Received 9 September 2004/Returned for modification 23 November 2004/Accepted 17 December 2004

Forty-eight *Streptococcus pneumoniae* isolates recovered from sputum samples from 26 cystic fibrosis (CF) patients attending our CF unit (1995 to 2003) were studied. Mean yearly incidence of isolation was 5.5%, and all were strains recovered from young patients (≤ 12 years). The isolation was linked to clinical exacerbation in 35% of the cases, but only 27% of these were not accompanied by other CF pathogens. Fifty percent of the patients presented with two to four isolates over the studied period. Pulsed-field gel electrophoresis-SmaI digestion revealed a high heterogeneity (32 pulsotypes among 48 isolates) and the persistence over a 6-month period of a single clone (clone A) in two patients. This clone, presenting a varied multiresistance phenotype, was identified as the Spain^{23F}-1 clone and was also recognized in six other patients, including two out of nine patients from the CF unit of Sant Joan de Dèu Hospital, Barcelona, Spain. In our isolates, 16 different serotypes were recognized, the most frequent being 23F (33.3%), 19F (18.8%), 6A (6.2%), and 6B (6.2%). High overall resistance rates were observed: to penicillin, 73%; to cefotaxime, 33%; to erythromycin, 42%; to tetracycline, 58%; to chloramphenicol, 48%; and to trimethoprim-sulfamethoxazole, 67%. Resistance to fluoroquinolones was not detected. Multiresistance was a common feature (60%). The percentage of *S. pneumoniae* strains with increased frequencies of mutation to rifampin resistance ($\geq 7.5 \times 10^{-8}$) was significantly higher ($P = 0.02$) in CF (60%) than among non-CF (37%) isolates in the same institution (M. I. Morosini et al., *Antimicrob. Agents Chemother.* 47:1464–1467, 2003). Even though a clear association with acute exacerbations could not be observed, long-term clonal persistence and variability, high frequency of antibiotic resistance, and hypermutability indicate the plasticity for adaptation of *S. pneumoniae* to the CF lung environment.

Streptococcus pneumoniae is the causative agent of severe infections, many of which may have strong epidemiological impacts, such as meningitis, otitis media, pneumonia, and sinusitis. The primary site of colonization of this pathogen is the nasopharyngeal epithelium, where it can persist as part of the commensal flora. The main cause of pneumonia is progression of the organism towards the lungs through aspiration, although its consolidation requires additional events (10, 38). The pathogenic role of *S. pneumoniae* in cystic fibrosis (CF) is controversial, and very few reports document its potential involvement in pulmonary damage (5, 15, 16). Gilligan (14) stated in 1991 that *S. pneumoniae* seems to play, if at all, a role secondary to that of other organisms that are clearly implicated in lung infections associated with CF. Studies in the early 1960s and 1970s established that *S. pneumoniae* isolates are occasionally recovered from the respiratory secretions of CF patients (15, 17, 18, 22). Isolation occurred predominantly in infants and young children but not at a frequency higher than in non-CF patients. The isolation of *S. pneumoniae* was associated with 5% of the acute-exacerbation episodes (16).

Although *S. pneumoniae*, in addition to nonencapsulated *Haemophilus influenzae* and respiratory viruses, has been considered to predispose patients to acute and chronic airway infections for other commonly encountered CF organisms, including mucoid *Pseudomonas aeruginosa* and *Staphylococcus aureus*, (19), recent studies and reviews have paid little attention to this pathogen (13, 21). Even the Cystic Fibrosis Foundation does not record the frequency of isolation of this organism in its annual reports (9). The population structure and the corresponding antibiotic susceptibility patterns of commonly encountered CF isolates have been repeatedly studied (30, 34) but have never included *S. pneumoniae* isolates from CF patients.

CF patients may be chronically colonized with mucoid *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and nonencapsulated *H. influenzae*, but this does not seem to be the case with *S. pneumoniae* (14, 30). Chronic colonization, high bacterial loads, and exposure to frequent antibiotic courses have traditionally been considered as important factors for antimicrobial resistance development in CF pathogens. More recently, the role of mutator populations has been highlighted to accelerate this process in CF patients (27, 30, 31). We and other authors have found that *P. aeruginosa*, *S. aureus*, and *H. influenzae* from CF patients are more frequently hypermutable than those from non-CF patients, and an association with mutational antibiotic resistance has been demonstrated. Although

the presence of mutators has also been studied in *S. pneumoniae* isolates in non-CF patients (23), their frequency in isolates from CF patients has not been documented.

The population structure of *S. pneumoniae* isolates consecutively recovered from CF patients is studied in this work to evaluate the possible persistence of the same strain and its potential role in pulmonary exacerbations. The serotype distribution, antimicrobial susceptibility pattern, and mutation frequencies of these isolates were also determined. This study was made possible by a long-term follow-up of patients (during 1995 through 2003).

MATERIALS AND METHODS

Bacterial isolates, patients, and medical chart review. From 1995 to 2003, a total of 26 CF patients (10 females and 16 males), clinically and microbiologically followed in the CF unit of the Ramón y Cajal University Hospital in Madrid, Spain, had at least one positive sputum or respiratory secretion culture for *S. pneumoniae*. Medical charts were reviewed, demographics and antimicrobial use in the 6 months prior to pneumococcal isolation were determined, and clinical and microbiological data were collected. The potential correlation of *S. pneumoniae* colonization/infection with pulmonary exacerbation was studied. The presence of *P. aeruginosa*, as well as other commonly encountered CF pathogens, was also recorded as outcome criteria for the evaluation of the progression of pulmonary disease. Microbiological data were recovered from 26 patients, and clinical data were recovered from only 20 patients. The nine *S. pneumoniae* isolates obtained from eight CF patients followed at Sant Joan de Dèu Hospital in Barcelona, Spain, from 1997 to 2003 were included only in the population structure study.

Bacterial isolation and identification. Respiratory samples collected during both scheduled clinical assessments and pulmonary exacerbations were homogenized with *N*-acetyl-cysteine and seeded in Columbia 5% blood, MacConkey, mannitol-salt, and a selective *Burkholderia cepacia* agar medium with a quantitative technique (37) and incubated in ambient air for 24 h at 35°C. In addition, bacitracin-chocolate agar was seeded and incubated in a 5% CO₂ atmosphere for 48 h at 35°C. *S. pneumoniae* isolates were identified on the basis of standard laboratory procedures, including colony morphology on blood agar, the optochin test, and the sodium deoxycholate solubility test (33). Isolates were stored in skim milk at -70°C and reidentified when they were recovered from storage for further studies. The National Center of Microbiology of Spain (Instituto Carlos III, Majadahonda, Madrid) performed the serotyping with the Quellung reaction, using antisera from the Statens Seruminstitut, Copenhagen, Denmark.

Bacterial-population analysis. Population structure was studied by pulsed-field gel electrophoresis (PFGE). Chromosomal DNA was prepared according to the classical gram-positive protocol with some modifications (R. Del Campo et al. unpublished data). DNA restriction was made with the endonuclease SmaI (Amersham Biosciences Europe GmbH, Freiburg, Germany). The electrophoresis was carried out in a CHEF DR-III apparatus (Bio-Rad, Birmingham, United Kingdom) for 23 h at 14°C, and the following settings were applied at 6 V/cm: 1 to 30 seconds. Wild-type laboratory R6 *S. pneumoniae* strain and a lambda ladder PFGE marker (New England Biolabs Inc., Beverly, MA) were used as an internal pneumococcal control and a molecular size standard, respectively. Genetic relatedness among the strains was analyzed visually and interpreted by the Phoretix 5.0 software (Nonlinear Dynamics Ltd., United Kingdom) using Dice's coefficient to construct the corresponding dendrogram.

Antimicrobial susceptibility testing. MICs of penicillin, ampicillin, amoxicillin-clavulanic acid, cefuroxime, cefotaxime, cefepime, meropenem, vancomycin, teicoplanin, erythromycin, clindamycin, tetracycline, ciprofloxacin, levofloxacin, trimethoprim, chloramphenicol, and rifampin were determined by the standard NCCLS technique (25) using cation-adjusted Mueller-Hinton broth supplemented with 5% lysed horse blood (Oxoid, Basingstoke, United Kingdom). Susceptibility panels were incubated overnight at 35°C in ambient air after inoculation. *S. pneumoniae* ATCC 49619 and *S. aureus* 29213 were used as controls in each run. MIC breakpoints recommended by the NCCLS were considered for all antibiotics (26). For cefotaxime, the NCCLS meningitis criterion was applied.

Determination of mutation frequencies. Three to five colonies from an overnight culture in 5% sheep blood agar plates (Oxoid) were resuspended in 10 ml of brain heart infusion (BHI) broth (Oxoid) and incubated for 6 to 8 h at 35°C without shaking. For total viable count determination, an aliquot of 100 µl was diluted in BHI broth and plated onto 5% sheep blood agar plates. The remaining culture was centrifuged for 5 min at 2,500 × *g*. The pellet was resuspended in 50

µl of BHI broth and seeded on 5% sheep blood agar plates containing 2 µg/ml of rifampin. Mutation frequency values are reported as the proportion of rifampin-resistant colonies (detected after 48 to 72 h of incubation in a 5% CO₂ atmosphere) versus total viable-cell counts. Results correspond to the mean value obtained in duplicate experiments, each with duplicate colony counts.

We estimated only mutation frequencies exceeding 5×10^{-9} , considering lower frequencies of mutation as possibly artifactual, due to the impaired growth of cells under the applied selective conditions. A strain was considered a mutator strain when its frequency was equal to or higher than 7.5×10^{-8} . This breakpoint was derived from the value which separated the two main populations (normo-mutable and hypermutable) in a previous study of 200 non-CF isolates (23). The DNA repair-proficient normo-mutable (2.6×10^{-8}) strain R800 (*ami*⁺ *aliA*⁺ *aliB*⁺ *hex*⁺) and its DNA repair-deficient hypermutable (1.06×10^{-7}) derivative strain R310 (*hexA*::_{syn}Spc) (1) were used as controls for normo- and hypermutator populations, respectively.

Statistic analysis. Statistical significance for comparison proportions was calculated by the chi-square test, and quantitative values were compared by Student's *t* test. A *P* of <0.05 was considered statistically significant.

RESULTS

Epidemiological background. A total of 48 *S. pneumoniae* isolates were recovered from 26 CF patients (one to four isolates per patient) who attended the CF unit of the Ramón y Cajal University Hospital (Madrid, Spain) from 1995 to 2003. The dates of isolation, genders, and ages of patients are presented in Table 1. The yearly incidence of patients infected or colonized with *S. pneumoniae* ranged from 2.4% to 13.5% (mean value from 1995 to 2003, 5.5%). For six patients, medical charts were not available and only data from microbiology laboratory files were used. *S. pneumoniae* isolates from each patient were always recovered during infancy or early childhood (range, <1 to 12 years; mean ± standard deviation, 5.3 ± 3.6 years). Thirteen patients (50%) presented with a single episode of pneumococcal colonization or infection over the studied period. For six patients, *S. pneumoniae* was isolated two different times (23%), for five other patients, it was isolated three different times (19%), and finally, for two patients it was isolated four different times (8%). No differences in the median ages of acquisition for patients with single or repetitive episodes were observed. Repetitive episodes were separated for a period of time ranging from 1 month to 53 months (mean ± standard deviation, 16 ± 16 months). Microbiological data revealed that *S. pneumoniae* isolates in our CF patients were recovered without the concomitant presence of other CF pathogens in 18 episodes (18/48, 37.5%). The corresponding figures of isolation with other pathogens were 16/48 (33.3%) for *S. aureus*, 15/48 (31.2%) for *H. influenzae*, 11/48 (22.9%) for *P. aeruginosa*, 4/48 (8.3%) for *Aspergillus* spp., and 2/48 (4.2%) for *Achromobacter xylosoxidans*.

Clinical findings. The retrospective analysis of medical charts from 20 patients revealed that only 7 presented evidence of acute exacerbation at the time of isolation of *S. pneumoniae* (35%). One of these patients had a single *S. pneumoniae* isolate along the entire period studied, and six patients had more than one isolate. In one of these patients acute exacerbations were consistently associated with the repetitive isolation of *S. pneumoniae*. When exacerbation was present (12 episodes for seven patients), *S. pneumoniae* was not recovered with other pathogens in 6 episodes (6/12, 50%), whereas it coexisted with *S. aureus* and *P. aeruginosa* in 3 episodes (3/12, 25%), with *S. aureus* and *H. influenzae* in two episodes (2/12, 17%), and with *S. aureus* and *Aspergillus* spp. in one episode (1/12, 8%) (Table

1). Bacterial counts (Table 1) showed that the bacterial loads of *S. pneumoniae* during exacerbation episodes ranged from 1 × 10⁷ to 3 × 10⁸ CFU per ml of sputum sample (geometric mean, 1 × 10⁷ CFU/ml) and from 2 × 10³ to 5 × 10⁸ (geometric mean, 5 × 10⁵ CFU/ml) during the nonexacerbation periods. Despite clear differences in geometric mean values, no statistical difference was observed.

On the other hand, chart review revealed that during the 6 months prior to pneumococcal isolation, patients received in

monotherapy or in combination a β-lactam (60%), fluoroquinolone (ciprofloxacin) (40%), or macrolide (20%) antibiotic.

Population structure. The serotype distribution determined for 48 *S. pneumoniae* isolates from Ramón y Cajal University Hospital and PFGE results are presented in Table 1. Serotype 23F was the most frequently observed (16 isolates), followed by serotypes 19F (9 isolates), 6A (3 isolates), and 6B (3 isolates). Other serotypes were represented by one or two isolates. PFGE-SmaI digestion and the subsequent computer analysis

clustered the 48 CF isolates in a total of 32 different pulsotypes. In 28 out of the 32 pulsotypes, a single isolate was present, whereas pulsotypes I, M, and AA (serotypes 19F, 6A, and 37, respectively) comprised two CF *S. pneumoniae* isolates each, and pulsotype A (serotype 23F) represented a total of 14 isolates (obtained from eight CF patients from 1995 to 2003). Within pulsotype A, five different genetically close related variants (A-1, A-2, A-3, A-4, and A-5) were observed. The PFGE-SmaI digestion-based genetic relationships were also investigated in the Sant Joan de Dèu Hospital CF *S. pneumoniae* collection (nine isolates from eight patients). Interestingly, two isolates from two patients corresponded also to two different variants of pulsotype A (A-6 and A-7), denoting a close relatedness with those isolates previously characterized in the Ramón y Cajal University Hospital collection (Fig. 1). It is of note that this pulsotype A, detected in both hospitals (which are geographically separated), corresponded to the major clone Spain^{23F}-1 and presented a uniform resistance phenotype. This included resistance to penicillin, chloramphenicol, and trimethoprim-sulfamethoxazole. Other subtypes within this clone presented various susceptibility patterns to other antimicrobials (see below).

Table 1 also shows the evolution of the different pulsotypes in each patient. The evolution of pulsotype A was particularly interesting in one patient (patient 26), in whom the original clone and subtype A-5 coexisted in 1996, whereas after nearly 5 years, in 2000, the A-3 variant was detected.

Antimicrobial susceptibility and multiresistance. Susceptibility results and the different antibiotic resistance combinations are shown in Tables 1. High rates of antibiotic resistance (intermediate plus resistant) were observed for antibiotics commonly used for the treatment of infections due to *S. pneumoniae*, such as penicillin (73.0%), cefotaxime (33.4%), erythromycin (41.7%), tetracycline (58.4%), chloramphenicol (48.0%), and trimethoprim-sulfamethoxazole (66.6%) (Table 2). Resistance to glycopeptides and quinolones was not ob-

served, and only one isolate was resistant to rifampin. To analyze the multiresistance status, combinations of phenotypic resistance markers to penicillin, cefotaxime, erythromycin, tetracycline, chloramphenicol, and trimethoprim-sulfamethoxazole were considered. More than 60% of isolates were resistant to three or more antibiotics, whereas 30% were susceptible to all antibiotics tested. It should be noted that nearly 50% of isolates were resistant to four or more antibiotics. Among these isolates the most frequent multiresistance combination was penicillin, tetracycline, trimethoprim-sulfamethoxazole, and chloramphenicol.

Several antibiotic resistance phenotypes were observed within isolates belonging to clone A (Table 1). The international clone Spain^{23F}-1 uniformly shows resistance to penicillin, tetracycline, chloramphenicol, and trimethoprim-sulfamethoxazole (11). Among the clone A isolates, this resistance pattern was detected in two out of three isolates; other isolates also showed resistance to cefotaxime. Other variants also included resistance to erythromycin and tetracycline.

Mutation frequency studies. Frequencies of mutation to rifampin in the CF *S. pneumoniae* isolates are shown in Fig. 2. Considering all isolates, we obtained frequencies of mutation ranging from 4.5×10^{-10} to 6.8×10^{-7} , but only mutation frequencies exceeding 5.10^{-9} were considered reliable for further calculations. Very low frequencies of mutation are possibly artifactual in *S. pneumoniae*, due to the impaired growth of cells under the applied selective conditions or autolysis during extended incubation. Within the accepted range, we obtained two main peaks, which corresponded to frequencies of 1×10^{-8} and 1×10^{-7} (10-fold difference), identical to those previously found in pneumococci from non-CF patients (23). Normomutable and hypermutable control strains had mutation frequencies around the corresponding peak distributions. Forty percent of the strains within the accepted range were included around the normal mutation frequency peak of the population distribution (5×10^{-9} to 7.4×10^{-8}), whereas 60%

FIG. 1. Dendrogram of genetic relatedness among CF *S. pneumoniae* isolates. ^aHSJD, isolates from the Hospital Sant Joan de Dèu collection; ^bNT, nontypeable isolate.

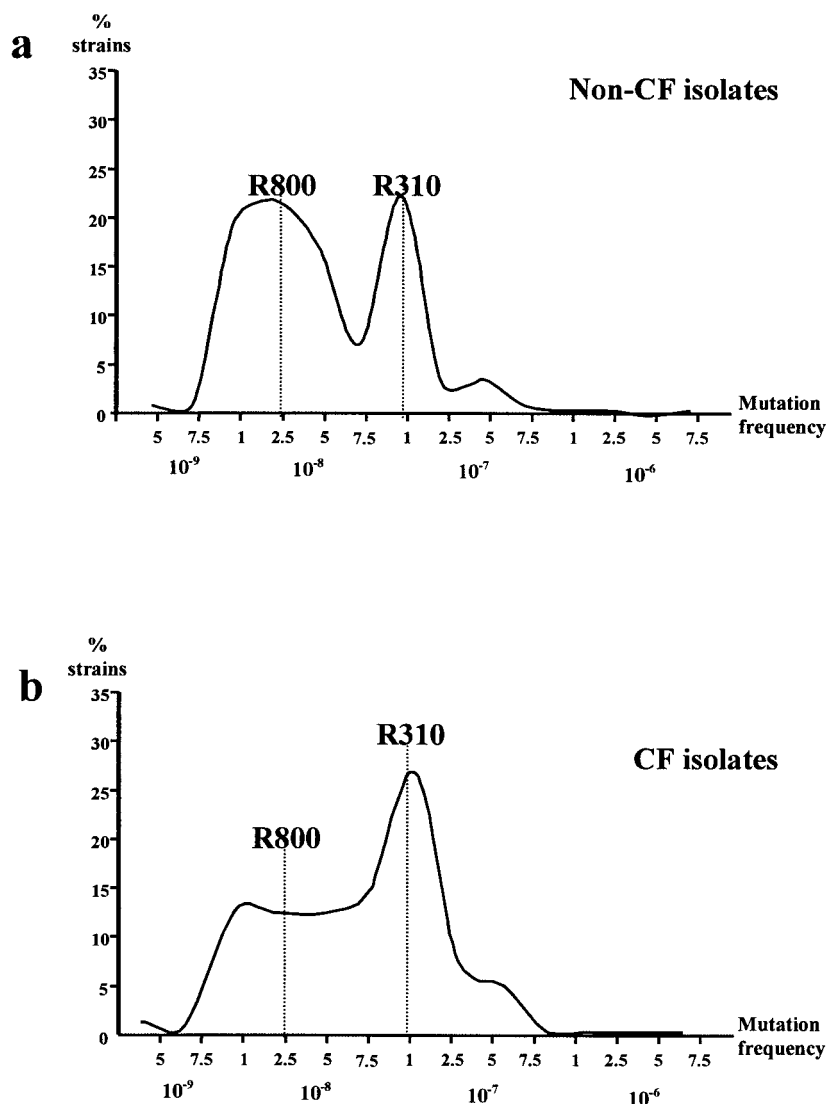

FIG. 2. Percentages of isolates exhibiting a given mutation frequency to rifampin resistance among (a) 195 *S. pneumoniae* isolates from non-CF patients (data are from reference 23) and (b) from 37 *S. pneumoniae* isolates from CF patients. The dotted lines show mutation frequencies of control strains as follows: for strain R800, normomutable (2.6×10^{-8}), and for R310, hypermutable (1.06×10^{-7}).

were distributed within the high mutation frequency peak (7.5×10^{-8} to 1×10^{-7}). In our previously published series of non-CF patients, the proportions of strains corresponding to the peaks of normal and high mutation frequency were 62% and 37%, respectively (23). These data suggest that the proportion of strains with increased mutation rates is higher among CF patients ($P = 0.02$).

A possible relationship between antibiotic resistance and hypermutable phenotypes was analyzed by the chi-square statistical method, but no significant correlation was observed. Similar antibiotic resistance percentages were observed among all categories of mutation frequency. We also investigated the distribution of the mutation figures among the pulsotypes and the serotypes of the isolates, corroborating a homogeneous distribution. When isolates with pulsotype A (corresponding to the serotype 23F) were taken into account, the mean mutation frequency was 7.53×10^{-8} , ranging from 1.07×10^{-7} to 9.4×10^{-8} . Four isolates

were located in the 10^{-7} category (mutator category), while the other seven isolates were in the 10^{-8} category.

DISCUSSION

Unlike that of *P. aeruginosa*, the role of *S. pneumoniae* in pulmonary damage occurring in CF patients is uncertain (14). Although this organism can be recovered from respiratory samples from CF patients in early stages of the disease (5, 16), there is no clear relationship with severe bacterial complications or with pulmonary deterioration (14). Older studies demonstrated that the level of isolation of *S. pneumoniae* from CF patients was not higher than from non-CF patients (17, 18, 22). More recently it has been shown that the majority of CF patients, like healthy individuals, have protective levels of antipneumococcal antibodies against the most-common circulating serotypes (20). From these data it could be considered that

the occurrence and epidemiology of *S. pneumoniae* in the nasopharynxes of CF patients might be similar to those of healthy carrier children. However, the results obtained in our study suggest that CF isolates present singular characteristics, including high antibiotic resistance rates, specific clonal relationships (at least in our isolates), and particularly increased rates of mutation frequencies compared with non-CF *S. pneumoniae* isolates previously described from the same institution (23).

The yearly occurrence of *S. pneumoniae* in CF patients ranged in our series from 2.4% to 13.5%, with a mean value of 5.5%. This value is much lower than that for *P. aeruginosa* (57.8%), *S. aureus* (49.7%), and *H. influenzae* (16.3%) in the 2002 CF Foundation Annual Data Report (9). Other authors in Germany have found similar occurrence rates (6.9%), but in other studies from Spain this value was higher (28.3%) (12), particularly when only a CF pediatric population was included in the study (50%) (24). In the United States, during a phase III national collaborative study of aerosolized tobramycin, the percentage of CF patients colonized with *S. pneumoniae* was 3.4% (6).

As in other studies, we cannot rule out the possibility that the isolation of *S. pneumoniae* was due to contamination of sputum samples with isolates from the oropharyngeal cavity. Doubtlessly the conditions of the bronchial epithelia of CF patients might facilitate *S. pneumoniae* deep colonization of the lung in the early stages of the process (8). Pneumococcal adherence might be facilitated by the increased exposure of cellular receptors, such as asialo-GM2, in damaged bronchial epithelia of CF patients, as a consequence of initial inflammatory events, following infections by respiratory viruses or mycoplasmas, or the actions of inflammatory cytokines (interleukin 1 [IL-1], IL-8, and tumor necrosis factor alpha), with a decreased production of the anti-inflammatory IL-10 (19, 38).

All *S. pneumoniae* isolates in our study were recovered from young patients, but only 35% of the patients had an exacerbation of their pulmonary symptoms at the time of isolation of this pathogen. The coexistence of this organism with others in 50% of exacerbation episodes, mainly *S. aureus* (50%), *P. aeruginosa* (25%), *H. influenzae* (16.7%), and *Aspergillus* spp. (8.3%), makes it difficult to evaluate its potential role in the exacerbation episodes of the studied CF patients. However, it may be possible that *S. pneumoniae* plays a role due to the nearly 100-fold difference that we found between geometric mean values of *S. pneumoniae* bacterial loads in sputum samples obtained from exacerbation and nonexacerbation episodes, although statistical significance was not reached.

Unlike other typical CF pathogens, *S. pneumoniae* is not known as a persistent colonizer and is considered as a transient organism in these patients (30). The evolution of individual clones with a theoretical new immunological aggression or acquisition of new strains may also suggest that in certain CF patients, *S. pneumoniae* may play a role in CF exacerbations favoring antimicrobial treatment. Eventually, the involvement of an *S. pneumoniae* strain in acute exacerbations of a particular patient may facilitate its replacement by newly acquired strains (36), as occurred in several patients in our study (Table 1). Nevertheless, the possibility of persistence of certain clones for years in the same patient was also suggested by our results. This is the case for the serotype 23 multiresistant clone A (patient 26) (Table 1). Interestingly, this clone was widely disseminated among the studied patients (8 out of 26 patients).

Two out of nine isolates collected in the Sant Joan de Dèu Hospital in Barcelona also corresponded to this clone. It is known that *S. pneumoniae* strains of the 23F serotype are widespread among children attending different day care centers in Portugal (35). Dissemination of *P. aeruginosa* clones among CF patients has previously been documented, even in very distant geographic areas (34), but to the best of our knowledge this has not been previously shown for *S. pneumoniae*.

Considering the possibility that certain clones of *S. pneumoniae* may be involved in early stages of lung inflammation in CF patients, a preventive therapeutic attitude could eventually be advisable to ensure eradication, as is recommended for *P. aeruginosa* (32). Data about the antibiotic resistance of *S. pneumoniae* strains isolated from CF patients remain scarce (7). Our CF pneumococcal pediatric isolates were unusually non-susceptible to antibiotics, if they are compared with those isolated from non-CF patients (11, 28), particularly to penicillin (75% versus 48.5%) and cefotaxime (33% versus 6.2%). We have previously reported similar differences for oropharyngeal streptococci belonging to the *viridans* group, which are significantly more resistant to penicillin and cefotaxime in CF patients than those of healthy children (2). Such observations suggest that the extended use of antimicrobial agents (including cefuroxime, ceftazidime, cefepime, and carbapenems) in CF patients might select for β -lactam-resistant pneumococci, including those belonging to particularly resistant clones. Unlike other pathogens from CF patients (7, 31), no fluoroquinolone-resistant *S. pneumoniae* isolates were observed. This fact may be related to the lower persistence of this pathogen in the pulmonary compartment in these patients and the lack of frequent administration of fluoroquinolones in monotherapy in our CF patients.

Our group and other authors have shown that increased rates of resistance in CF patients may be related to the high frequency of hypermutable *P. aeruginosa*, *S. aureus*, and *H. influenzae* CF isolates (27, 30, 31). The present study indicated that the frequency of pneumococcal strains with increased frequencies of mutation was also significantly ($P = 0.02$) higher in isolates from CF patients (62%) than in those from non-CF patients in the same institution (37%) (23). As in our previously published work on hypermutation in *S. pneumoniae* (23), we did not demonstrate any significant association of CF mutant strains with antibiotic resistance.

The knowledge of serotype distribution in *S. pneumoniae* isolates may have epidemiological and clinical implications. It has been recommended that all CF patients older than 2 years should receive the 23-valent polysaccharide vaccine against *S. pneumoniae* (3). Recent data from the Spanish Pneumococcal Reference Laboratory show that the most-prevalent serotypes accounting for nearly 60% of all pathogenic isolates are serotypes 14, 19F, 1, and 6B (28). In our CF series, 64.5% of the isolates correspond to serotypes 23F (33.3%), 19F (18.8%), 6A (6.2%), and 6B (6.2%), but 16 different serotypes were detected. PFGE-SmaI digestion demonstrated a genetic diversity among isolates of all serotypes, with the exception of the predominant clonal structure of serotype 23F (clone Spain^{23F}-1), the serotype most frequently involved in high-level penicillin resistance (MIC ≥ 2 μ g/ml) (28). The use of the seven-valent conjugate vaccine in CF patients may also reduce the carriage

of the 23F serotype, eventually reducing the high rates of β -lactam resistance.

In summary, *S. pneumoniae* might play a role in the early stages of lung colonization or infection in CF patients, and eventually some clones could persist and evolve within the host during prolonged periods of time and consequently facilitate the acquisition of high levels of resistance to β -lactam agents. The early use of vaccines and the application of antibiotics with low resistance rates in CF isolates may be suggested as measures to limit the possible impact of *S. pneumoniae* in CF patients.

ACKNOWLEDGMENTS

Rosa del Campo is a recipient of a contract from the Spanish Pneumococcal Infection Study Network (G03/103). This work was partially supported by research grants from the Spanish Pneumococcal Infection Study Network (G03/103) and the Microbial Sciences Foundation.

General coordination for the Spanish Pneumococcal Infection Study Network (G03/103) was provided by Román Pallarés. The following Spanish Pneumococcal Infection Study Network (G03/103) members and centers participated in this study: Ernesto García, Centro de Investigaciones Biológicas, Madrid; Julio Casal, Asunción Fenoll and Adela G. de la Campa, Centro Nacional de Microbiología, Instituto de Salud Carlos III, Madrid; Emilio Bouza, Hospital Gregorio Marañón, Madrid; Fernando Baquero, Hospital Ramón y Cajal, Madrid; Francisco Soriano and José Prieto, Fundación Jiménez Díaz y Facultad de Medicina de la Universidad Complutense, Madrid; Román Pallarés and Josefina Liñares, Hospital Universitario de Bellvitge, Barcelona; Javier Garau and Javier Martínez Lacasa, Hospital Mutua de Terrassa, Barcelona; Cristina Latorre, Hospital Sant Joan de Déu, Barcelona; Emilio Pérez-Trallero, Hospital Donostia, San Sebastián; Juan García de Lomas, Hospital Clínico, Valencia; and Ana Fleites, Hospital Central de Asturias.
