Abstract: Genome-wide association studies performed in patients with coronavirus disease 2019 (COVID-19) have uncovered various loci significantly associated with susceptibility to SARS-CoV-2 infection and COVID-19 disease severity. However, the underlying *cis*-regulatory genetic factors that contribute to heterogeneity in the response to SARS-CoV-2 infection and their impact on clinical phenotypes remain enigmatic. Here, we used single-cell RNA-sequencing to quantify genetic contributions to *cis*-regulatory variation in 361,119 peripheral blood mononuclear cells across 63 COVID-19 patients during acute infection, 39 samples collected in the convalescent phase, and 106 healthy controls. Expression quantitative trait loci (eQTL) mapping across cell types within each disease state group revealed thousands of *cis*-associated variants, of which hundreds were detected exclusively in immune cells derived from acute COVID-19 patients. Patient-specific genetic effects dissipated as infection resolved, suggesting that distinct gene regulatory networks are at play in the active infection state. Further, 17.2% of tested loci demonstrated significant cell state interactions with genotype, with pathways related to interferon responses and oxidative phosphorylation showing pronounced cell state-dependent variation, predominantly in $CD14^+$ monocytes. Overall, we estimate that 25.6% of tested genes exhibit gene-environment interaction effects, highlighting the importance of environmental modifiers in the transcriptional regulation of the immune response to SARS-CoV-2. Our findings underscore the importance of expanding the study of regulatory variation to relevant cell types and disease contexts and argue for the existence of extensive gene-environment effects among patients responding to an infection.

Keywords: single-cell RNA-seq, expression quantitative trait loci (eQTL), SARS-CoV-2 infection, COVID-19, gene-environment interactions

Main text:

Susceptibility to viral infection varies widely among individuals, influenced by a combination of host genetics and environmental factors. However, the precise contribution of each to immune response variation and disease progression remains unclear. Recent advances have demonstrated the considerable role of host genetics in shaping human immune response variation through expression quantitative trait loci (eQTL) mapping, applied to various immune cell subsets both at baseline and after exposure to immune stimuli and live pathogens. These 'immune response eQTL' studies have identified numerous genetic variants that underlie differences in immune responses to infection, including both cell type-specific eQTL and eQTL induced only upon infection (i.e., response eQTL)[1–5]. However, a significant limitation of these studies is that immune response measurements were largely collected *in vitro*, raising questions about the role of gene-environment interactions during viral infection *in vivo*.

More recently, efforts have expanded to explore other forms of genetic interaction effects, facilitated by the availability of population-scale cohorts genotyped and characterized by single-cell RNA sequencing[6]. Continuous cell state-dependent eQTL—eQTL that interact with specific cellular contexts defined at single-cell resolution—have been shown to explain more variation in gene expression than conventional, non-interacting eQTL[7]. Notably, autoimmune risk variants were enriched in these state-dependent loci[7,8], highlighting the critical importance of cellular context in understanding disease-relevant genetic variants.

The global COVID-19 pandemic highlighted the possible consequences of the spread of a novel virus in a naïve population. Particularly in the initial waves of the pandemic, substantial immune response variation and disease heterogeneity was observed among individuals infected with SARS-CoV-2, the virus that causes COVID-19. While a fraction of individuals succumbed

87   to severe disease, some developed typical influenza-like symptoms, while others harbored

88   asymptomatic SARS-CoV-2 infections[9]. Although much of this variation can be attributed to

89   environmental and social determinants[10], genetic factors also clearly play a role.

90   Genome-wide association studies (GWAS) conducted for SARS-CoV-2 susceptibility and

91   COVID-19 severity phenotypes revealed a handful of genome-wide significant loci associated

92   with these traits[11–13], often in genes related to viral immunity, including *IFNAR2* and *OAS1*[13]. An

93   eQTL mapping study performed in peripheral blood mononuclear cells (PBMCs) collected from

94   healthy individuals exposed to SARS-CoV-2 *in vitro* also found that response eQTL were highly

95   cell type-dependent, often specific to the SARS-CoV-2 infection condition in the myeloid

96   compartment[5]. Despite these findings, few studies have examined how genome-wide *cis*-

97   regulatory genetic variation influences immune response diversity directly in patients during active

98   viral infection[14].

99   In this study, we explore the nature of genetic interaction effects in the context of *bona fide*

100 SARS-CoV-2 infection, using patient cells sampled prior to the rollout of COVID-19 vaccines and

101 during longitudinal follow-up. We specifically investigate cell type-specific, disease state-specific,

102 and cell state-dependent gene regulatory heterogeneity, providing new insights into how genetic

103 variation shapes immune responses *in vivo*.

104

105 **Single-cell profiling reveals severity-dependent cellular restructuring in COVID-19 patients**

106 In this study, we used single-cell RNA-sequencing to profile the transcriptomes of PBMCs

107 collected from 106 healthy control donors, 63 hospitalized COVID-19 patients during the acute

108 stage of infection (days after symptom onset [DSO] ≤ 20 days, mean DSO at time of sampling =

109 12.1 days), and 39 samples obtained from a subset of recovered COVID-19 patients resampled at

4

110   various time points following their initial primary infection ("follow-ups", DSO > 20 days, mean

111   DSO = 128.8 days) (Fig. 1A, Fig. S1A, Table S1). Across individuals, we captured 361,119 high-

112   quality single-cell transcriptomes (n = 163,639 cells from controls, n = 131,457 cells from acute

113   patients, and n = 66,023 cells from follow-ups). Clustering followed by cell type label transfer

114   annotation from a multimodal human PBMC reference dataset (Hao et al.[15], detailed in Methods)

115   revealed 30 distinct immune cell types at fine-scale resolution (Fig. 1B).

116   We next sought to dissect the extent to which SARS-CoV-2 infection induces shifts in

117   underlying cell type composition across acutely-infected individuals compared to non-infected

118   healthy controls and recovered donors. Although all COVID-19 patients included in this study

119   were hospitalized at the time of sample collection, these patients spanned a range of clinical disease

120   severity, allowing us to evaluate the effect of severity on various molecular phenotypes. Disease

121   severity was assessed using a five-point scale of respiratory support needed at the time of acute

122   patient sampling, encompassing the following categories: Moderate (MOD, n = 16), Severe (SEV,

123   n = 17), 2-Critical (CRIT2, n = 9), 3-Critical (CRIT3, n = 20), and 4-Critical (CRIT4, n = 1). A

124   summary of basic demographic information stratified by disease severity can be found in Table

125   S1. Non-critical patients were defined as those requiring no oxygen supplementation (moderate

126   disease) or oxygen supplementation through a nasal cannula (severe disease), whereas critical

127   patients required mechanical ventilation, ranging from non-invasive ventilation (CRIT2) and

128   intubation (CRIT3) to extracorporeal membrane oxygenation (CRIT4).

129   We found that SARS-CoV-2 infection remodels the baseline cell type composition of

130   PBMCs observed in healthy individuals, with the magnitude of disease severity further modifying

131   this effect. The myeloid compartment displayed the most obvious infection- and severity-

132   dependent changes: classical CD14$^+$ monocytes were markedly expanded in all patient groups

133   compared to healthy donors ($p < 1 \times 10^{-10}$ for all comparisons against controls; here, all critical

134   patients [CRIT2 – 4] were considered as a single group), with the greatest expansion seen in severe

135   and critical cases (Fig. 2A). In the follow-up samples, CD14$^+$ monocyte proportions reverted back

136   to frequencies similar to those seen in baseline healthy control donors (Fig. 2A), suggesting that

137   this monocytic expansion is indeed infection-induced. Further, we observed that the frequency of

138   CD14$^+$ monocytes was strongly associated with disease severity, with more severe cases

139   consistently displaying a greater proportion of classical monocytes (Pearson's r = 0.60, p = 6.8 x

140   10^{-6}) (Fig. 2B).

141   We also detected reductions of CD56^{bright} natural killer (NK) cells ($p < 2 \times 10^{-4}$) and

142   plasmacytoid dendritic cells (pDC) ($p < 4 \times 10^{-3}$) in all severity groups compared to non-infected

143   individuals (Fig. 2A). pDCs are known for their ability to secrete large quantities of type I

144   interferon (IFN) following viral infection[16], and NK cells are key facilitators of antiviral immunity,

145   with CD56^{bright} NK cells being efficient producers of IFN-γ, TNF-α, and GM-CSF[17]. Our

146   observations are in line with previous studies showing reductions in frequencies of both NK cells

147   and pDCs in critical patients compared to healthy controls[18–21]. Together, this suggests that SARS-

148   CoV-2 infection induces atypical cell type composition that largely resolves after the infection

149   clears, particularly in cell populations known to be important in cytokine production and antiviral

150   immune responses.

151

152   **Disease severity underlies variation in the transcriptional response to SARS-CoV-2 in**

153   **hospitalized COVID-19 patients**

154   To tease apart how variation in disease severity influences the transcriptional immune

155   response to SARS-CoV-2 across cell types, we formally modeled the effect of severity on global

156   gene expression estimates among COVID-19 patients sampled during the acute phase of disease

157   (n = 63) within each cell type independently. In these analyses, we defined a set of top-level cell

158   type populations by combining our fine-scale clusters into major groups corresponding to the six

159   main cell types that comprise PBMCs, including CD4$^+$ T cells, CD8$^+$ T cells, B cells, NK cells,

160   CD14$^+$ monocytes, and CD16$^+$ monocytes. Within this broader set of cell populations, we

161   collapsed our single-cell gene expression estimates into pseudobulk estimates per sample,

162   generating six bulk-like gene expression matrices that were used for subsequent modeling. We

163   considered respiratory support score (described above) as a proxy for overall disease severity, and

164   modeled severity score as a numeric variable, which allowed us to capture genes with expression

165   levels linearly correlated with severity.

166   By far, CD14$^+$ monocytes showed the largest number of genes associated with severity (n

167   = 1,613, 14.8% of the transcriptome; FDR < 0.05), while other cell types had much less prominent

168   effects (< 1.0% severity-associated genes) (Table S2). As expected, severity-associated genes

169   largely overlapped those distinguishing COVID-19 patients from healthy controls (i.e., infection-

170   associated genes, |log$_2$FC| > 0.5, FDR < 0.05) across cell types (gene set overlap: 2.1-fold, p < 1 x

171   10^{-10}) (Fig. S1B, S1C, Table S3). Principal component analysis (PCA) on the CD14$^+$ monocyte

172   pseudobulk expression data revealed that variation in disease severity had a noticeable impact on

173   the transcriptional response of these cells, reflected in principal component (PC) 1 (10.9% percent

174   variance explained [PVE]) and PC2 (7.9% PVE), which both separated non-critical patients

175   (moderate/severe) from critical patients (Fig. 2C).

176   We then performed gene set enrichment analysis for the MSigDB Hallmark pathways[22] to

177   define the functional pathways differentiating the transcriptional signatures of COVID-19 patients

178   along the spectrum of disease severity in our cohort (Fig. 2D, Table S4). We identified various

179   immune response pathways significantly associated with severity, including TNF-α signaling via

180   NF-κB in all cell types tested (FDR = 0.03 in CD16$^+$ monocytes and FDR < 2 x 10^{-3} in other cell

181   types), and IFN-γ response (FDR < 4 x 10^{-4}), IFN-α response (FDR < 0.08), and inflammatory

182   response (FDR < 4 x 10^{-4}) in CD14$^+$ monocytes, CD4$^+$ T cells, and CD8$^+$ T cells (Fig. 2D). All of

183   these enrichments were detected among genes more highly expressed in less severe cases,

184   suggesting that such patients engage stronger proinflammatory and antiviral immune responses

185   compared to those with more severe disease presentations. Importantly, these findings are unlikely

186   to be confounded by potential sampling biases, as sampling time point (i.e., DSO) showed no

187   significant association with respiratory support score (Pearson r = 0.11, p = 0.37) (Fig. S1D). With

188   the exception of TNF-α signaling, these pathway enrichments were cell type-specific, implicating

189   classical monocytes, helper T cells, and cytotoxic T cells as the subsets most influenced by

190   variation in disease severity and morbidity. Only the oxidative phosphorylation pathway was

191   consistently elevated in more severe cases (FDR < 1.5 x 10^{-3} in CD4$^+$ T cells, CD8$^+$ T cells, NK

192   cells, and CD16$^+$ monocytes), suggesting a rewiring of metabolism in patients who poorly respond

193   to SARS-CoV-2 (Fig. 2D).

194   To better characterize severity-associated heterogeneity in the transcriptional immune

195   response, we computed single-sample gene set enrichment analysis (ssGSEA) scores capturing the

196   activity of various functional pathways within each sample across cell types (detailed in Methods).

197   Consistent with our enrichment analyses, the level of respiratory support was negatively correlated

198   with ssGSEA inflammatory response scores (Pearson r = -0.30, p = 0.016) (Fig. 2E) and TNF-α

199   signaling scores (Pearson r = -0.40, p = 1.1 x 10^{-3}) (Fig. 2F) in B cells and CD8$^+$ T cells,

200   respectively. Similarly, respiratory support score was also positively associated with oxidative

201   phosphorylation scores in CD4$^+$ T cells (Pearson r = 0.33, p = 7.7 x 10^{-3}) (Fig. 2G). Moreover, we

202   created an antigen processing and presentation score based on the corresponding Biological

203   Process gene set[23], given the previously reported finding that SARS-CoV-2 inhibits the major

204   histocompatibility complex (MHC) class I pathway, a pathway that plays a crucial role in antiviral

205   immunity in lung epithelial cells[24]. Antigen processing scores were negatively correlated with

206   severity in $CD14^+$ monocytes (Pearson r = -0.38, p = 2.1 x 10^{-3}) (Fig. 2H), while no significant

207   association was found in any other cell type that we tested (p > 0.20), indicating that antigen

208   presentation-associated functions are shut down in circulating classical monocytes in severe

209   patients.

210

211   Genetic interaction effects shape transcriptional response variation during acute SARS-

212   CoV-2 infection

213   All individuals were genotyped for 4.19 million single nucleotide polymorphisms (SNPs),

214   allowing us to delineate the role of *cis*-regulatory genetic and gene-environment interaction effects

215   in the context of SARS-CoV-2 infection in patient-derived cells. To directly measure the

216   contribution of cell type-specific and disease state-specific genetic variation during the course of

217   a viral infection, we mapped *cis*-eQTL, defined as SNPs located either within or flanking (±100

218   kilobases, kb) each gene of interest, using the pseudobulk expression estimates for all six major

219   cell types independently in i) healthy controls and ii) COVID-19 patients sampled during acute

220   infection. To increase our power to detect shared and cell type- or disease state-specific effects,

221   we utilized a multivariate adaptive shrinkage framework (mash)[25] to leverage information about

222   the underlying correlation structure within our dataset.

223   Across cell types and infection conditions, we identified 2,725 genes with at least one

224   significant *cis*-eQTL [local false sign rate (lfsr) < 0.10 in at least one cell type-condition pair,

225   35.6% of genes tested; referred to as eGenes] (Fig. 3A, Table S5). B cells (n eGenes = 1,481) and

226   CD16$^+$ monocytes (n eGenes = 1,438) exhibited the fewest genetic effects, while CD14$^+$

227   monocytes displayed the greatest number (n eGenes = 2,127) (Fig. 3A). Most genetic effects were

228   shared between healthy individuals and COVID-19 patients within a given cell type—84.8% on

229   average, referred to as 'shared' eGenes (lfsr$_{CTL}$ < 0.1 and lfsr$_{COVID}$ < 0.3 or vice versa)—and many

230   of these shared eGenes were also common across cell types, with 59.0% shared across four or

231   more cell types (Fig. S2).

232   In stark contrast, some cell types, particularly CD14$^+$ monocytes and NK cells, displayed

233   a substantial proportion of condition-specific eGenes, where genetic effects were observed

234   exclusively in either control or COVID-19 conditions. Notably, CD14$^+$ monocytes and NK cells

235   displayed the greatest fraction of infection-dependent genetic effects (24.8% in NK cells and

236   22.3% in CD14$^+$ monocytes), much higher than the average of 11.0% in other cell types. Strikingly,

237   across all cell types, the overwhelming majority of condition-specific genetic effects (86.3–97.0%)

238   were eQTL observed exclusively in COVID-19 patients rather than in healthy individuals,

239   underscoring the virus's profound impact on the genetic regulation of immune responses (Fig. 3A).

240   Condition-specific eGenes were highly cell type-specific, with monocytes possessing a

241   particularly large number of COVID-19-specific eGenes (CD14$^+$ monocytes n = 370, CD16$^+$

242   monocytes n = 129), further highlighting the abundance of SARS-CoV-2 response eQTL in the

243   myeloid lineage (Fig. 3B). One prime example of a monocyte-specific response eQTL is the top

244   *cis*-eQTL for *SCAMP1* (rs6453393), a gene involved in cytokine secretion, vesicular trafficking,

245   and membrane transport[26]. This variant exhibited a strong genetic effect unique to CD14$^+$

246   monocytes in COVID-19 patients (lfsr = 2.5 x 10^{-7}), but no significant effect in other cell types or

247 conditions (lfsr > 0.50) (Fig. 3C). These findings highlight the crucial role of genetic factors in

248 shaping the monocyte response to SARS-CoV-2 infection *in vivo*.

249

250 **Response eQTL effects are substantially weaker in the innate immune cells of recovered**

251 **individuals**

252 Given the abundance of disease state-specific regulatory variation present in COVID-19

253 patients and absent in healthy individuals, we hypothesized that these eGenes detected only in

254 patients may represent genetic effects only observed during the active infection state. To test

255 whether these genetic effects disappear as infection resolves, we mapped *cis*-eQTL in our cohort

256 of recovered COVID-19 patients who were resampled at various time points following primary

257 SARS-CoV-2 infection (DSO > 20 days, n = 39). We then focused on the innate immune cell

258 compartment (i.e., monocytes and NK cells) to determine how disease state-specific regulatory

259 variation may shift in the convalescent period, as these cell types displayed the greatest number of

260 SARS-CoV-2 response-specific genetic effects ('response eGenes', n reQTL: 370 in CD14$^+$

261 monocytes, 262 in NK cells, and 129 in CD16$^+$ monocytes) (Fig. 3B). Among these cell type-

262 specific response eGene sets, effect sizes were significantly higher in acute patients compared to

263 follow-ups (p < 1 x 10^{-10} in all three cell types). Indeed, for many eGenes, the effect sizes in follow-

264 up individuals reverted back to the magnitude observed in healthy controls (Fig. 4A), an outcome

265 that was seen across cell types. This result held true even after adjusting for sample size differences

266 across disease state groups and when focusing on the 21 individuals with paired acute and follow-

267 up samples (Fig. S3A).

268 To explicitly measure the extent of reQTL effect size reversion coinciding with recovery,

269 we calculated a paired ΔreQTL metric, defined as the difference in magnitude of a response

270 eGene's effect size in follow-ups compared to COVID-19 patients (i.e., |follow-up β_{reQTL}| -

271 |COVID-19 patient β_{reQTL}|) specifically in CD14+ monocytes. Here, we considered only the effect

272 size magnitude because the vast majority of response eGenes had effect sizes with concordant

273 signs in the patient and follow-up groups (Fig. S3B). For comparison, we also computed this

274 change in response magnitude for the set of shared eGenes between COVID-19 patients and

275 healthy controls (n = 1,653). The mean ΔreQTL for response eGenes was below zero (mean

276 ΔreQTL = -0.10), substantially lower than that for shared eGenes (mean = 0.07) (Fig. 4B). This

277 value was also significantly lower than expected by chance (p < 0.001), as determined by randomly

278 sampling the same number of genes (n = 370) from shared CD14+ monocyte eGenes 1,000 times

279 (Fig. S3C). These results indicate that infection mediates dynamic genetic effects and plays a

280 significant role in disease state-dependent gene-environment interactions.

281

282 **Cell state-dependent *cis*-regulatory effects are prevalent in CD14+ monocytes and can**

283 **capture clinical features of patient cohorts**

284   We identified several immune and metabolism-related pathways, including TNF-α

285 signaling via NF-κB, oxidative phosphorylation, IFN-γ and IFN-α responses, inflammatory

286 response, and apoptosis, as being strongly associated with disease severity across multiple cell

287 types in COVID-19 patients (Fig. 2D). Given this, we hypothesized that some of the patient-

288 specific genetic effects detected might be driven by heterogeneity in functional cell states within

289 these clinically relevant pathways. To determine whether cell states defined at the single-cell level

290 are dynamically regulated by *cis* variation, we directly mapped single-cell eQTL in COVID-19

291 patients using our comprehensive single-cell data.

292   To measure cell state-dependent *cis*-regulatory effects, we applied a continuous measure

293   of cell state, which has been shown to capture more state-dependent regulatory variation than

294   discrete classifications. For each pathway, we calculated a numeric score summarizing the activity

295   for each single cell using ssGSEA (see Methods for details). To map continuous state-dependent

296   *cis*-eQTLs within each cell type, we used a poisson mixed-effects interaction model, a method that

297   has proven successful in identifying state-dependent eQTLs in CD4$^+$ T cells[7]. This model tests for

298   genotype-cell state interactions by modeling unique molecular identifier (UMI) counts per gene as

299   a function of genotype at the eQTL variant. We controlled for donor- and cell-level covariates,

300   including age, sex, gene expression PCs, genotype PCs, total UMI count, and mitochondrial UMI

301   percentage (illustrated in Fig. 5A).

302   For each cell type, we focused on the top gene-SNP pairs identified as eQTLs in COVID-

303   19 patients from the pseudobulk analysis (ranging from 1,395 genes in B cells to 2,084 genes in

304   CD14$^+$ monocytes) to assess cell state-dependent genotype effects. Of the six pathways

305   considered, we detected 1,022 significant cell state-dependent interactions with genotype

306   (likelihood ratio test [LRT] q value < 0.10) across all cell type and cell state combinations, mapping

307   to 468 unique eGenes total (17.2% of tested genes) (Fig. 5B, Table S6). CD14$^+$ monocytes

308   displayed the largest number of cell state-dependent eQTL across pathways (n = 569 eGenes),

309   while other cell types exhibited more modest state-dependent effects (n = 0 – 171 eGenes). In

310   CD14$^+$ monocytes, five of the six pathways were associated with over 50 state-dependent loci,

311   including oxidative phosphorylation (n = 223), IFN-α response (n = 99), IFN-γ response (n = 98),

312   TNF-α signaling via NF-κB (n = 73), and inflammatory response (n = 66) (Fig. 5B).

313   Oxidative phosphorylation stood out as the functional state most associated with dynamic

314   state-dependent genetic effects, with 223 eGenes detected, corresponding to 10.7% of those tested.

315   One of the top oxidative phosphorylation-dependent variants was rs835044 (LRT q = 8.2 x 10^{-3}),

316   a lead *cis*-eQTL 2 kb upstream of *NDUFA12*, a gene encoding the A12 subunit of mitochondrial

317   complex I[27], which shows a strong genetic effect in cells with high oxidative phosphorylation

318   scores (quantiles 4 - 6) but virtually no genetic effect in cells with low scores (quantile 1) (Fig.

319   5C). Loss-of-function variants in *NDUFA12* have been linked to a wide array of clinical

320   phenotypes, most frequently a progressive neurodegenerative disorder known as Leigh

321   syndrome[27,28], suggesting that variation in A12 subunit levels can have substantial clinical

322   consequences.

323   Many cell state-dependent eQTL were also found for the IFN-α and IFN-γ response

324   pathways, with 4.0% and 3.9% of tested eGenes showing state-dependent genetic variation,

325   respectively. One such variant was rs1937023, a lead *cis*-eQTL upstream of *IFI44*, an interferon-

326   stimulated gene encoding interferon-induced protein 44, which only displays a genetic effect in

327   cells with high IFN-α response scores (LRT q = 0.041) (Fig. 5D). Experimental knockout of *IFI44*

328   in mammalian airway epithelial cells led to increased respiratory syncytial virus (RSV) titers[29],

329   suggesting that variation in *IFI44* levels can have functional repercussions specifically in the

330   context of viral infection.

331

332   ***Cis*-genetic signals colocalize with COVID-19 disease severity risk loci exclusively in COVID-**

333   **19 patients**

334   Genome-wide association studies (GWAS) provide a means to link regions of the genome

335   with particular traits of interest, giving us the ability to uncover associations with complex disease

336   phenotypes. *Cis*-genetic effects that colocalize with GWAS signals are strongly enriched for causal

337   drivers of variation in disease susceptibility across individuals[30]. To evaluate whether our response

14

338 eQTL may mechanistically underlie any known COVID-19 GWAS risk loci, we performed

339 colocalization analysis using GWAS results derived from the COVID-19 Host Genetics

340 Initiative[11], a consortium that has conducted the largest COVID-19 GWAS to date[13]. We integrated

341 our eQTL mapping data in healthy controls, COVID-19 patients, and follow-ups across cell types

342 with two GWAS meta-analyses for COVID-19 disease severity phenotypes: critical illness (A2,

343 very severe respiratory-confirmed COVID-19 versus population) and hospitalization (B2,

344 hospitalized versus population)[11] to test for common etiological genetic signals.

345 Across cell types and disease states, we detected 19 signals across 6 unique eGenes that

346 significantly colocalized (posterior probability of colocalization [PP4] > 0.80) with critical illness

347 or hospitalization GWAS risk loci (defined as GWAS SNP meta p-value $< 1 \times 10^{-4}$) (Table S7).

348 Of these eGenes, 50% (3 out of 6) colocalized with eQTL exclusively found in COVID-19 patients:

349 *IFNAR2* in CD4$^+$ T cells (critical illness and hospitalization GWAS), *JAK1* in CD16$^+$ monocytes

350 (hospitalization GWAS only), and *SNRPD2* in CD14$^+$ monocytes (hospitalization GWAS only).

351 Notably, two of these genes, *JAK1* and *IFNAR2,* are key canonical mediators of the immune

352 response, both playing critical roles in cytokine signal transduction and interferon response

353 pathways[31,32]. The lead SNP driving the colocalization signal for *IFNAR2* in CD4$^+$ T cells of

354 patients, rs9636867 (PP4$_{A2}$ = 0.84, PP4$_{B2}$ = 0.84) (Fig. 6A, right), has previously been shown to

355 colocalize for severe COVID-19 outcomes in whole blood and CD4$^+$ T cells of COVID-19 patients

356 and was estimated to be causal[33,34]. This colocalization signature was noticeably absent in healthy

357 controls (Fig. 6A, left) and in follow-ups (Fig. S4A). Similarly, the lead SNP driving the eQTL

358 signal in *SNRPD2*, rs7246757, colocalized in CD14$^+$ monocytes of acute COVID-19 patients

359 (PP4$_{B2}$ = 0.87) (Fig. 6B, right), and the gene itself has been implicated as a protein-protein

360 interaction network hub gene associated with SARS-CoV-2 infection[35]. Again, this colocalization

15

361   signature was entirely absent in control (Fig. 6B, left) and follow-up samples (Fig. S4B), indicating

362   that variation in severe COVID-19 outcomes may, in part, be due to *cis*-regulatory variants that

363   exert their effects in disease-specific and cell type-specific manners.

364

365   **Discussion**

366   Prior studies have leveraged *in vitro* pathogen challenges and immune stimulations to

367   probe gene regulatory variation in cells, reporting hundreds of response eQTL in different infection

368   contexts[1–5,36,37]. This experimental approach involves the isolation and culture of primary immune

369   cells from healthy donors, which are then subsequently challenged in laboratory settings. Unlike

370   previous immune response eQTL studies, here we measure genetic effects directly in cells derived

371   from patients responding to a pathogen, revealing considerable context specificity in genetic

372   regulation that is arguably more relevant to disease associations than that measured in controlled

373   *in vitro* systems. We show that cell type-specific, disease state-specific, and cell state-dependent

374   genetic variation is abundant, affecting 25.6% of all genes tested across cell types and disease

375   states and is particularly common in CD14$^+$ monocytes and NK cells. Further, we establish that

376   single cells can harbor distinct genetic effects that are dependent on their underlying

377   immunological or metabolic functional states and that, in certain cases, these continuous states are

378   associated with clinical features of patients. More broadly, genetic interaction effects likely play a

379   role in dynamically modulating immune responses throughout the course of an infection and may

380   also contribute to differential disease outcomes, especially considering the fact that monocytes,

381   and more generally cells in the myeloid compartment, are susceptible to immune dysregulation

382   following SARS-CoV-2 infection[38,39].

383   Of particular clinical interest is biological variation in the interferon response, a critical

384 antiviral pathway induced upon the detection of viral pattern recognition receptors. This response

385 involves the induction of IFNs, a group of cytokines that directly inhibit viral replication and

386 activate bystander immune cells, such as dendritic cells and monocytes[40]. Variation in the timing

387 and magnitude of the IFN response across individuals is well-documented, particularly in the

388 context of SARS-CoV-2 infection[41–44]. Multiple studies have linked this variation with differences

389 in COVID-19 severity and disease progression, revealing a dual role for IFNs in the clinical course

390 of COVID-19[45,46]. In the blood, the upregulation of type I IFNs and IFN-stimulated genes (ISGs)

391 shortly after initial infection is associated with protection[21], but their delayed induction is a

392 hallmark of severe disease[47–49]. Sustained IFN signaling has also been shown to inhibit the

393 development of appropriate antibody responses, ultimately leading to increased disease pathology

394 and severity[44]. We also observe a relationship between IFN signaling and severity, with milder

395 COVID-19 cases displaying elevated expression of IFN-α and IFN-γ response genes specifically

396 in T cells and CD14[+] monocytes.

397   Of note, we detect 224 eGenes (47.8% of all state-dependent eGenes identified) across cell

398 types with expression levels simultaneously dependent on both underlying genetic variation and

399 the magnitude of the IFN response itself, revealing it to be one of the pathways most associated

400 with cell state-dependent genetic interaction effects. This finding only adds to the complexity of

401 how dynamic immune response variation is connected to variation in molecular traits, here through

402 an interaction with host genetics, which may ultimately have downstream effects on disease

403 phenotypes. Indeed, we find that IFN response scores calculated at the single-cell level correlate

404 with patient severity. Together, our results argue that gene-environment interactions are abundant

405 and likely play a direct role in the clinical setting.

406   While we identify only a handful of colocalizing eQTL, of the eGenes that colocalize with

407   COVID-19 disease severity phenotypes, half are detected only in COVID-19 patients, indicating

408   that SARS-CoV-2 infection is necessary to induce these signals. Similar disease state-dependent

409   colocalization has been described previously, with the variant rs8176719 colocalizing only in T

410   effector memory cells 16 hours post-anti-CD3/CD28 stimulation for both severity and

411   susceptibility COVID-19 GWAS at the *RALGDS2* locus[33]. In the same study, the intronic risk

412   variant in *IFNAR2*, rs9636867, the same lead SNP-eGene pair for which we identify a patient-

413   specific colocalization signal in CD4[+] T cells, colocalized with severe COVID-19 disease only for

414   symptomatic individuals who were SARS-CoV-2[+] in CD4[+] T cells[33]. A different COVID-19-

415   associated intronic risk variant in *IFNAR2*, rs13050728, has also been shown to increase *IFNAR2*

416   expression in classical monocytes specifically in COVID-19 patients compared to healthy controls

417   in an independent study[14].

418   These findings highlight the role that context specificity plays in the genetic regulation of

419   disease associated-traits and stress the importance of measuring molecular phenotypes in pertinent

420   environmental conditions and cell types. They also raise the question of how gene-environment

421   interactions may contribute to the problem of missing heritability, the phenomenon in which only

422   a small fraction of overall trait heritability is explained by trait-associated variants[50,51]. Although

423   trait-associated loci are enriched for eQTL[52], only ~40% of GWAS variants colocalize with eQTL

424   in relevant tissues, which drops to ~20% for autoimmune trait GWAS[53,54]. More recently, trait

425   mapping studies have been extended to incorporate a larger array of quantitative traits, including

426   alternative splicing[55], chromatin accessibility, and histone modification levels[37]. The inclusion of

427   alternative regulatory mechanisms has significantly increased the number of colocalizing loci and

428   heritability estimates of GWAS phenotypes, yet a large proportion of heritability remains

429   unexplained, potentially due to context-specific gene-environment interactions.

430   Although we have described how gene-environment interactions can shape immune

431   responses in one specific viral infection setting, it is necessary to define how such effects contribute

432   to a wider range of disease states and environmental contexts to better understand the genetic and

433   environmental underpinnings of immune response variation across individuals. As the number of

434   patient cohorts with single-cell phenotyping and genotyping data rise, it will be important to extend

435   this framework to other single-cell eQTL mapping studies to measure the full extent of cell state-

436   dependent regulatory heterogeneity.

619   and Biomedical Research Centre based at Guy's and St Thomas' NHS Foundation Trust in

620   partnership with King's College London. These funding agencies had no role in the design,

621   implementation, or interpretation of this study. The Biobanque Québécoise de la COVID-19

622   (BQC19) is supported by the FRQS Génome Québec and the Public Health Agency of Canada.

623

624   **Author contributions:** L.B.B. supervised the study. H.E.R. and L.B.B. designed the experiments.

625   E.B.R., T.N., C.L., A.P., N.A., A.F., M.D., J.B.R., and D.E.K. provided patient samples and

626   curated data. H.E.R., V.L., E.K., C.B., and A.D. performed the experiments and sample

627   collections. H.E.R., R.A.G., and T.N. performed computational analyses. H.E.R. and L.B.B. wrote

628   the manuscript, with input from all authors.

629

630   **Disclosures/competing interests:** J.B.R.'s institution has received investigator-initiated grant

631   funding from Roche, Eli Lilly, GlaxoSmithKline, and Biogen for projects unrelated to this

632   research. J.B.R. is the CEO of, and holds shares in, 5 Prime Sciences (www.5primesciences.com),

633   which provides research services for biotech, pharma, and venture capital companies to enable

634   genetics-based drug development.

635

636   **Data and materials availability:** Further information and requests for resources should be

637   directed to Luis B. Barreiro (lbarreiro@uchicago.edu). Raw data contained in BQC19, including

638   whole genome sequencing files, are stored on SecureData4Health (https://www.sd4health.ca/),

639   and are accessible via BQC19's access procedures. To access these files, a data access request

640   must be submitted. Instructions on how to submit this request are available at

641   https://www.bqc19.ca/en/access-data. Researchers from both academia and private entities are

642   eligible to apply, and the research project must be approved by a research ethics board. A Data

643   Access Committee will then review the application, and the data will be made available to the

644   applicant upon approval.
Fig. 1. Summary of the study cohort and aims. (A) Study design (left) and examples of various gene-environment interactions, including cell type-, disease state-, and cell state-dependent effects, evaluated in this study (right). **(B)** UMAP visualization of all cells (n = 361,119) collected across healthy control, acute COVID-19 patient, and follow-up samples (n = 208 samples). ASDC: AXL+SIGLEC6+ dendritic cells, CD4+ CTL: cytotoxic CD4+ T cells, cDC: conventional dendritic cells, dnT: double-negative T cells, Eryth: erythrocytes, gdT: gamma delta T cells, HSPC: hematopoietic stem and progenitor cells, ILC: innate lymphoid cells, MAIT: mucosal associated invariant T cells, mono: monocytes, NK: natural killer, pDC: plasmacytoid dendritic cells, TEM: T effector memory, TCM: T central memory.

655
Fig. 2. Effects of COVID-19 disease severity on underlying cell type composition and transcriptional signatures in hospitalized patients. (A) Cell type proportions stratified by disease severity at the time of sample collection. **(B)** Correlation between respiratory support score at the time of patient sampling and frequency of $CD14^+$ monocytes. **(C)** PCA decomposition of the $CD14^+$ monocyte expression data in COVID-19 patients colored by respiratory support score. **(D)** Hallmark enrichments for severity effects in COVID-19 patients across cell types. Colored circles represent pathways with FDR < 0.10; gray circles represent non-significant pathways. Only pathways significant in three or more cell types are shown. **(E-H)** Correlation between respiratory support score and ssGSEA scores in various cell types for **(E)** inflammatory response, **(F)** TNF-α

31

665   signaling, **(G)** oxidative phosphorylation, and **(H)** antigen processing. In **(B)** and **(E-H)**, p-values

666   and best-fit lines were obtained from linear regression models.
Fig. 3. *Cis*-regulatory effects are cell type-specific and disease state-specific. (A) Number of shared and disease state-specific eGenes within each cell type. **(B)** Significant condition-specific eGene (lfsr$_{CTL}$ < 0.10 and lfsr$_{COVID}$ > 0.30, lfsr$_{COVID}$ < 0.10 and lfsr$_{CTL}$ > 0.30) sharing patterns across cell types in healthy controls and COVID-19 patients. Patient-specific eGene sets are highlighted by color per cell type. **(C)** Example of a patient-specific genetic effect (i.e., SARS-CoV-2 response eQTL) present only in CD14$^+$ monocytes in the gene *SCAMP1* (healthy controls, top plots; COVID-19 patients, bottom plots).

Fig. 4. SARS-CoV-2 response eQTL effects revert to baseline in longitudinal follow-up samples. (A) Effect sizes for the cell type-specific reQTL gene sets plotted across innate immune cell types in healthy controls, patients, and follow-up samples. All eQTL effect sizes correspond to mash posterior effect sizes. **(B)** Distribution of the change in eQTL effect sizes between follow-up and patient samples (defined as |follow-up β_{eQTL}| - |COVID-19 patient β_{eQTL}|) for response eQTL (n = 370, blue) and shared eQTL (n = 1,653, gray) in CD14$^+$ monocytes. Dashed lines represent the mean Δ response magnitude for the respective gene sets.

Fig. 5. Cell state-dependent single-cell eQTL are prevalent, particularly in CD14+ monocytes of COVID-19 patients. (**A**) Schematic of how cell state-dependent single-cell eQTL were evaluated. For each cell type independently, a poisson mixed effects (PME) model was fit to the UMI counts for each gene, correcting for various biological and technical covariates, to test for the interaction between genotype (0, 1, 2) and various functional cell state scores (represented by the green gradient bar). In this instance, no genetic effect is observed among cells with a low immune score (light green), whereas cells with a high immune score display a substantially larger genotype effect (dark green). (**B**) Number of significant cell state-dependent eQTL (LRT q-value < 0.10) for

35

694   each functional cell state tested (x-axis) across cell types. **(C-D)** UMAP visualizations of all CD14$^+$

695   monocytes in COVID-19 patients colored by **(C)** oxidative phosphorylation score quantiles and

696   **(D)** IFN-α response score quantiles (left), and examples of cell state-dependent eQTL for each of

697   the corresponding functional pathways (right). In these examples, single-cell gene expression

698   estimates (y-axis) are plotted by genotype and binned by cell state score quantiles for each

699   visualization, although we treated cell state as a continuous variable in our models. The quantiles

700   shown directly correspond to the UMAP quantile scale.

701

702
Fig. 6. Colocalization signals for COVID-19 disease severity phenotypes are specific to COVID-19 patients. (A) The lead SNP for *IFNAR2*, rs9636867, colocalizes in CD4[+] T cells for hospitalization due to severe COVID-19 in patients (right) but not controls (left). **(B)** The lead SNP for *SNRPD2*, rs7246757, colocalizes in CD14[+] monocytes for hospitalization due to severe COVID-19 in patients (right) but not controls (left). For both **(A)** and **(B)**, the larger plots on the left show the correlation between GWAS p-values (x-axis) and eQTL p-values (y-axis) in controls and patients. The smaller plots on the right show Manhattan plots for the GWAS signal (top) and the eQTL signal in the COVID-19 patients (bottom). The lead SNP is depicted as a purple diamond.

717

Materials and Methods

Participants and samples. We prospectively investigated hospitalized COVID-19 patients between April 2020 and December 2021 who initially presented with a symptomatic infection and positive SARS-CoV-2 nasopharyngeal swab polymerase chain reaction. All participants were admitted to the Centre Hospitalier de l'Université de Montréal (CHUM) and recruited into the Biobanque Québécoise de la COVID-19 (BQC19)[56]. Patients had no known prior exposure to SARS-CoV-2 (i.e., all infections were primary infections), were not vaccinated at the time of primary sampling (days after symptom onset [DSO] $\leq$ 20), and did not undergo plasma transfer therapy. Blood draws were performed during the acute phase of SARS-CoV-2 infection (defined as DSO $\leq$ 20 days, mean DSO = 12.1 days, DSO range = 6 - 20 days, n = 63 samples) and during various convalescent follow-up time points (defined as DSO > 20 days, mean DSO = 128.8 days, DSO range = 31 - 370 days) for a subset of individuals sampled during the acute phase (n = 39 samples). Additionally, PBMCs collected prior to the COVID-19 pandemic from healthy control individuals living in Montréal, Canada (n = 18 samples) were processed for single-cell data collection in parallel with infected patient samples. We also computationally integrated a set of publicly available healthy controls (n = 90 individuals) described in Randolph et al. (2021)[4], which is detailed below ("Single-cell RNA-sequencing data processing and integration"). The study was approved by the respective IRBs (multicentric protocol: MP-02-2020-8929 for BQC19 participants; CHUM protocol 19.387 for control individuals) and written, informed consent was obtained from all participants or, when incapacitated, their legal guardian before enrollment and sample collection.

DNA sequencing and imputation. DNA was extracted from whole blood using the Chemagic™

DNA Blood 400 H96 kit (Perkin Elmer, CMG-1091). SNP genotyping was conducted using the

Axiom™ Precision Medicine Research Array from Applied Biosystems (Applied Biosystems,

902981) per the manufacturer's instructions. The array was processed using the GeneTitan™

Multi-Channel instrument (Applied Biosystems). All samples were grouped with the Axiom

Analysis Suite 5.1.1 software, and the "Best Practice Workflow" was performed using the

following high-quality call rate parameters: Axiom_PMRA.r3 library and threshold configuration

Human.v5 with minimum call rate of 97.0%. Marker quality control tests were performed on a

subset of ancestrally homogeneous participants, who were determined via comparison to 2,504

individuals across 5 super populations from the 1000 Genomes Project Phase 3 data [57]. Batch effect

quality control and replicate discordance checks were performed, and variants that failed either

test were removed. Only single nucleotide variants with single character allele-codes (A, C, G, or

T) (PLINK --snps-only 'just-acgt' option) were retained. Additionally, variants with low allele

frequencies (minor allele frequency [MAF] < 0.001), low genotyping call rates (marker-wise

missingness < 0.01), a deviation from Hardy-Weinberg equilibrium (HWE) (p-value < 1×10^{-6}),

and positioned in regions of high link disequilibrium (LD) were removed.

Sample quality filtering was performed considering the set of filtered genotypes described

above. Outlier samples with a high genotype missingness rate (overall missing genotype rate >

0.04) or high/low principal component corrected heterozygosity rate on autosomal chromosomes

(> ±3SD, respectively) were considered low quality and removed. Sex chromosome composition

was determined by estimating X chromosome marker heterozygosity using PLINK (--check-sex

0.4 0.7). Individuals with discordant self-reported sex and genetic sex were removed prior to

genotype imputation. All other samples that passed quality control filters were used for imputation.

40

763 Genotype phasing and imputation was performed using the Michigan Imputation Server[58] with the

764 TOPMed reference panel[59]. After imputation, variants with a posterior genotype probability (GP)

765 < 90% were set to missing within each individual using QCTOOL (v2.0.7, -threshold 0.9 filter).

766

767 **Whole blood processing.** At the time of sampling, whole blood was collected in up to three tubes

768 containing acid citrate dextrose (ACD) and processed within 6 hours of collection. Blood from the

769 same donor was pooled and centrifuged at 400 g for 10 min at room temperature (RT). After

770 centrifugation, plasma was collected, aliquoted, and stored at -80°C. The remaining blood was

771 topped up to 30 ml with HBSS medium at RT. Ficoll-Paque separation was then used to isolate

772 PBMCs. PBMCs were washed with R+ (RPMI 1640 + 0.1M HEPES + 20 U/ml Penicillin-

773 Streptomycin), resuspended in 5 ml R+ with 10% fetal bovine serum (FBS), and counted with

774 Trypan blue. Cells were spun down at 400 g for 10 min at 4°C and resuspended in cold FBS at 20

775 M/ml. A freezing solution of FBS with 20% DMSO was added drop-by-drop to the cell suspension

776 while the tube was continuously agitated. Cell suspensions were transferred into cryovials (1

777 ml/vial), immediately placed into Mr. Frosty Freezing Containers, and stored at -80°C. The

778 following day, PBMCs were transferred to liquid nitrogen for long-term storage.

779

780 **Sample processing for single-cell RNA-sequencing.** PBMCs were thawed in groups of 3 to 4

781 samples (processing batch 1) or 16 to 19 samples (processing batch 2), rested for 2 hours in RPMI

782 1640 supplemented with 10% FBS (Corning, MT35015CV), 2 mM L-glutamine (ThermoFisher

783 Scientific, 25-030-081), and 10 ug/ml gentamicin (ThermoFisher Scientific, 15710064), and

784 subsequently processed for single-cell collection. Cells from different samples were pooled per

785 processing batch for a total of 29 multiplexed sample batches (n = 124 samples). For each

786   multiplexed cell pool, 12,000 cells were targeted for collection using the Chromium Next GEM

787   Single Cell 3' Reagent (v3.1 Dual Index chemistry) kit (10x Genomics, 1000268). After GEM

788   generation, the reverse transcription (RT) reaction was performed in a thermal cycler as described

789   (53°C for 45 min, 85°C for 5 min), and post-RT products were stored at -20°C for up to one week

790   until downstream processing.

791

792   **Single-cell RNA-sequencing library preparation and sequencing.** Post-RT reaction cleanup,

793   cDNA amplification and sequencing library preparation were performed as described in the Single

794   Cell 3' Reagent Kits v3.1 (Dual Index) User Guide (10x Genomics). Briefly, cDNA was cleaned

795   with DynaBeads MyOne SILANE beads (ThermoFisher Scientific, 37002D) and amplified in a

796   thermal cycler using the following program: 98°C for 3 min, [98°C for 15 s, 63°C for 20 s, 72°C

797   for 1 min] x 11 cycles, 72°C 1 min. After cleanup with the SPRIselect reagent kit (Beckman

798   Coulter, B23317), libraries were constructed by performing the following steps: fragmentation,

799   end-repair, A-tailing, double-sided SPRIselect cleanup, adaptor ligation, SPRIselect cleanup,

800   sample index PCR (98°C for 45 s, [98°C for 20 s, 54°C for 30 s, 72°C for 20 s] x 14 cycles, 72°C

801   1 min), and double-sided SPRIselect size selection. Prior to sequencing, all multiplexed single-cell

802   libraries were quantified using the KAPA Library Quantification Kit for Illumina Platforms

803   (Roche, 50-196-5234). For each processing batch (n = 2), libraries were pooled in an equimolar

804   ratio and sequenced 100 base pair paired-end on an Illumina NovaSeq 6000 (processing batch 1

805   average mean reads per cell = 48,613, average median genes detected per cell = 1,627; processing

806   batch 2 average mean reads per cell = 59,246, average median genes detected per cell = 2,007).

807

808 **Single-cell RNA-sequencing data processing and integration.** FASTQ files from each

809 multiplexed capture library were mapped to the pre-built GRCh38 human reference transcriptome

810 (downloaded 10x Genomics) using the cellranger (v6.0.2) count function[60]. souporcell (v2.0,

811 Singularity v3.4.0)[61] in --skip_remap mode was used to demultiplex cells into samples based on

812 genotypes from a common variants file (1000 Genomes Project samples filtered to SNPs with ≥

813 2% allele frequency in the population, downloaded from https://github.com/wheaton5/souporcell).

814 For each sample batch, hierarchical clustering of the known genotypes obtained from DNA-

815 sequencing and cluster genotypes estimated by souporcell was used to assign individuals to

816 souporcell cell clusters. All samples except for three were successfully demultiplexed; samples

817 unable to be confidently assigned to a set of cells were removed (n samples retained = 121). After

818 demultiplexing, Seurat (v4.3.0, R v4.0.3)[62] was used to perform cell-level quality control filtering.

819 One sample was removed due to a very low number of cells captured (n = 20 cells total), leaving

820 a total of 120 samples. High-quality cells were retained for downstream analysis if they had: 1) a

821 "singlet" status called by souporcell, 2) between 500 – 4000 genes detected (nFeature_RNA), 3) a

822 mitochondrial UMI percentage < 20%, and 4) less than 25,000 total molecules (nCount_RNA),

823 leaving 236,143 cells. Gene filtering was performed using the CreateSeuratObject min.cells

824 parameter, in which only genes present in at least five cells were kept (n = 30,986 genes).

825 Due to the large discrepancy between the number of cells assayed in healthy control

826 individuals (n = 38,663) versus acute and convalescent samples (n = 197,480) in our dataset, we

827 integrated a publicly available set of high-quality cells derived from control, non-infected

828 individuals (n = 124,976 cells, 90 samples) described in Randolph et al., (2021)[4], hereafter referred

829 to as the "non-infected IAV controls". First, we removed IAV-derived transcripts (n = 10 genes)

830 from the raw count matrix of the non-infected IAV controls. Next, we merged all datasets, split

43

831   the resulting Seurat object by dataset ("COVID batch1", "COVID batch2" or "IAV controls"), and

832   ran SCTransform[63] to normalize and scale the UMI counts within dataset. We simultaneously

833   regressed out variables corresponding to experiment batch, percent mitochondrial UMIs per cell,

834   and individual label in all datasets, and additionally, regressed out sampling time point (e.g.,

835   control, acute, follow-up) in the COVID data. We then integrated the three datasets together using

836   the SelectIntegrationFeatures, PrepSCTIntegration, FindIntegrationAnchors, and IntegrateData

837   framework[62]. After integration, dimensionality reduction was performed via UMAP (RunUMAP

838   function, dims = 1:30) and PCA (RunPCA function, npcs = 30). A Shared Nearest Neighbor Graph

839   was constructed using the FindNeighbors function (dims = 1:20, all other parameters set to

840   default), and clusters were subsequently called using the FindClusters algorithm (resolution = 0.5,

841   all other parameters set to default)[62]. In total, our integrated dataset consisted of 361,119 high-

842   quality cells across all samples (n = 236,143 from the combined COVID datasets, n = 124,976

843   from the non-infected IAV dataset, n = 208 samples altogether).

844

845   **Cell type assignment.** We performed cell type annotation via label transfer to map cell type

846   information onto our data. To perform the label transfer, we downloaded a multimodal human

847   PBMC reference dataset derived from scRNA-seq paired with CITE-seq as described in Hao et

848   al.[15]. We followed the Seurat v4 Reference Mapping workflow, consisting of the

849   FindTransferAnchors and MapQuery functions, with the Hao et al. reference dataset used as our

850   reference UMAP and the following parameters: normalization.method = "SCT" and

851   reference.reduction = "spca". These fine-scale populations were then collapsed into the following

852   broad super populations encompassing the six major cell types found in PBMCs using the

853   predicted.celltype.l2 definitions derived from Hao et al.: CD4[+] T cells = c("CD4 CTL", "CD4

854 Naive", "CD4 Proliferating", "CD4 TCM", "CD4 TEM", "Treg"), CD8$^+$ T cells = c("CD8 Naive",

855 "CD8 Proliferating", "CD8 TCM", "CD8 TEM"), NK cells = c("NK", "NK Proliferating",

856 "NK_CD56bright"), CD14$^+$ monocytes = "CD14_monocytes", CD16$^+$ monocytes =

857 "CD16_monocytes", and B cells = c("B intermediate", "B memory", "B naive"). In total, we

858 annotated 342,127 high-quality cells falling into the major PBMC populations across all

859 individuals and conditions (n CD4$^+$ T cells = 153,479, CD8$^+$ T cells = 53,562, CD14$^+$ monocytes

860 = 70,060, CD16$^+$ monocytes = 5,446, B cells = 34,805, NK cells = 24,775).

861

862 **Calculation of pseudobulk estimates.** Pseudobulk estimates were used to summarize single-cell

863 expression values into bulk-like expression estimates within samples. This was performed for all

864 six major cell types (CD4$^+$ T cells, CD8$^+$ T cells, B cells, CD14$^+$ monocytes, CD16$^+$ monocytes,

865 NK cells). Within each cell type cluster for each sample, raw UMI counts were summed across all

866 cells assigned to that sample for each gene using the sparse_Sums function in textTinyR (v1.1.3)

867 (https://cran.r-project.org/web/packages/textTinyR/textTinyR.pdf), yielding an n x m expression

868 matrix, where n is the number of samples included in the study (n = 208) and m is the number of

869 genes detected in the single-cell analysis (m = 30,986) for each of the 6 clusters.

870

871 **Calculation of residuals for modeling.** For each cell type, lowly-expressed genes were filtered

872 using cell type-specific cutoffs (removed if they had a median logCPM < 1.0 in CD14$^+$ monocytes,

873 < 1.5 in CD4$^+$ T cells, < 2.0 in B cells and CD8$^+$ T cells, < 2.5 in CD16$^+$ monocytes, and < 3.0 in

874 NK cells), leaving the following number of genes per cell type: CD4$^+$ T cells = 10,337, CD8$^+$ T

875 cells = 10,036, B cells = 10,179, CD14$^+$ monocytes = 10,882, CD16$^+$ monocytes = 9,398, and NK

876 cells = 9,882. Within each cell type, only samples with ≥ 5 cells per sample were kept for

877   downstream modeling. Further, three samples were removed for downstream analysis because they

878   consistently clustered as outliers on gene expression PCAs for multiple cell types (one COVID-19

879   patient at the acute infection time point and two non-infected IAV controls), leaving the following

880   number of samples per cell type:

Cell type	N healthy controls	N patients	N follow-ups
B	106	63	38
CD4$^+$ T	106	63	39
CD8$^+$ T	106	63	39
CD14$^+$ monocytes	106	63	39
CD16$^+$ monocytes	47	44	39
NK	63	63	39

881

882   After removing lowly-expressed genes, normalization factors to scale the raw library sizes were

883   calculated using calcNormFactors in edgeR (v 3.26.8)[64]. The voom function in limma (v3.40.6)[65]

884   was used to apply these size factors, estimate the mean-variance relationship, and convert raw

885   pseudocounts to logCPM values. The inverse variance weights calculated by voom were obtained

886   and included in the respective lmFit call for all downstream models unless otherwise noted[65].

887

888   **Calculation of per-individual ssGSEA scores.** To construct the ssGSEA Hallmark pathway

889   scores, we calculated single sample Gene Set Enrichment Analysis (ssGSEA) scores from the

890   pseudobulk COVID-19 patient logCPM gene expression estimates corrected for age, sex, dataset,

891   and the number of cells for a given cell type collected per sample using the Gene Set Variation

892   Analysis (GSVA, v1.32.0) package in R with default parameters and method = "ssgsea"[66]. ssGSEA

893   is a method that allows you to summarize gene expression patterns for any desired target gene set,

894   and for each sample, it will return a score representative of that gene set. These scores were

895   calculated per cell type, and for each of the pathway-specific ssGSEA scores, the input gene set

896   was derived from either a Hallmark or Gene Ontology (GO) Biological Process gene set[22]. The

897   following gene sets were used to define the per-sample pathway scores: (1) inflammatory response

898   score – Hallmark inflammatory response pathway, (2) TNF-α score – Hallmark TNF-α signaling

899   via NF-κB pathway, (3) oxidative phosphorylation score – Hallmark Oxidative phosphorylation

900   pathway, and (4) antigen processing score – GO Biological Process antigen processing and

901   presentation pathway.

902

903   **Modeling SARS-CoV-2 infection effects.** Only healthy controls and COVID-19 patients sampled

904   during the primary infection time point were retained for modeling of infection effects (i.e., follow-

905   up samples were excluded). The following linear model was used to identify genes differentially

906   expressed between healthy control individuals and COVID-19 patients:

907

908
$$
E(i,j) \sim \begin{cases} \beta_0(i) + \beta_{age}(i) \cdot age(j) + \beta_{sex}(i) \cdot sex(j) + \beta_{dataset}(i) \cdot dataset(j) + \\ \quad \beta_{counts}(i) \cdot counts(j) + \varepsilon^{ctl}(i,j) \text{ if condition } = ctl \\ \\ \beta_0(i) + \beta_{COVID}(i) + \beta_{age}(i) \cdot age(j) + \beta_{sex}(i) \cdot sex(j) + \\ \beta_{dataset}(i) \cdot dataset(j) + \beta_{counts}(i) \cdot counts(j) + \varepsilon^{COVID}(i,j) \text{ if condition } = COVID \end{cases}
$$

909

910   Here, $E(i,j)$ represents the expression estimate of gene i for individual j, $\beta_0(i)$ is the global intercept

911   accounting for the expected expression of gene i in a non-infected female measured in the COVID

912   batch 1 dataset, and $\beta_{COVID}(i)$ represents the global estimate of the effect of SARS-CoV-2 infection

913   in patients per gene. Age represents the mean-centered, scaled (mean = 0, sd = 1) age per

914 individual, with $\beta_{age}(i)$ being the effect of age on expression levels, sex represents the self-

915 identified sex for each individual (factor levels = "Female", "Male"), with $\beta_{sex}(i)$ capturing the

916 effect of sex on expression, dataset represents the dataset in which the sample was obtained (factor

917 levels = "COVID batch 1", "COVID batch 2", "IAV controls"), with $\beta_{dataset}(i)$ capturing the dataset

918 effect, and counts represents the number of cells captured within that cell type for sample j, with

919 $\beta_{counts}(i)$ capturing the effect of cell number on expression. Finally, ε^{cdt} represents the residuals for

920 each respective condition (control or COVID) for each gene i, individual j pair. The model was fit

921 using the lmFit and eBayes functions in limma[65], and the estimates of the global infection effect

922 $\beta_{COVID}(i)$ (i.e., the differential expression effects due to SARS-CoV-2 infection) were extracted

923 across all genes along with their corresponding p-values. We controlled for false discovery rates

924 (FDR) using an approach analogous to that of Storey and Tibshirani[2,67], which derives the

925 distribution of the null model empirically. To obtain a null, we performed 10 permutations, where

926 infection status label (i.e., control/COVID) was permuted across individuals. We considered genes

927 significantly differentially expressed upon infection if they had β_{COVID} $|\log_2\text{FC}| > 0.5$ and an FDR

928 < 0.05.

929

930 **Modeling COVID-19 disease severity effects within patients.** To model the effect of COVID-

931 19 disease severity on gene expression, we restricted our analyses to COVID-19 patients sampled

932 during the primary infection time point for which we had information about disease severity (n =

933 63). Disease severity was assessed using a five-point scale of respiratory support needed at the

934 time of patient sampling that includes the following categories: 0-Moderate = no supplemental

935 oxygen (n = 16); 1-Severe = nasal cannula (n = 17); 2-Critical = non-invasive ventilation (n = 9);

936 3-Critical = intubation (n = 20); 4-Critical = extracorporeal membrane oxygenation (ECMO) (n =

937   1). The following model was used to evaluate the effect of severity at the time of patient sampling

938   on expression:

939    $$E(i,j) \sim \beta_0(i) + \beta_{severity}(i) \cdot severity(j) + \beta_{age}(i) \cdot age(j) + \beta_{sex}(i) \cdot sex(j) + \beta_{BMI}(i) \cdot BMI(j) +$$

940    $$\beta_{dataset}(i) \cdot dataset(j) + \beta_{counts}(i) \cdot counts(j) + \varepsilon(i,j)$$

941   Here, $E(i,j)$ represents the expression estimate of gene i for individual j, $\beta_0(i)$ is the global intercept

942   accounting for the expected expression of gene i in a female COVID-19 patient, and $\beta_{severity}(i)$

943   indicates the effect of severity on gene i during the primary sampling time point. Severity

944   ($severity(j)$) represents respiratory support score per individual and was treated as a numeric

945   variable. Body mass index (BMI) represents the mean-centered, scaled (mean = 0, sd = 1) BMI

946   per individual, with $\beta_{BMI}(i)$ being the effect of BMI on expression levels. If BMI was not reported

947   for an individual (n missing = 26), this missing data was filled with the average BMI across

948   patients. All other terms in the model are equivalent to that described in "Modeling SARS-CoV-2

949   infection effects". The model was fit using the lmFit and eBayes functions in limma[65], and the

950   estimates of $\beta_{severity}(i)$ were extracted across all genes along with their corresponding p-values.

951   We again controlled for false discovery rates (FDR) by empirically deriving the null distribution.

952   To obtain a null, we performed 10 permutations, where respiratory support score (i.e., 0 - 5) was

953   permuted across patients. We considered genes significantly correlated with disease severity if

954   they had an FDR < 0.05.

955

956   **Gene set enrichment analyses.** The R package fgsea (v1.10.1)[68] was used to perform gene set

957   enrichment analysis for the severity effects using the H hallmark gene sets[23]. Ranked t-statistics

958   for each cell type were obtained directly from the topTable function in limma[65], and the

959   background set for a cell type was the set of genes sufficiently expressed (i.e., passed the lowly-

960   expressed gene filter threshold) for that cell type. Pre-ranked t-statistics were used to perform the

961   enrichment using fgsea with the following parameters: minSize = 15, maxSize = 500, nperm =

962   100,000. Normalized enrichments scores (NES) and Benjamini-Hochberg adjusted p-values

963   output by fgsea were collected for each analysis.

964

965   **eQTL mapping and integration with mashr.** eQTL mapping was performed for each cell type

966   using the pseudobulk expression data. A linear regression model was used to ascertain associations

967   between SNP genotypes and expression levels. Input expression matrices were quantile-

968   normalized within each set of disease state samples (i.e., healthy controls, acute COVID-19

969   patients, and follow-ups) prior to association testing. eQTL were mapped separately for each

970   disease state using the R package MatrixEQTL (v2.3)[69]. Prior to mapping, SNPs were filtered

971   using the following criteria in our COVID-19 dataset and the Randolph et al. dataset separately:

972   1) keep those with a minor allele frequency > 5% across all individuals, 2) exclude those with >

973   10% of missing data, and 3) exclude those that deviate from Hardy-Weinberg equilibrium at $p <$

974   10^{-5} (--maf 0.05 --geno 0.10 --hwe 0.00001 PLINK v1.9 filters)[70]. Only SNPs that passed these

975   filters and were present in both datasets were retained and merged across datasets (n = 4,194,100

976   SNPs kept). Local associations (i.e., putative *cis*-eQTL) were tested against all SNPs located

977   within the gene body and 100 kilobases upstream and downstream of the transcription start site

978   (TSS) and transcription end site (TES) for each gene tested.

979   Within our follow-up samples, some individuals were sampled multiple times during the

980   convalescent period. To avoid counting these genetically duplicate samples more than once when

981   eQTL mapping, we downsampled the follow-ups to include only a single sample with DSO > 20

982   per individual. For each individual with multiple follow-up time points, we chose to keep the

983 sample with the maximum DSO, which dropped our sample size from n = 39 to n = 26. This

984 duplicate sampling structure was not present in the healthy control or acute COVID-19 samples,

985 so the full sample set was used to map eQTL for these disease states.

986 We accounted for unmeasured surrogate confounders by performing PCA on a correlation

987 matrix based on the gene expression data. Subsequently, up to 15 principal components (PCs) were

988 regressed out prior to performing the association analysis for each gene. A specific number of PCs

989 to regress in each cell type-disease state pair, corresponding to the number of PCs that led to the

990 detection of the largest number of eQTL in each condition, was then chosen empirically (Table

991 S8). To avoid spurious associations resulting from population structure, the first two eigenvectors

992 obtained from a PCA on the genotype data using SNPRelate (v1.20.1, gdsfmt v1.22.0)[71] were

993 included in the linear model. Other covariates included were age (mean-centered, scaled), sex,

994 number of cells detected per sample, and dataset.

995 To gain power to detect *cis*-eQTL effects, we implemented mashr[25], which leverages

996 sharing information across cell types and disease states. We considered a set of shared genes that

997 were expressed across all cell types (n = 7,646). For each of these genes, we chose the single top

998 *cis*-SNP, defined as the SNP with the lowest FDR across all cell types (n = 6) in the acute COVID-

999 19 patient condition, to input into mashr. We extracted the effect sizes and computed the standard

1000 errors of these betas from the Matrix eQTL outputs for each gene-SNP pair across cell types and

1001 conditions. We defined a set of strong tests (i.e., the 7,646 top gene-SNP associations) as well as

1002 a set of random tests, which we obtained from randomly sampling 200,000 rows of a matrix

1003 containing all gene-SNP pairs tested merged across conditions. The mashr workflow was as

1004 follows: i) the correlation structure among the null tests was learned using the random test subset,

1005 ii) the data-driven covariance matrices were learned using the strong test subset (from 5 PCs), iii)

1006   the mash model was fit to the random test subset using canonical and data-driven covariance

1007   matrices, and iv) the posterior summaries were computed for the strong test subset. We used the

1008   local false sign rate (lfsr) to assess significance of our posterior eQTL effects and considered a

1009   gene-SNP pair to have a significant eQTL effect if the lfsr was < 0.10.

1010

1011   **Calculation of functional cell state scores per cell.** To obtain the cell state scores used for

1012   modeling cell state-dependent single-cell eQTL, first, the raw single-cell UMI counts across all

1013   samples were obtained per cell type. All subsequent processing steps were performed for each cell

1014   type independently. Raw cell counts in the form of a Seurat object were split by dataset, and

1015   SCTransform was used to normalize and scale the UMI counts within dataset, regressing the

1016   effects of experiment batch, percent mitochondrial UMIs per cell, and age in all datasets, and

1017   additionally, sex in the COVID batch 1 and batch 2 datasets. The SelectIntegrationFeatures,

1018   PrepSCTIntegration, FindIntegrationAnchors, and IntegrateData pipeline was then used to

1019   integrate cells, returning all features following integration (features.to.integrate = all_features)[60].

1020   The scaled data matrix (@scale.data slot) of the integrated data, which holds the residuals of the

1021   corrected log-normalized integrated counts, was obtained, and these values were used to calculate

1022   ssGSEA scores (using the same parameters described above in "Calculation of per-individual

1023   ssGSEA scores") per cell for our pathways of interest. Here, we applied ssGSEA to the full scaled

1024   SCTransform gene *x* cell matrix, allowing us to generate cell state scores for each single cell in the

1025   dataset. Our pathways of interest included the following immune-related and metabolism-related

1026   pathways in the MSigDB Hallmark gene sets (n = 6)[22]: Apoptosis, Inflammatory response,

1027   Interferon-α response, Interferon-γ response, Oxidative phosphorylation, and TNF-α signaling via

1028   NF-κB.

1029

1030   **Modeling cell state-genotype interaction effects.** We used a poisson mixed effects model to test

1031   for cell state-dependent eQTL because this model has previously been used to detect significant

1032   cell state-genotype interaction effects in single-cell data[7]. Only COVID-19 patients sampled

1033   during the primary infection time point were included in these analyses (n = 63). Single-cell eQTL

1034   modeling was performed independently in each cell type; for each cell type, we tested the gene-

1035   SNP pairs for which we had evidence of a significant eQTL (lfsr < 0.10) within patients in the

1036   pseudobulk eQTL analysis (n genes: B cells = 1,395, CD4$^+$ T cells = 1,804, CD8$^+$ T cells = 1,508,

1037   CD14$^+$ monocytes = 2,084, CD16$^+$ monocytes = 1,410, NK cells = 1,523). For CD4$^+$ T cells, we

1038   downsampled the number of cells prior to constructing the model inputs to 60,000 cells due to

1039   vector size constraints in R. To control for genetic background and latent confounders, we included

1040   both genotype and expression PCs in our cell state eQTL models. We computed genotype PCs

1041   using the same approach as above in "eQTL mapping and integration with mashr". Expression

1042   PCs were calculated from non-batch corrected integrated and scaled counts using the same method

1043   as described in "Calculation of functional state scores per cell," but omitting the batch correction

1044   step (i.e., no variables were regressed in the SCTransform call). PCA was run on the cell x gene

1045   matrix of non-corrected integrated and scaled counts subset on the top 3,000 variable features

1046   using the prcomp_irlba function in the R package irlba (v2.3.5.1)[72].

1047   To test for interactions with cell state, we used the following poisson mixed effects

1048   interaction model, where each gene's UMI counts were modeled as a function of genotype as well

1049   as additional donor-level and cell-level covariates. For each gene:

1050

1051

1052
$$\log(E_i) \sim \beta_0 + \beta_G X_{d,G} + \beta_{dataset} X_{d,dataset} + \beta_{age} X_{d,age} + \beta_{sex} X_{d,sex} + \beta_{nUMI} \log(X_{i,nUMI})$$

1053
$$+ \beta_{MT} X_{i,MT} + \sum_{k=1}^{3} \beta_{gPC_k} X_{d,gPC_k} + \sum_{k=1}^{5} \beta_{ePC_k} X_{i,ePC_k} + \beta_{cell\,state} X_{i,cell\,state}$$

1054
$$+ \beta_{G \times cell\,state} X_{d,G} X_{i,cell\,state} + (\phi_d \mid d) + (\kappa_b \mid b) + \varepsilon$$

1055
1056 Here, E is the expression of the gene in cell i, β_0 is the intercept, and ε represents the residuals. All

1057 other βs represent fixed effects for various covariates in cell i, donor d, or experimental batch b as

1058 follows: G = genotype at the eQTL variant, *dataset* = dataset from which sample originates, *age* =

1059 scaled age of donor, *sex* = sex of donor, *nUMI* = number of UMI per cell (accounts for sequencing

1060 depth), *MT* = percent of mitochondrial UMIs per cell, *gPC* = genotype PCs, *ePC* = single-cell

1061 expression PCs prior to batch correction, and *cell state* = functional cell state score per cell

1062 (described above). Donor was modeled as a random individual effect ($\phi_d \mid d$) to account for the

1063 fact that multiple cells were sampled per individual, and experimental batch was also modeled as

1064 a random effect ($\kappa_b \mid b$). Finally, $\beta_{G \times cell\,state} X_{d,G} X_{i,cell\,state}$ represents the cell state x genotype

1065 interaction term of interest.

1066   Single-cell poisson mixed interaction models were fit using the glmer function in the lme4

1067 R package (v 1.1-29) with the following parameters: family = "poisson", nAGQ = 0, and control

1068 = glmerControl(optimizer = "nloptwrap")[73]. To determine significance, we used a likelihood ratio

1069 test (LRT) comparing two models, one with and one without the cell state interaction term and

1070 calculated a p-value for the test statistic against the Chi-squared distribution with one degree of

1071 freedom. To correct for multiple hypothesis testing, we performed one permutation in which cell

1072 state scores were permuted across all cells per pathway tested, and we obtained a null LRT p-value

1073 distribution using the same framework as above with our permuted data. We then calculated q-

54

1074   values for the cell state-genotype interaction term using the empirical p-value distribution across

1075   all tested eQTL using the empPvals and qvalue functions from the qvalue package (v2.16.0)[74].

1076

1077   **Colocalization of GWAS and eQTL signals.** Specifically for colocalization analyses, eQTL were

1078   remapped in each cell type-disease state pair with Matrix eQTL[69] using a 1 megabase (Mb) *cis-*

1079   window, with all other modeling parameters kept constant, to broaden our search space and

1080   increase our probability of detecting colocalized variants. We assessed colocalization between our

1081   identified eQTLs in each cell type-disease state pair and the COVID-19 GWAS meta-analyses of

1082   European-ancestry subjects from the COVID-19 Host Genetics Initiative (HGI)[11] release 7

1083   (https://www.covid19hg.org/results/r7/). We tested two outcomes: "critical illness" and

1084   "hospitalization" (named A2 and B2, respectively by the COVID-19 HGI). A Bayesian analysis

1085   was implemented using the coloc (v5.1.0.1)[75] R package with default settings to analyze all

1086   variants in the 1 Mb genomic locus centered on the lead eQTL in the single-cell data. We only

1087   considered GWAS loci with associations below 1×10^{-4}. We defined colocalization as PP4 > 0.8,

1088   where PP4 corresponds to the posterior probability of colocalization between eQTL and GWAS

1089   signals. Colocalization was visualized using the R package LocusCompareR (v1.0.0)[76] with

1090   default parameters, except for the genome parameter which was set to "hg38". LD r^2 with the lead

1091   SNP was calculated using the default "EUR" population.

1092
Fig. S1. Sampling time points and global SARS-CoV-2 infection effects. **(A)** Distribution of days since symptom onset (DSO) at the time of sample collection across acute and convalescent COVID-19 patients in our cohort. Samples were considered to be in the acute phase of infection if DSO ≤ 20 (red line), and samples with DSO > 20 were considered follow-ups. **(B)** Numbers and proportions (y-axis) of genes significantly differentially expressed ($|\log_2FC| > 0.5$, FDR < 0.05) in COVID-19 patients compared to healthy controls. **(C)** Overlap between the set of significantly differentially expressed genes upon infection (blue circle, left) and the set of genes significantly correlated with disease severity (red circle, right). **(D)** Correlation between respiratory support score and days since symptom onset (DSO). P-value and best-fit slope were determined from a linear regression model correcting for dataset.

**Fig. S2**. **Sharing patterns among disease-state-shared eGenes.** Significant eGene sharing patterns among disease-state-shared eGenes (lfsr$_{CTL}$ < 0.1 and lfsr$_{COVID}$ < 0.3 or lfsr$_{COVID}$ < 0.1 and lfsr$_{CTL}$ < 0.3) in healthy controls and COVID-19 patients across cell types.

1110

58

1111   **Fig. S3. Cell type-specific response eQTL patterns. (A)** Distribution of effect sizes for the cell

1112   type-specific reQTL sets plotted across cell types in healthy controls ("ctl"), patients ("COVID-

1113   19"), and follow-ups ("follow-up") for the full sample set, as well as a downsampled set in the

1114   control ("ctl downsample") and patient ("COVID-19 downsample") groups. Downsampled sets

1115   mirrored the follow-up data structure (n = 26 samples) and were derived as follows: i) for controls,

1116   26 individuals were randomly sampled from the control group, and ii) for patients, the 21 follow-

1117   up individuals with a corresponding acute infection time point sample were included. Here, all

1118   eQTL effect sizes are taken directly from Matrix eQTL (i.e., prior to running mash). **(B)** Paired

1119   reQTL effect sizes in COVID-19 patients ("COVID") and follow-ups ("FOLLOW") across cell

1120   types. The change in effect size for each gene from patient to follow-up samples is plotted as a

1121   black line. **(C)** The observed mean Δ response magnitude across the 370 CD14$^+$ monocyte-specific

1122   reQTL (red dotted line) compared to the null expectation when permuting random sets of shared

1123   eGenes of the same size (n = 370) and computing their mean (n permutations = 1,000, null shown

1124   in gray). The observed mean is significantly lower (p < 0.001) than random expectation.

1125
Fig. S4. Colocalization patterns in COVID-19 follow-up samples. (A) The colocalization signal for the lead SNP rs9636867 (*IFNAR2*, CD4+ T cells, GWAS: hospitalization due to severe COVID-19) is absent in follow-ups. **(B)** The colocalization signal for the lead SNP rs7246757 (*SNRPD2*, CD14+ monocytes, GWAS: hospitalization due to severe COVID-19) is absent in follow-ups. For both **(A)** and **(B)**, the larger plot on the left shows the correlation between GWAS p-values (x-axis) and eQTL p-values (y-axis) in follow-ups. Smaller plots on the right show Manhattan plots for the GWAS signal (top) and the eQTL signal in follow-ups (bottom). The lead SNP is depicted as a purple diamond.

1135   **Table S8. Gene expression principal components (PCs) regressed in the pseudobulk eQTL**

1136   **analysis.** PCs regressed and number of significant eQTL per cell type and disease state are

1137   reported.

Cell type	N Regressed PCs			N genes < 0.10 FDR, Matrix eQTL		
	Control	*COVID-19*	*Follow-up*	*Control*	*COVID-19*	*Follow-up*
CD14+ monocytes	1 to 3	1 to 14	1 to 2	430	1286	56
CD16+ monocytes	1	1	1	10	49	6
CD4+ T	1 to 10	1 to 4	1 to 2	1665	730	77
CD8+ T	1 to 12	1 to 13	1 to 3	424	274	25
B	1 to 5	1 to 8	1	285	192	9
NK	1 to 13	1 to 6	1 to 2	74	230	9

1138
