Surgical avulsion of the nail plate as therapy for resistant onychomycosis: case series and literature review*

Dear Editor,

Onychomycosis is a fungal infection of the nails caused by dermatophytes, non-dermatophytic filamentous fungi (NDFF), and yeasts, and is the most commonly observed nail disease in clinical practice.^{1,2} Although common, treatment can be challenging, given the rise in reported resistant cases, either due to an increase in the number of cases related to NDFF that have recognized resistance to classical treatment,^{1,2} or due to virulence factors related to pathogens such as biofilm production, or due to the host's immunological inability to defend himself.^{3,4}

Contrary to what was previously thought, the fungi involved in onychomycosis are capable of alternating between the planktonic form and the biofilm presentations.⁴ The term planktonic refers to isolated fungal cells, freely suspended in a medium, whereas in the form of biofilms, these cells adhere to a surface and form extensive col-

laborative multicellular communities surrounded by an extracellular matrix.^{4,5} In fact, despite being recognized as susceptible to antifungal drugs, the reasons why onychomycosis tends to be refractory to treatments are still uncertain, with a possible relationship with the microenvironment of the nail apparatus and the formation of biofilms suggested as possibilities.⁵

Ideally, biofilms should be removed before starting drug treatment, implying the need for combination therapies.⁵ Procedures such as onychoabrasion, laser, photodynamic therapy, chemical or surgical avulsion are some of the techniques suggested for removing/rupturing the biofilm, thus facilitating drug action.^{4,6}

A retrospective study was conducted, analyzing patients treated at the Dermatology Clinic between January 2016 and December 2023 with onychomycosis refractory to classical drug treatment, who underwent surgical avulsion as alternative therapy. Cases with clinical and onychoscopic suspicion of onychomycosis, and with direct mycological examination (DME) and fungal culture positive were included. The combination of oral antifungals (terbinafine and/or itraconazole) with topical antifungals in nail polish formulation (ciclopirox olamine 5% or amorolfine 8%) was considered as the classical treatment and those who did not show any clinical improvement after one year of pharmacological treatment were considered to be resistant.

Eight patients with 12 treated nails were included in the study (Table 1). All had DME with evidence of fungi;

* Study conducted at the Dermatology Clinic, Hospital da Santa Casa de São Paulo, São Paulo, SP, Brazil.

Table 1 Clinical personal history of patients with refractory onychomycosis undergoing nail plate avulsion: gender, age and comorbidities.

Identification			
Number	Gender	Age	Comorbidities
1	Male	69	SAH, DLP
2	Male	69	SAH, DLP
3	Male	69	SAH, DLP
4	Female	37	None
5	Female	59	Hypothyroidism, fibromyalgia, osteoporosis
6	Male	58	SAH
7	Male	58	SAH
8	Female	67	SAH, iS, MCTD, panic syndrome
9	Female	44	None
10	Female	57	None
11	Female	57	None
12	Female	26	None

SAH, systemic arterial hypertension; DLP, dyslipidemia, iS, ischemic stroke; MCTD, mixed connective tissue disease.

the etiological agent was isolated as NDFF in nine cases, *Neoscytalydium dimidiatum* var. *hyalinum* in six, *Fusarium* sp in three, in addition to one with *Trichophyton rubrum* and another with *Candida* sp. (Table 2). Regarding nail surgery, in eight cases it was performed via the proximal approach of the nail plate and in the other four via the distal approach. The distal technique was indicated for patients with evident onycholysis where nail detachment can be performed in a less traumatic manner. None of the patients developed complications in the postoperative period and all had nail plate growth after the procedure (Table 3). Because this is a procedure with low morbidity (with the use of local anesthesia) and short surgical time, none of the patients were excluded from the study.

Two surgical techniques were used: proximal total nail avulsion and distal total nail avulsion. Proximal digital blockade was used because the authors believe it is efficient and not very painful, with 2% xylocaine as a vasoconstrictor. After the digit was completely anesthetized, a tourniquet was applied. In the proximal technique, the nail plate is completely detached from the proximal nail fold using a nail remover tool, supporting the remover tool on the nail plate so as not to lose the correct plane. Once completely detached, the proximal portion of the nail is pulled above the proximal nail fold using a lever. This movement begins in the central portion of the nail and then extends to the lateral horns. Once the entire proximal portion of the nail plate has been retracted, it is gently detached from proximal to distal. In the distal technique, the nail plate is detached globally at all its connections with the nail folds, from distal to proximal, using a nail remover tool, and then the nail is removed. This technique tends to be more traumatic and it is not very useful when there is severe onychodystrophy.

After surgery, classic topical and oral antifungal treatment was maintained in all patients until the nail plate had grown back completely. The nine nails showed growth of the new plate without signs of infection during the follow-up period (Fig. 1). Three cases showed growth of the nail

plate with dystrophy. After the avulsion only clinical signs were observed and no laboratory tests (DME or culture for fungi) were performed. The choice of using medication after the avulsion of the plate aimed at reducing pathogens in the nail apparatus (matrix, bed, folds) which could be a reservoir for recontamination, just as *tinea pedis* is in patients with recurrent onychomycosis.¹ Several studies propose a combination of biofilm-targeted therapies and conventional drug treatments to increase the success rate in the treatment of refractory onychomycosis.^{4,6,7} Avulsion is a valid choice in this scenario, and according to the experience of the who conducted the study has a satisfactory cure rate.

Analyzing the cases in which the nail plate presented dystrophy after surgical avulsion, it is suggested that the condition may not be solely of infectious origin but may be associated with other factors such as nail trauma caused by patients walking habits.⁶⁻⁸ Given the considerable number of isolated NDFF, it is also possible to consider the hypothesis that these pathogens would not be the sole cause of the nail alteration, but rather secondary agents of onychomycotization. In these cases, it would be necessary to combine other therapeutic and behavioral measures in addition to fighting the infectious process to achieve complete improvement of the condition.^{1,4,6} It is important to emphasize that no patient developed an unfavorable condition after the procedure: in the worst scenario, the nail persisted with the previously observed dystrophy, with no case developing bleeding, infection, or pain.

The study data are promising and open perspectives for more robust studies, so it is important to discuss, at this time, avulsion as an alternative option for refractory cases, in association with systemic treatment. However, the study has limitations that need to be clarified: the small number of patients, lack of uniformity in the postoperative treatment, the fact that it is a retrospective study and no DME or culture was performed on the nails after the end of the treatment, especially in cases with dystrophy, which makes it difficult to

Table 2 Characteristics of onychomycoses treated by nail avulsion: affected digit, results of mycological examinations and treatments performed prior to the procedure.

Identification Number	Preoperative

Treatment of nail psoriasis with intralesional methotrexate: report of four cases demonstrating an effective and safe approach with lower doses[☆]

Dear Editor,

The prevalence of nail psoriasis (NP) ranges from 10% to 82% among patients with psoriasis, with a lifetime incidence of 80% to 90%. It is considered one of the most difficult regions to treat, with 5% to 10% of cases manifesting in the absence of cutaneous symptoms. It may be associated with pain, inflammation with paronychia, aesthetic concerns, and impaired finger function, which significantly impacts the quality of life of individuals.^{1,2}

Topical and injectable therapies are recommended for disease affecting a few nails (<3) and involve local injections of steroids, such as triamcinolone acetonide (TAC), methotrexate, and also cyclosporine. Studies indicate TAC as the most investigated therapy. Intramatrix injection of methotrexate showed the greatest benefit with minimal side effects and results comparable to TAC injection. Cyclosporine was the least effective medication and had the most side effects.^{1,3}

Due to the reported efficacy of intralesional MTX in recent studies, it can be considered among the first-line therapies, especially in cases of nail matrix involvement, and also when efficacy with minimal side effects is prioritized. Studies indicate a dose of 2.5 mg per session (0.1 mL of a 25 mg/mL solution) in the nail bed, with local pain being the main reported side effect.^{4–6}

Systemic treatment, including biologicals, is recommended in resistant cases, when three or more nails are affected, in cases of extensive involvement of the skin and joints, or/and a significant impact on patient quality of life.^{7–9}

Herein, the authors report a series of four cases treated in their service, using intramatrix methotrexate at a reduced

dose, with details of the technique used and satisfactory results.

Patient 1

A 53-year-old female patient, previously diagnosed with fibromyalgia, dyslipidemia, and diabetes, was taking amitriptyline, simvastatin and metformin. She had had a diagnosis of psoriasis vulgaris with nail involvement for more than ten years. She was receiving subcutaneous methotrexate 25 mg/week and folic acid 5 mg/week, and the skin condition was under control. She was also receiving topical clobetasol 8% in nail polish twice a week. She underwent intramatrix infiltration of methotrexate in both thumbs and hallux. The technique consisted of aspirating 12.5 mg of the medication (0.5 mL) with 0.5 mL of saline solution, of which 0.05 mL (0.625 mg of methotrexate) was applied divided into two injections bilaterally (0.025 mL at each site located 3 mm from the proximal digital fold – angle of intersection of the nail with the digital fold) on each thumb and hallux. The total dose for the patient was 2.5 mg; a 100 IU (1 mL) BD syringe was used.

Patient 2

A 68-year-old female hypertensive patient, with heart disease, dyslipidemia, and hypothyroidism, had had a diagnosis of NP for more than one year. Previous treatments included topical corticosteroids and oral biotin. She underwent three sessions of intramatrix methotrexate, at monthly intervals, with the application of 0.625 mg (0.05 mL of the solution) in all fingernails, according to the technique described above. The total dose per session was 6.25 mg.

Patient 3

A 78-year-old male hypertensive patient, with heart disease, benign prostatic hyperplasia, labyrinthitis, diverticulitis, and urticaria, had had a diagnosis of NP and lichen planus for more than two years. Previous treatments included topical corticosteroids, urea, erythromycin, terbinafine, oral acitretin (25 mg/day), and oral zinc. He underwent the same protocol as patient number 2.
