Abstract

This systematic review and meta-analysis was performed to assess effectiveness of home-based exercise compared with control interventions for functional rehabilitation in elderly patients after hip fracture surgery. Comprehensive literature search was performed on PubMed, EMBASE, Web of Science, Cochrane library, and Clinicaltrials.gov to identify eligible randomized controlled trials (RCTs). Standard mean difference (SMD) and risk ratio (RR) with 95% confidence interval (CI) was calculated. The certainty of evidence of each outcome was assessed by using Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach. A total of 28 articles reporting 21 unique RCTs ($n = 2470$) were finally included. Compared with control interventions, home-based exercise significantly improved Berg balance scale (BBS, SMD = 0.28, 95%CI: 0.03 to 0.53, $P = 0.030$), timed-up-and-go test (TUG, SMD = -0.28, 95%CI: -0.50 to -0.07, $P = 0.009$), Short Fort-36 physical component score (SF-36 PCS, SMD = 0.49, 95%CI: 0.28 to 0.70, $P < 0.001$), and knee extensor strength (SMD = 0.23, 95%CI: 0.09 to 0.37, $P = 0.001$). No significant improvement was observed in gait speed, 6-minute walking test, short physical performance battery performance (SPPB), activities of daily living (ADL), or fear of falling in the home exercise group. Risk of adverse events, including emergency department visits, hospital readmissions, and falls, did not differ between both groups. According to GRADE, the overall certainty of evidence was moderate for usual gait speed, SPPB, ADL, fear of falling, and SF-36 PCS, and was low or very low for the other outcomes. Our meta-analysis demonstrated home-based exercise had positive effect on physical function after hip fracture surgery. Home-based rehabilitation might be recommended for rehabilitation of fractured patients after hospital discharge.

Introduction

Hip fracture is a major traumatic injury and a devastating disease for older adults, and the incidence increases with age in older population aged 65 or above [1–3]. The number of hip

fractures each year is expected to increase to 4.5 million by 2050 [4]. Hip fracture limits the independence of activities of daily living (ADL) and significantly reduces physical activity and quality of life during inpatient period and for a long time after discharge [5]. It is associated with high disability and mortality in older adults with a 1-year mortality rate of approximately 14–30% [6]. Despite surgical treatment, only 40–60% of fractured patients restore their pre-fracture level of mobility, and 40–70% recover level of ADL'S independence [7]. The impact of hip fractures on physical function and quality of life is long-lasting, and many patients still need long-term nursing care in an institution or at home after hip fractures [8].

Structured post-surgery rehabilitation is critical for the recovery of physical function and self-care ability. Recent meta-analyses demonstrated that postoperative exercise significantly improved mobility, ADL, muscle strength and balance in older adults after fracture surgery [9, 10]. However, due to the shortage of beds and high cost for supervised institution-based exercise, most of fractured patients will eventually return home. Thus, apart from acute or sub-acute in-hospital rehabilitation, post-discharge exercise is still warranted for long-term functional recovery. More and more attention is given to home-based rehabilitation programs to extend rehabilitation guidance from the hospital to the home. Home-based exercise with high feasibility, low cost, and incorporation with daily-life function, is recommended as an alternative for rehabilitation and is suitable for frail patients who cannot attend training programs outside the home [11]. Yet, the effectiveness of home-based exercise in older adults after hip fracture surgery is still in controversy. Several randomized controlled trials (RCTs) showed superior performance of home-based exercise than control interventions by reducing hospital stay and fear of falling, and improving physical activity, mobility, and independence of ADL [12–16]. The other trials failed to find significant differences of functional recovery between home-based rehabilitation and control interventions such as standard care or active controls [17, 18].

Considering the conflicting results of published RCTs, we performed the present systematic review and meta-analysis to investigate the effectiveness of home-based exercise on balance, mobility, independence in ADL, lower extremities strength, quality of life, and fear of falling in older adults after hip fracture surgery.

Methods

Literature search and selection

This meta-analysis was conducted in compliance with the Preferred Reporting Items for Systematic review and meta-analysis guideline ([S1 Checklist](#)) [19]. Electronic literature databases, including PubMed, EMBASE, Web of Science, Cochrane library, and Clinicaltrials.gov, were comprehensively searched from inception to June 31st, 2023 to identify potentially relevant articles. The following search terms were used: (hip fracture* OR femoral fracture*) AND (home-based OR in-home OR home) AND (rehabilitation OR exercise OR physiotherapy OR training). The reference lists of relevant reviews, meta-analyses and research articles were manually reviewed to identify additional eligible articles. There was no language restriction.

Eligible studies were selected according to PICOS framework as follows. Participant (P): older adults after hip fracture surgery. Intervention (I): home-based rehabilitation. Control (C): other exercise, rehabilitation or usual care. Outcome (O): mobility, balance, activities of daily living (ADL), muscle strength, quality of life, and adverse events including emergency department visits, falls, and hospital readmissions. Study design (S): RCTs. Reviews, case reports, studies with incomplete or missing data or inappropriate controls, and non-randomized studies were all excluded.

Outcome measurements

Balance was measured by Berg balance score (BBS) and timed-up-and-go test (TUG). Independence in ADL was assessed using Barthel index and instrumental ADL. Mobility indexes included fast and usual gait speed, 6-minute walking test (6MWT), short physical performance battery (SPPB), and walking outdoors. Fear of falling was assessed by falls efficacy scale. Knee extensor strength was measured for muscle strength. Quality of life was assessed using Short Form-36 (SF-36) questionnaire physical component score (PCS) and mental component score (MCS). Adverse events included emergency department visits, falls, and hospital readmissions.

Risk of bias assessment

The Cochrane Collaboration's tool for assessing risk of bias (RoB) was used to assess the risk of bias in terms of random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, incomplete outcome data, selective reporting, and other bias. The risk of bias of each domain was judged as low, unclear or high.

Data extraction

The following information of each study included in meta-analysis was extracted: first author, publication year, country, sample size, mean age, percentage of females, activities and component of home-based rehabilitation and control, initiation time and duration of interventions, time points of outcome assessment, and outcome measurements. Two independent authors performed literature search and selection, risk of bias assessment, and data extraction. Discrepancies, if occurring, were resolved by further discussion.

Statistical analysis

Statistical analysis was conducted by using STATA 16.0 (Stata Corporation, TX, USA). The heterogeneity was assessed by using I^2 statistic and Q test. $I^2 < 50\%$ and P value of Q test > 0.10 indicated low between-study heterogeneity, and a fixed-effect model was used for quantitative synthesis. Otherwise, a random-effect model was used for meta-analysis with high heterogeneity. Standard mean difference (SMD), measured by cohen's d, with 95% confidence interval (CI) were calculated for pooled effect size of continuous variables. The effect size of SMD was categorized as small (0.1 to 0.4), medium (0.5–0.7) or large (0.8 or greater) [20]. Risk ratio (RR) with 95%CI was calculated to assess the association strength between home-based exercise and categorical variable outcomes including walking outdoors, emergency department visits, falls, and hospital readmissions. We noted that several trials measured outcomes repeatedly at different time point during follow-up. Thus, the outcome measurements of the longest follow-up were synthesized for overall analysis. Besides, outcomes measured at a time point of ≤ 6 months of follow-up were pooled for short-term effect analysis, whereas those measured at a time point of > 6 months of follow-up were synthesized for long-term effect analysis. Further subgroup analysis were performed according to intervention initiation time after surgery (≤ 3 months, > 3 months), intervention duration (≤ 3 months, > 3 months), and rehabilitation type (multicomponent, exercise only). Here, "multicomponent home-based rehabilitation" was defined as programs including components of exercise, education, and evaluation and modification of environment while "exercise only" was defined as those including only home exercise [21]. Sensitivity analysis applying a Leave-One-Out method was performed to evaluate the robustness of pooled results [22–24]. Potential publication bias was assessed by funnel plot and Egger's test. P value < 0.05 was considered statistically significant.

Certainty of evidence

Two independent authors assessed the certainty of evidence of pooled results using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach [25]. The overall certainty of evidence was graded as very low, low, moderate, and high by evaluating the certainty in terms of study design, risk of bias, inconsistency, indirectness, imprecision and publication bias. Conflicts were resolved by further discussion.

Results

Baseline characteristics of trials included in meta-analysis

As shown in Fig 1, 1433 articles were retrieved from literature search, and 59 full-text articles were further reviewed for eligibility. After excluding trials with inappropriate controls (n = 8), trials without outcomes of interest (n = 6), meta-analysis (n = 4), non-randomized studies (n = 6), and protocols of randomized trials (n = 7), 28 articles reporting 21 unique RTCs were finally included for meta-analysis [12–18, 26–46] (S1 Table). A total of 1291 older adults after hip fracture surgery were assigned to home-based exercise group and 1179 patients were assigned to the control group. Five articles reported the primary or original outcomes of 5 unique RCTs [14, 16, 17, 36, 42], and 7 articles reported the long-term follow-up outcomes or secondary outcomes of interest of these 5 RCTs [33, 35, 37–39, 41, 45]. For control interventions, two trials used in-hospital rehabilitation [12, 17], two used active controls [18, 44], and the others used usual care. The time to initiate home-based exercise ranged from immediately after discharge to at average 7 months after fractures, with 13 trials initiating home exercise early after surgery (≤ 3 months) [12–16, 26, 29, 32, 34, 35, 40, 42, 46] and 7 initiating intervention late after surgery (> 3 months) [18, 27, 28, 30, 31, 43, 44]. The home-based exercise duration of included trials varied between 1 month and 12 months, with 10 trials administering ≤ 3 months of intervention and 11 providing > 3 months of exercise. Nine trials implemented multicomponent home-based rehabilitation programs [12, 14, 16–18, 29, 32, 35, 42], and the others applied only home exercise. Three trials had 2 arms of home-based exercise [28, 31, 36], and another trial had 2 arms of home-based exercise as well as 2 arms of control interventions [15]. The baseline characteristics of all trials included in meta-analysis were summarized in Table 1. The reported outcomes and time points of outcome assessment of each trial were listed in S2 Table. The extracted analytic data are presented in S3 and S4 Tables.

Risk of bias

Since blinding of physiotherapists and patients was impossible, the bias of blinding of participants and personnel (performing bias) of all included RCTs was deemed as unclear risk. One trial reported the outcome assessors were not blinded to assignment, and therefore had high risk of detection bias [28]. Four trials were considered to have unclear risk of bias of selective reporting, as they reported the primary or original outcomes and other secondary outcomes in different articles [14, 17, 35–37, 39, 41, 42, 45]. The quality assessment of risk of bias was shown in Figs 2 and 3.

Balance

Five trials, including 326 patients in home exercise group and 324 in control group, reported BBS outcome after intervention [12–14, 26, 29]. Meta-analysis using a random-effect model demonstrated a significantly improved BBS score in home exercise group than the control group (SMD = 0.28, 95%CI: 0.03 to 0.53, $P = 0.030$, $I^2 = 50.6\%$, Fig 4). TUG was measured in 5 trials comprising 170 patients in home exercise group and 177 in control

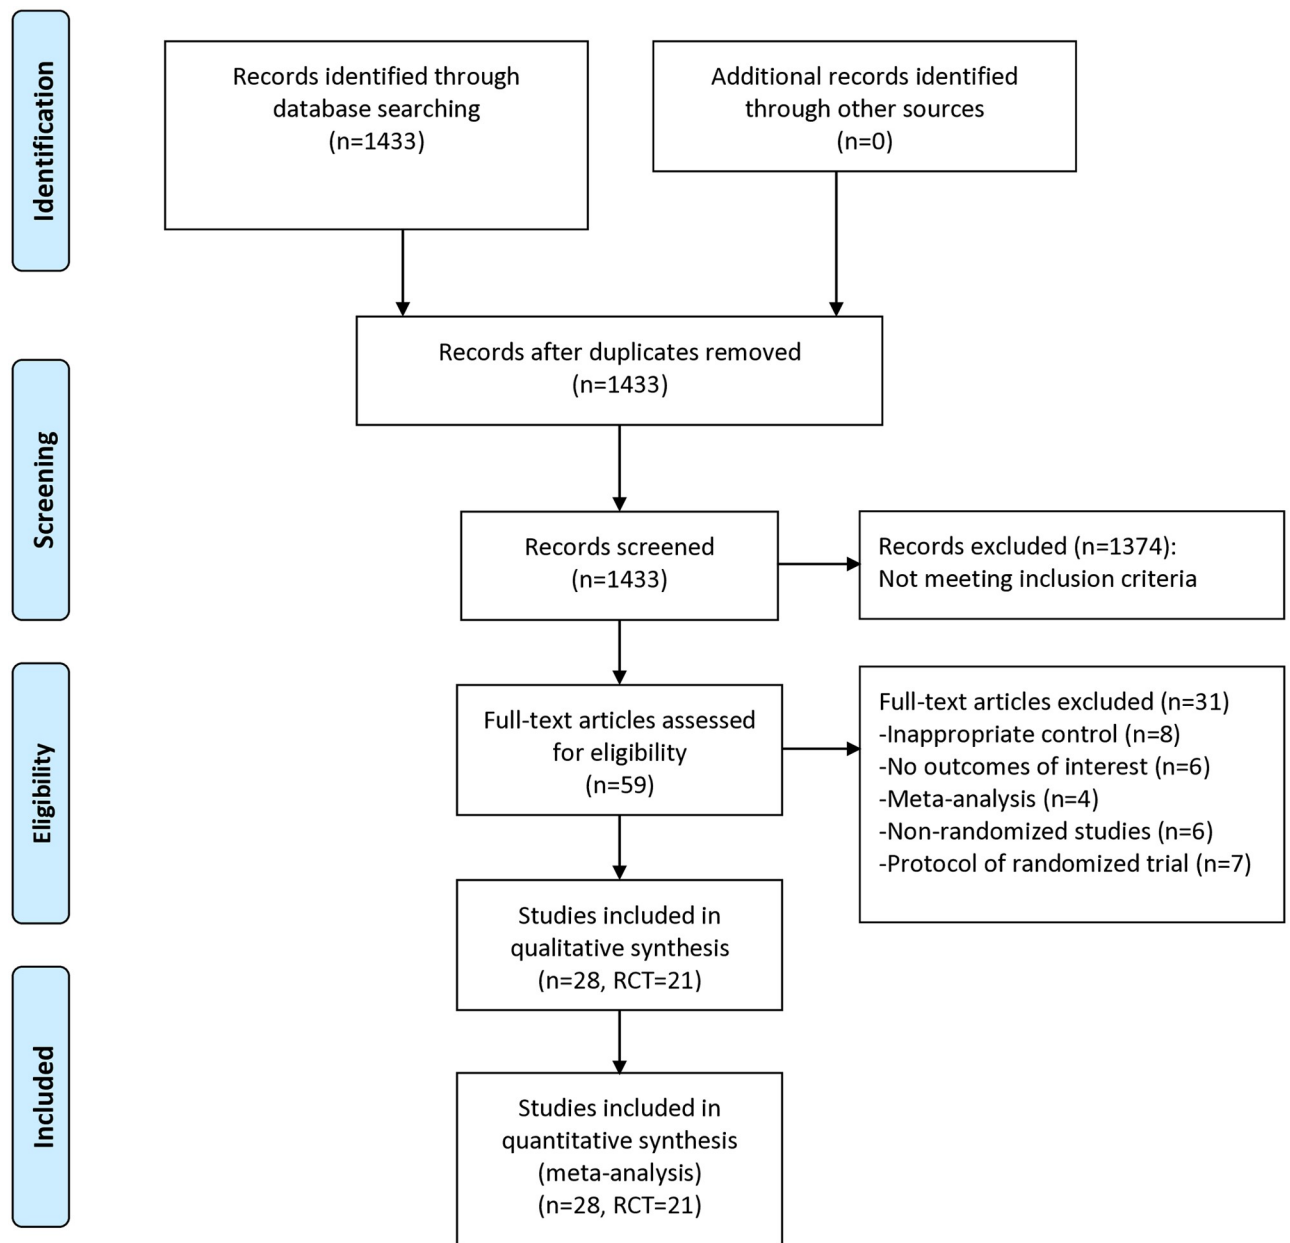

Fig 1. Flowchart of literature search and selection.

<https://doi.org/10.1371/journal.pone.0315707.g001>

group [12, 15, 16, 26, 40]. Using a fixed-effect model, quantitative synthesis yield a SMD of -0.28 (95%CI: -0.50 to -0.07, $P = 0.009$, Fig 5), indicating a significantly improved balance of home exercise group than control group. However, the SMD effect sizes of both balance measurements were small.

Mobility

Fast gait speed was measured in 5 RCTs involving 172 individuals in home exercise group and 168 in control group [17, 18, 25, 30, 44]. Usual gait speed was reported in 9 RCTs including

420 cases in home exercise group and 411 in control group [17, 18, 27, 29–31, 43, 44]. The SMD of fast gait speed was 0.29 (95%CI: -0.08 to 0.66, $P = 0.120$, Fig 6), which was not statistically significant. Similarly, there was no significant difference of usual gait speed between both groups (SMD = 0.07, 95%CI: -0.06 to 0.21, $P = 0.302$, Fig 6).

Fig 2. Risk of bias graph of included trials.

<https://doi.org/10.1371/journal.pone.0315707.g002>

Pooled analysis of 5 trials showed no significant difference of SPPB performance between the home exercise group and the control group (SMD = 0.30, 95%CI: -0.10 to 0.69, $P = 0.138$, [S1 Fig](#)). Additionally, meta-analysis demonstrated home exercise did not have significantly impact on 6MWT (SMD = 0.37, 95%CI: -0.19 to 0.92, $P = 0.199$, [S2 Fig](#)) and walking outdoors (RR = 1.0, 95%CI: 0.83 to 1.21, $P = 0.975$, [S3 Fig](#)) compared to control group.

Independence in ADL

Five RCTs including 202 fractured older adults in each group reported Barthel's ADL, which showed no significant difference of ADL between both groups (SMD = 0.05, 95%CI: -0.29 to 0.38, $P = 0.792$, [S4 Fig](#)) after pooling analysis using a random-effect model. Similarly, instrumental ADL did not differ between home exercise group and control group (SMD = 0.15, 95%CI: -0.06 to 0.36, $P = 0.159$, [S5 Fig](#)).

Quality of life

SF-36 PCS was measured in 4 trials and SF-36 MCS was reported in 2 trials. Using a fixed-effect model, meta-analysis demonstrated a significantly improved SF-36 PCS in home exercise group than control group (SMD = 0.49, 95%CI: 0.28 to 0.70, $P < 0.001$) but no MCS difference between both groups (SMD = 0.08, 95%CI: -0.15 to 0.31, $P = 0.486$, [Fig 7](#)). The SMD effect size of SF-36 PCS was moderate.

Muscle strength

Knee extensor strength was measured in 7 trials [[13](#), [15](#), [26–29](#), [32](#)], which included 417 and 385 patients in home exercise group and control group, respectively. The SMD was 0.23 (95%CI: 0.09 to 0.37, $P = 0.001$, [Fig 8](#)), indicating a significantly improved strength in home exercise group than control group. However, the effect size of SMD was small.

Fear of falling

Pooling analysis of 6 trials reporting falls efficacy scale demonstrated no significantly improved fear of falling in patients receiving home-based exercise than those in control group (SMD = 0.32, 95%CI: -0.07 to 0.71, $P = 0.110$, [S9 Fig](#)).

Adverse events

There was no significant risk difference in terms of emergency department visits (RR = 0.85, 95%CI: 0.51 to 1.42, [S6 Fig](#)), hospital readmissions (RR = 0.87, 95%CI: 0.70 to 1.10, [S7 Fig](#)), and falls (RR = 0.98, 95%CI: 0.83 to 1.16, [S8 Fig](#)) between home exercise group and control group.

Subgroup analysis

Subgroup analyses according to follow-up duration were performed to explore the short-term (≤ 6 months) and long-term (> 6 months) effect of home-based exercise in older adults after

Fixed-effects inverse-variance model

Fig 5. Forest plot of meta-analysis of timed-up-and-go test.

<https://doi.org/10.1371/journal.pone.0315707.g005>

hip fracture surgery (S5 and S6 Tables). Subgroup analysis demonstrated significant short-term impact of home exercise on TUG, falls efficacy scale, knee extensor strength, SF-36 PCS, and risk of emergency department visits. Yet, long-term impact was only observed on SF-36 PCS.

Since there were less than 10 available trials for each outcome, we did not perform meta-regression analysis to evaluate the association of intervention initiation and duration as continuous variables with the effect size. Our study revealed that early initiation of home exercise after surgery (≤ 3 months) was significantly associated with improved BBS, TUG, knee extensor strength and SF-36 PCS and reduced risk of hospital readmission, whereas late initiation

Fixed-effects inverse-variance model

Fig 7. Forest plot of meta-analysis of Short Form-36 physical and mental component scores.

<https://doi.org/10.1371/journal.pone.0315707.g007>

(>3 months) was only associated with improved knee extensor strength and SF-36 PCS (S7 Table). Both short (≤ 3 months) and long (>3 months) duration of home exercise showed improvement in knee extensor strength and SF-36 PCS without significant between-subgroup differences (S7 Table).

Regarding rehabilitation types, exercise-only rehabilitation exhibited greater improvement in BBS (0.50 vs 0.11, $P = 0.022$), fast gait speed (0.63 vs 0.02, $P = 0.018$), and knee extensor strength (0.38 vs 0.03, $P = 0.015$) compared to multicomponent rehabilitation (S7 Table). On the contrary, multicomponent rehabilitation showed greater improvement in falls efficacy scale (0.91 vs 0.07, $P = 0.002$) and reduction in risk of emergency department visit (0.62 vs 1.52, $P = 0.012$) compared to exercise only (S7 Table).

Sensitivity analysis and publication bias

Sensitivity analysis indicated the pooled effect sizes were not significantly influenced by the omission of a single study. Egger’s test showed no evidence of potential publication bias in analyses of all outcomes except fast gait speed and knee extensor strength ($P = 0.007$ and 0.008 , respectively; S8 Table). Using a trim-and-filled method, there was still significant difference of knee extensor strength between both groups (SMD = 0.15, 95%CI: 0.02 to 0.28, S9 Fig).

Fixed-effects inverse-variance model

Certainty of evidence

According to GRADE approach, there was moderate certainty of evidence for outcomes of usual gait speed, SPPB, Barthel’s ADL, IADL, falls efficacy scale, and SF-35 PCS (Table 2). The overall certainty of evidence was graded as low for BBS, TUG, 6MWT, and knee extensor strength, and was very low for fast gait speed (Table 2).

Discussion

By pooling 21 RCTs with a total sample size of 2470 older adults after hip fracture surgery, this meta-analysis demonstrates that home-based exercise, compared with control interventions, significantly improved knee extensor strength, BBS, TUG, and SF-36 PCS. GRADE assessment shows moderate certainty of evidence for SF-36 PCS and low certainty of evidence for knee extensor strength, BBS, and TUG. These results indicate that home-based exercise is effective in improving lower extremity strength, balance, mobility, and quality of life, which can be recommended for post-discharge functional rehabilitation of older adults after hip fracture surgery.

The muscle strength, balance, and mobility gradually decline in older adults [47]. Subsequent to hip fractures without timely rehabilitation, patients will rapidly lose muscle strength and physical function. Adequate skeletal muscle strength is vital for maintaining hip function and balance in postural maintenance and dynamic daily activities [48]. Post-surgery exercise training, especially those focusing on muscle strength, could significantly improve lower extremity strength, balance, and mobility [49, 50]. Higher intensity and frequency of exercise tend to be associated with greater stronger effects of functional improvement [51, 52]. Yet, whether fractured patients could benefit from home-based exercise, which is usually at a low

Table 2. Assessment of the certainty of evidence using GRADE approach.

intensity, is unclear. Our meta-analysis demonstrated a small, clinically-meaningful increase in lower extremity muscle strength (SMD = 0.23, 95%CI: 0.09 to 0.37) and balance (BBS: SMD = 0.28, 95%CI: 0.03 to 0.53; TUG: SMD = -0.28, 95%CI: -0.50, to -0.07), and a moderate, clinically-meaningful improvement in quality of life (SF-36 PCS: SMD = 0.49, 95%CI: 0.28 to 0.70) in home exercise group compared with the control group. Further analyses revealed that the improvement in quality of life were significant in both short-term and long-term assessments, suggesting that patients may persistently gain benefit for quality of life once starting home exercise. However, the benefits in improving TUG test, increasing knee extensor strength, and reducing fear of falling and risk of emergency department visit were only observed within 6-month follow-up after intervention initiation, which vanished in the long-term follow-up. More studies regarding the long-term and persistent effect of home-based exercise are needed.

The first 3 months after surgery is the best period for functional recovery, and timely initiation of rehabilitation training plays a crucial role in restoring muscle strength, improving balance, and achieving hip function [53]. In addition to benefits in muscle strength and quality of life in both early initiation (≤ 3 months) and late initiation (> 3 months) of home exercise after surgery, our meta-analysis revealed that early initiation significantly improved balance (BBS,

TUG) and reduced the risk of hospital admission compared to control interventions (S7 Table). These findings support that fractured patients will gain more benefits if they start home exercise early after surgery. The exercise duration varied greatly among included trials, and 6 RCTs implemented a yearlong home-based program [14, 15, 29, 34, 36, 42]. A 12-month individualized, multicomponent home-based rehabilitation was found to improve mobility recovery and increase physical activity after hip fractures compared with standard care, and the effect was still maintained at 1-year follow-up [14, 38, 54]. Another yearlong home-based, progressive exercise program exhibited favorable functioning and physical performance than usual care in terms of changes of IADL score, SPPB score and handgrip strength [42, 45].

The rehabilitation component is one of the major concerns affecting the functional recovery after hip fracture surgery [55, 56]. Several trials implemented a multicomponent strategy that combined home exercise with other components, such as environmental evaluation and modification, nutrition advice, pain management, and guidance for safe walking, while some only included exercise component. Multicomponent programs may enhance patient's motivation, self-efficacy, and confidence in their ability to function in the environment in which their injury occurred [12]. As expected, subgroup analysis demonstrated that multicomponent rehabilitation exhibited greater reduction in fear of falling and risk of emergency department visit compared to exercise only. The efficacy of non-exercise components in reducing fear of falling is also observed in another multicomponent intervention, the community ageing in place, advancing better living for elders (CAPABLE), which addresses individual capacities and repairs home environment [57]. Moreover, this program is more effective in improving ADLs and IADLs [57]. Conversely, we observed greater improvements in BBS, fast gait speed, and knee extensor strength for exercise-only programs compared to multicomponent rehabilitation. However, these results need to be cautiously interpreted. Most home-based exercises in our study only applied low-intensity programs while several exercise-only programs used moderate- or high-intensity exercises. Hauer *et al.* implemented a high-intensity progressive resistance training program, which was effective to increase strength and functional performance [26]. Mangione *et al.* found high-intensity resistance training and moderate-intensity aerobic training both significantly improved low extremity force compared to control intervention [31]. Another moderate-intensity walking program increased daily physical activity [46]. Yet, the optimal exercise intensity is still debatable, as a previous study found no difference of knee extensor strength between a high-intensity exercise group and a low-intensity exercise group [58]. While usual care was used as control intervention in most trials, comparison to in-hospital rehabilitation or active control may weaken the efficacy of home-based exercise. Karlsson *et al.* observed similar results between multicomponent home-based rehabilitation and in-hospital rehabilitation in terms of gait speed and independence in ADL [17, 41]. Another trials showed comparable efficacy in BBS, TUG, and quality of life when comparing multicomponent home-based rehabilitation to in-hospital rehabilitation [12]. Magaziner *et al.*, comparing multicomponent program to active control that included active range-of-motion exercises and transcutaneous electrical nerve stimulation, found no difference in 6MWT, balance, gait speed [18]. Collectively, the findings of subgroup analyses suggest that multicomponent home-based rehabilitation with more intensive exercises and initiation as early as possible after surgery may be more effective and safer for functional recovery. Future studies are needed to explore the essential rehabilitation components and optimal exercise intensity and duration for developing an effective and standardized multicomponent home-based rehabilitation program with long-lasting efficacy.

Our meta-analysis has some limitations. Firstly, the majority of included trials have low methodological quality according the risk of bias assessment. Secondly, several trials have very small sample sizes (<50), which could results in overestimated effects of home-based exercise.

Thirdly, the between-study heterogeneity of several outcomes is large, which may be caused by the difference in exercise duration, intensity, frequency of home-based rehabilitation and follow-up duration. Fourthly, the exercise programs and muscles involved were highly heterogeneous across trials, making it challenging to draw a conclusion for the efficacy of a specific exercise program. Finally, the strength and balance tools varied among trials, which needs to be unified and standardized in future trials. Therefore, the results of our meta-analysis need to be cautiously interpreted.

Conclusions

Our meta-analysis shows home-based exercise is effective in improving lower extremity strength, balance, mobility, and quality of life in older patients after hip fracture surgery. Multicomponent rehabilitation with more intensive exercises and earlier initiation can be recommended for patients after hip fracture to achieve a better functional recovery. The long-term effect and the optimal duration, intensity, frequency of home-based exercise need to be investigated in more well-designed, large-scaled RCTs.
