended for 1 h at RT on a gentle rotator. Samples were rinsed multiple times in 0.1 M cacodylate buffer, centrifuging to re-pellet as needed. Following supernatant removal, pellets were stabilized in 2% agarose in PBS, and the agarose-embedded pellets were then dehydrated using a graded series of ethanols to 100%, followed by a brief (10 min) dehydration in 100% propylene oxide. Dehydrated samples were then pre-infiltrated O/N in a 1:1 mix of propylene oxide:Eponate resin (Ted Pella, Redding, CA) on a gentle rocker at RT. The following day, samples were placed into fresh 100% Eponate, which was allowed to infiltrate for several hours before embedding with additional 100% Eponate in flat molds. Resin was then allowed to polymerize 24–48 h at 60 °C. Thin (70 nm) sections were cut on a Leica EM UC7 ultramicrotome using a diamond knife (Diatome U.S., Fort Washington, PA) and collected onto formvar-coated grids. Sections were then contrast-stained with 2% uranyl acetate and Reynold's lead citrate, followed by examination on a JEOL JEM 1011 transmission electron microscope at 80 kV. Images were collected using an AMT digital camera and imaging system with proprietary image capture software (Advanced Microscopy Techniques, Danvers, MA).

For the purposes of morphometric quantification a minimum of 38 nucleated cells/biological replicate sample were captured at 20,000X magnification. The number of storage bodies and lipid structures in each cell was then counted from intact cells in the images (i.e. full cell must have been visible in the image) until a total of 38 nucleated cells/biological replicate sample was reached (totaling 114 cells/genotype), and quantification data were further plotted and analyzed using GraphPad Prism.

### TEM of optic nerves

Mice were euthanized with CO<sub>2</sub> (according to the guidelines by the State Office of Health and Social Affairs Berlin), blood was removed by transcardial perfusion with PBS containing heparin and tissue was fixed by perfusion with 4% PFA and 2% glutaraldehyde in cacodylate buffer. Optic nerves were collected, postfixed overnight, osmicated, and processed for light and electron microscopy as previously described<sup>31,32</sup>; morphometric quantification of neuropathological alterations was performed using a LEO906 E electron microscope (ZEISS) and corresponding software iTEM v.5.1 (Soft Imaging System). On average, 5 regions of interest (approximately 1000 fibers per individual optic nerve) were analyzed per optic nerve per mouse. The percentages of fibers showing myelin aberrations were identified individually by their characteristic morphological features in electron micrographs and related to the number of all investigated fibers per optic nerve per mouse. Images were processed (rotation, cropping, addition of symbols and pseudocolor) to generate figures using Photoshop CS6 and Illustrator CS6 (Adobe).

### Motility assay

20,000 microglial cells were seeded per 96 Well Black/Clear Bottom Plate (TC Surface, cat number 165305). Microglial cells were imaged on a IncuCyte® Live-Cell Analysis System (Sartorius), at 20X, every 15 min, for 5 h. Image sets were exported from the software as 8-bit .tif files, imported into FIJI image analysis software, and an image stack file was created. As described previously, the center of the nucleus on each image for every cell during the time course was tracked using the Manual Tracking plugin of ImageJ, and the velocity ( $\mu\text{m}/\text{min}$ ) of each cell was quantified using the Chemotaxis Tool plugin of ImageJ and a Rose diagram graph data presentation<sup>80</sup>.

### Image analysis

For intensity comparisons, color images were converted to gray, and using CellProfiler, both the primary (nucleus) and the secondary (cells) objects were identified. Each cell's specific channel intensity was thresholded and measured using the MeasureObjectIntensity module to analyze the total intensity of a specific channel in each cell.

For the lysosomal diameter quantification, the method used by Cao et al.<sup>81</sup> was used with the following specific details. 32 cells were analyzed for wild type microglia and 40 cells were analyzed for homozygous *Cln3<sup>Δex7/8</sup>* microglia. Using ImageJ, all of the lysosomes from cells containing a minimum of three lysosomes with diameters bigger than 2  $\mu\text{m}$  were measured. The minimum size of a quantified vesicle diameter was set to 0.25  $\mu\text{m}$  and the average vesicle diameter per cell was plotted.

To quantify the number of lysotracker positive vesicles per cell, nuclei were identified as primary objects and expanded to identify cells using CellProfiler. The IdentifyPrimaryObjects module was used to identify and threshold vesicles from the identified cells' images. The RelateObjects module was used to identify the vesicles and their numbers in each cell.

For the Golgi compactness calculation, the primary (nucleus; A), secondary (cell; B), and tertiary (Golgi; B-A) objects were identified using CellProfiler. The MeasureObjectSizeShape module was used to see each cell's compactness value for the Golgi<sup>82,83</sup>.

For the mitochondrial fragmentation and length analysis, the primary (nucleus; A), secondary (cell; B), and tertiary (mitochondria; B-A) objects were identified using CellProfiler. Mitochondria features were suppressed and thresholded, and the MorphologicalSkeleton module was used to get the mitochondrial skeleton. Primary objects were identified from the skeleton image to identify each mitochondria in each cell. Mitochondrial primary objects were shrunk, and endpoints were added by the Morph module. Primary objects were identified and shrunk from the endpoint data. Lastly, the MeasureObjectSkeleton module was used to have the values for mitochondrial fragmentation and the length of each mitochondria from every cell<sup>84</sup>.

For the LD analysis, primary objects were identified and expanded to identify cells using CellProfiler. The IdentifyPrimaryObjects module was used again to identify LDs from the identified cells' images. The RelateObjects module was used to identify the LDs of each cell and calculate their numbers in every single cell.

For MBP and PLP fluorescent intensity measurement, tile scan images captured using the Zeiss Celldiscoverer 7 microscope were initially processed through the ImageJ "Make Binary" tool for binary image conversion. Subsequently, the region of interest was delineated using the ImageJ "Freehand Selections" tool on the binary image. The region of interest was the outline of the tissue section, with folds in the tissue excluded. The ImageJ "Measure" tool was employed to directly assess the mean intensity values for MBP and PLP fluorescence by utilizing the "mean grey value" readout. Mean MBP and PLP fluorescent intensities were measured in three separate brain sections per animal, which were then averaged for subsequent statistical analysis, as done previously<sup>85</sup>.

### Statistical analysis

An unpaired Student's t-test with a two-tailed distribution was used to compare the two groups (Figs. 1, 2, 3, 4a–c, 6) (Supplementary Figs. 3, 4, 7). One-way ANOVA followed by Tukey's multiple comparisons test was used to compare multiple groups (Fig. 5) (Supplementary Fig. 6). Two-way ANOVA followed by Sidac's multiple comparison test was used to compare the mean differences between groups split into two independent variables (Fig. 4e) (Supplementary Fig. 5). GraphPad Prism 10.0.2 was used for all. A value of  $P \leq 0.05$  was considered significant ( $*P \leq 0.05$ ;  $**P \leq 0.01$ ;  $***P \leq 0.001$ ;  $****P \leq 0.0001$ ).

### Ethics approval and consent to participate

Studies involving use of mice underwent thorough review and approval by the Subcommittee on Research Animal Care at MGH, ensuring adherence

to government regulations and guidelines for animal welfare (Protocol # 2008N000013).

### Reporting summary

Further information on research design is available in the Nature Portfolio Reporting Summary linked to this article.

### Data availability

The authors declare that the source data supporting the findings of this study are available within the paper and the associated supplementary information files (Supplementary Figs., Supplementary Data 1–3). All other data are available from the corresponding author on reasonable request. The mass spectrometry proteomics data have been deposited to the ProteomeXchange Consortium via the PRIDE partner repository with the name “Proteomics of CLN3-deficient murine microglia identifies a disease associated phenotype with lysosomal alterations” and with the dataset identifier PXD048550.
