

ATP-sensitive potassium channelopathies: focus on insulin secretion

Frances M. Ashcroft

University Laboratory of Physiology, Oxford University, Oxford, United Kingdom.

ATP-sensitive potassium (K_{ATP}) channels, so named because they are inhibited by intracellular ATP, play key physiological roles in many tissues. In pancreatic β cells, these channels regulate glucose-dependent insulin secretion and serve as the target for sulfonylurea drugs used to treat type 2 diabetes. This review focuses on insulin secretory disorders, such as congenital hyperinsulinemia and neonatal diabetes, that result from mutations in K_{ATP} channel genes. It also considers the extent to which defective regulation of K_{ATP} channel activity contributes to the etiology of type 2 diabetes.

General properties of ATP-sensitive potassium channels

Physiological roles

ATP-sensitive potassium (K_{ATP}) channels couple cell metabolism to electrical activity of the plasma membrane by regulating membrane K^+ fluxes (1). A reduction in metabolism opens K_{ATP} channels, producing K^+ efflux, membrane hyperpolarization, and suppression of electrical activity. Conversely, increased metabolism closes K_{ATP} channels. The consequent membrane depolarization stimulates electrical activity and may thereby trigger cellular responses such as the release of hormones and neurotransmitters, or muscle contraction.

Studies on isolated cells and tissues, and more recently on genetically modified mice and patients with mutations in K_{ATP} channel genes, have demonstrated that K_{ATP} channels play a multitude of physiological roles (1). They contribute to glucose homeostasis by regulating insulin secretion from pancreatic β cells (2–7), glucagon secretion from pancreatic α cells (8), somatostatin secretion from D cells (9), and GLP-1 secretion from L cells (10). In ventromedial hypothalamic neurons they mediate the counter-regulatory response to glucose (11), and in arcuate nucleus neurons they may be involved in appetite regulation (12). In these glucose-sensing cells, K_{ATP} channels respond to fluctuating changes in blood glucose concentration. In many other tissues, however, they are largely closed under resting conditions and open only in response to ischemia, hormones, or neurotransmitters. In cardiac muscle and central neurons the resulting reduction in electrical activity helps protect against cardiac stress and brain seizures (13–17). K_{ATP} channels are involved in ischemic preconditioning in heart (18) and the regulation of vascular smooth muscle tone (opening of K_{ATP} channels leads to relaxation) (19–21). They also modulate electrical activity and neurotransmitter release at synapses

in many brain regions, including the hippocampus, substantia nigra, and hypothalamus (12, 22–27).

Given their critical role in regulating electrical excitability in many cells, it is perhaps not surprising that disruption of K_{ATP} channel function can lead to disease. To date, mutations in K_{ATP} channel genes have been shown to cause neonatal diabetes (7, 28–33), hyperinsulinemia (6, 34–40), and dilated cardiomyopathy (41) in humans. Studies on genetically modified mice have also implicated impaired K_{ATP} channel function in Prinzmetal angina (20–21). This review will focus on recent advances in our understanding of the role of the K_{ATP} channel in insulin secretory disorders.

The central importance of K_{ATP} channels in insulin secretion was first established over 20 years ago (Figure 1) (2, 42). At substimulatory glucose concentrations, K^+ efflux through open K_{ATP} channels keeps the β cell membrane at a negative potential at which voltage-gated Ca^{2+} channels are closed. An increase in plasma glucose stimulates glucose uptake and metabolism by the β cell, producing changes in cytosolic nucleotide concentrations that result in closure of K_{ATP} channels. This leads to a membrane depolarization that opens voltage-gated Ca^{2+} channels, initiating β cell electrical activity, Ca^{2+} influx, a rise in intracellular calcium concentration ($[Ca^{2+}]_i$), and thereby exocytosis of insulin granules. Glucose metabolism has additional effects on insulin release (5, 43), but under physiological conditions K_{ATP} channel closure is an essential step in stimulus-secretion coupling in β cells. This explains why sulfonylurea drugs, such as tolbutamide and glibenclamide, which close K_{ATP} channels (44), are such effective insulin secretagogues and are widely used to treat type 2 diabetes. They bypass β cell metabolism by binding directly to the K_{ATP} channel. Conversely, the K channel opener diazoxide opens K_{ATP} channels and inhibits insulin secretion, independently of blood glucose levels (45).

Metabolic regulation

K_{ATP} channels are subject to complex regulation by numerous cytosolic factors, the most important being the adenine nucleotides ATP and ADP, which interact with 2 sites on the channel, one inhibitory and the other stimulatory (46–49). These can be distinguished experimentally because nucleotide binding to the stimulatory, but not the inhibitory, site requires Mg^{2+} (47, 49). Thus, in the absence of Mg^{2+} only the inhibitory effect is observed. Within the cell, however, where Mg^{2+} is always present, channel activity is determined by the balance between the inhibitory and stimulatory effects of

Nonstandard abbreviations used: DEND syndrome, developmental delay, muscle weakness, epilepsy, dysmorphic features, and neonatal diabetes; GCK, glucokinase; GDH, glutamate dehydrogenase; HI, congenital hyperinsulinism of infancy; K_{ATP} , ATP-sensitive potassium (channel); MIDD, maternally inherited diabetes with deafness; MODY, maturity-onset diabetes of the young; PNDM, permanent neonatal diabetes mellitus; Po, open probability; SCHAD, L-3-hydroxyacyl-CoA dehydrogenase; SUR, sulfonylurea receptor; TNDM, transient neonatal diabetes mellitus.

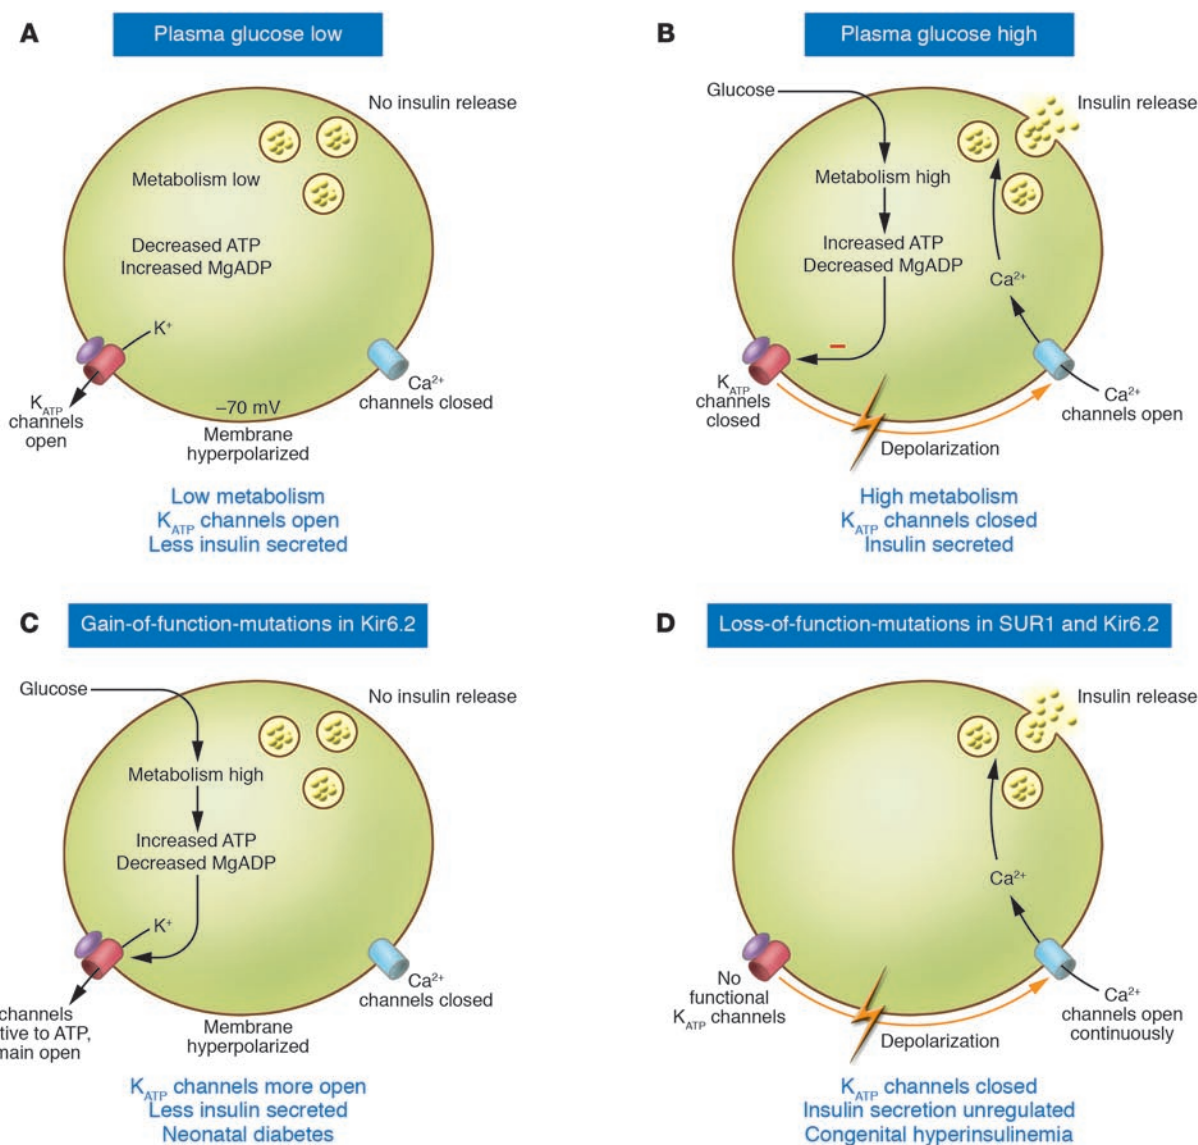

Figure 1

The K_{ATP} channel couples glucose metabolism to insulin secretion. Glucose enters the cell via the GLUT2 transporter, and via glycolytic and mitochondrial metabolism leads to an increase in ATP and a fall in MgADP in the immediate vicinity of the K_{ATP} channel. This results in K_{ATP} channel closure, membrane depolarization, opening of voltage-gated Ca^{2+} channels, Ca^{2+} influx, and exocytosis of insulin granules.

nucleotides. At nucleotide concentrations found in cells, ATP is predicted to block the channel and MgADP to reverse channel inhibition by ATP (42, 49). Consequently, reciprocal changes in the intracellular concentrations of ATP and MgADP are suggested to mediate metabolic regulation of the K_{ATP} channel.

Molecular structure

The K_{ATP} channel is an octameric complex of 4 Kir6.x and 4 SURx subunits (Figure 2) (50, 51). The pore-forming Kir6.x subunit belongs to the inwardly rectifying family of potassium channels (52–54). There are 2 isoforms: Kir6.1, which is found in vascular smooth muscle (54), and Kir6.2, which has a widespread tissue distribution (53). Binding of ATP to Kir6.x causes K_{ATP} channel closure (48, 55).

The sulfonylurea receptor (SUR) belongs to the ABC transporter family (56). It functions as a regulatory subunit, endowing the

channel with sensitivity to (a) stimulation by Mg nucleotides, via its 2 cytosolic nucleotide-binding domains (57, 58); (b) activation by K channel opener drugs (e.g., diazoxide); and (c) inhibition by sulfonylureas (e.g., glibenclamide, tolbutamide) (48, 56). Variations in SUR subunit composition produce K_{ATP} channels with different sensitivities to metabolism and drug regulation (22, 44). SUR1 is found in pancreas and brain (56), SUR2A in cardiac and skeletal muscle (59, 60), and SUR2B in a variety of tissues including brain and smooth muscle (61).

A digression on β cell electrical activity

Electrical activity of the β cell membrane, in the form of Ca^{2+} -dependent action potentials, is essential for insulin secretion: no insulin is secreted in its absence, and the extent of insulin secretion and that of electrical activity are directly correlated (62). The

K_{ATP} channel thus both initiates electrical activity and regulates its extent at suprathreshold glucose concentrations (2, 63). This is because the resting potential in pancreatic β cells is primarily controlled by the K_{ATP} channel.

The K_{ATP} channel also determines the electrical resistance of the β cell membrane, which is low when K_{ATP} channels are open and high when they are closed. The membrane potential is given by the product of the electrical resistance of the membrane and the

current flowing across it. This means that when K_{ATP} channels are open and membrane resistance is low, small currents will affect the membrane potential (and thus insulin secretion) only minimally, whereas when K_{ATP} channels are (largely) closed and membrane resistance is high, the same current will elicit β cell depolarization, electrical activity, and insulin secretion. This explains why potentiators of insulin secretion such as acetylcholine and arginine, which produce *small* inward currents (64, 65), are effective secretagogues

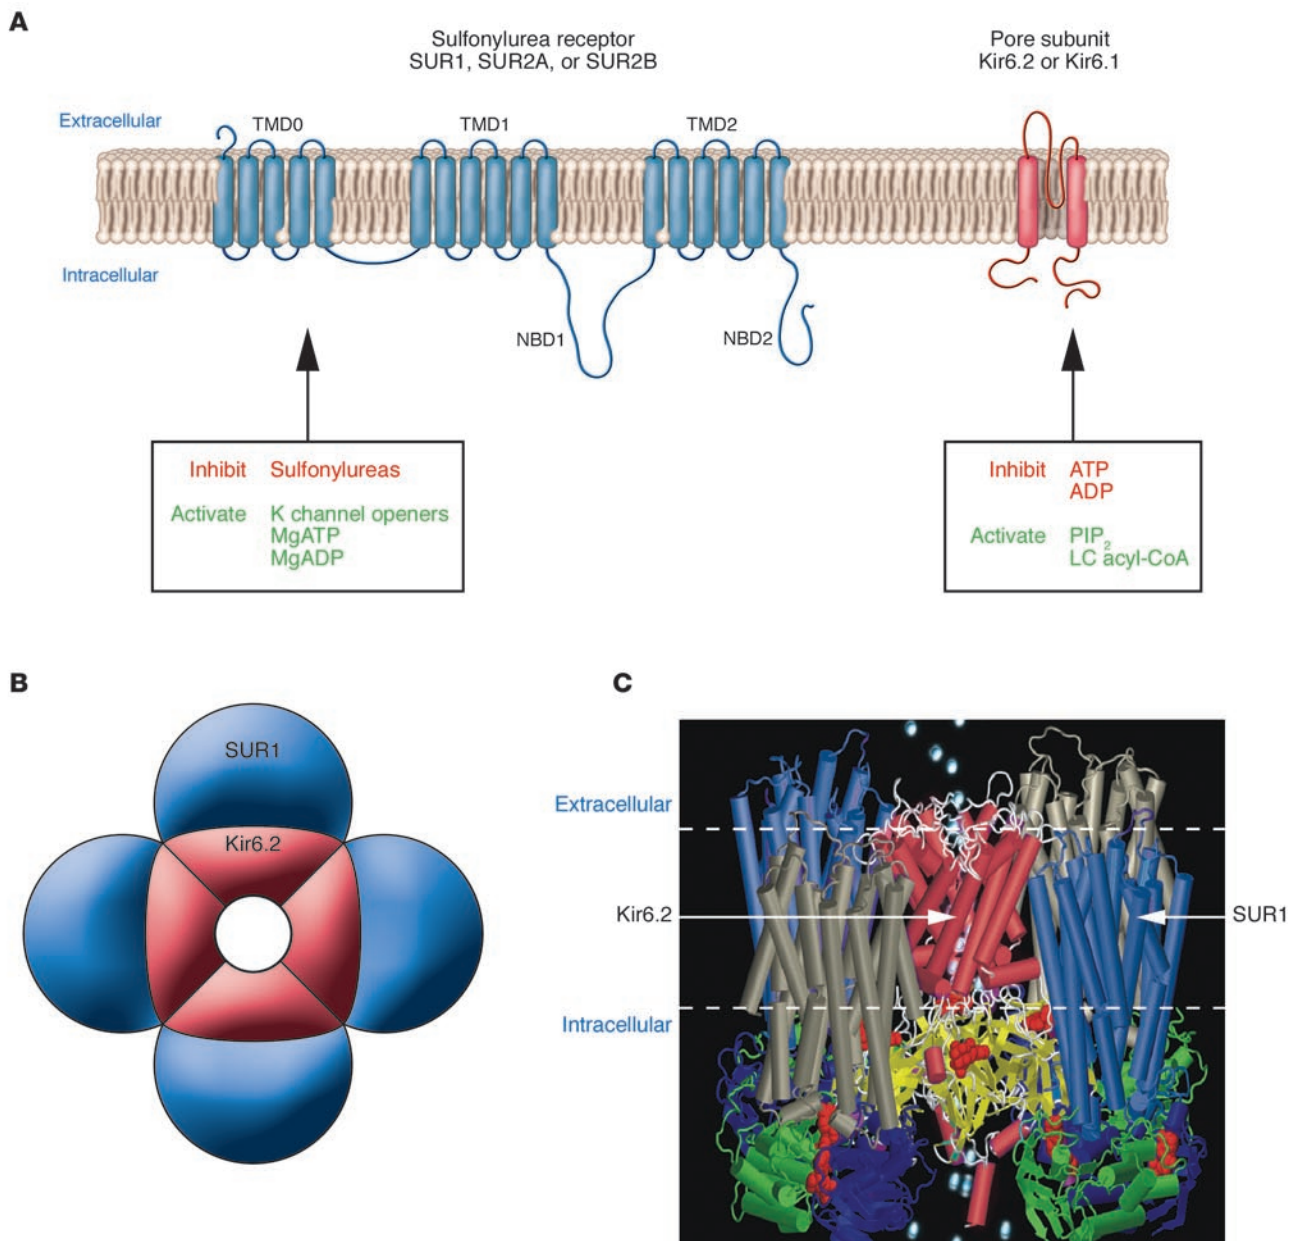

Figure 2

Molecular structure of the K_{ATP} channel. **(A)** Schematic representation of the transmembrane topology of a single SURx (left) or Kir6.x (right) subunit. Mg-nucleotide binding/hydrolysis at the nucleotide-binding domains (NBD1, NBD2) of SUR stimulates channel activity. Sulfonylureas (stimulatory) and K channel openers (inhibitory) also bind to SUR1. Binding of ATP or ADP to Kir6.2 closes the pore, an effect that does not require Mg^{2+} . Conversely, binding of phospholipids such as PIP_2 , or long-chain (LC) acyl-coAs, stimulates K_{ATP} channel activity and decreases its ATP sensitivity. **(B)** Schematic representation of the octameric K_{ATP} channel complex viewed in cross section. Four Kir6.2 subunits come together to form the pore through which K^+ ions move, and each is associated with a regulatory SURx subunit. **(C)** Model of how SUR1 and Kir6.2 might assemble to form the K_{ATP} channel. The SUR model is described in ref. 115 and the Kir6.2 model in ref. 116. The model illustrates that the channel complex contains 4 ATP-binding sites (on Kir6.2) and 8 Mg nucleotide-binding sites (on SUR1).

Table 1
Kir6.2 mutations associated with insulin secretory disorders

Position	Mutation	Clinical phenotype			Functional effect		Reference
		Insulin secretion	Neurol. features	Epilepsy	ATP sensitivity	Po

Mutations in Kir6.2 that cause HI or monogenic diabetes. TMs, transmembrane domains; neurol. features, neurological features (i.e., developmental delay, epilepsy, or other symptoms). The numbers in parentheses refer to the number of cases. Position refers to the position of the residue in the primary sequence of the protein.

only at glucose concentrations that shut most K_{ATP} channels. It also implies that these agents will be *more* effective in disease states that lead to decreased K_{ATP} channel activity (congenital hyperinsulinism of infancy) and *less* effective under conditions that enhance K_{ATP} channel activity (diabetes).

The K_{ATP} channel plays a lesser role in regulating electrical activity of muscle and nerve cells because additional channels contribute to the resting membrane potential and membrane resistance. Thus, equivalent changes in K_{ATP} channel activity are expected to have less dramatic effects in these cell types.

Congenital hyperinsulinism of infancy

Congenital hyperinsulinism of infancy (HI) is characterized by continuous, unregulated insulin secretion despite severe hypoglycemia (6), and, without therapy, the hypoglycemia may cause irreversible brain damage. The disease usually presents at birth or within the first year of life. In the general population, the incidence is estimated as 1 in 50,000 live births, but this can be higher in isolated communities (e.g., 1 in 2,500 in the Arabian peninsula) (6, 34). Most cases of HI are sporadic, but familial forms have been also described, and the disease may result from homozygous, compound heterozygous, or heterozygous mutations (35, 36, 39, 40). Mild cases can be managed with diazoxide or even diet, but more severe forms require subtotal pancreatectomy (commonly about

90–95%). This results in pancreatic insufficiency, and a high incidence of iatrogenic diabetes. The main features of HI are summarized here; further details can be found in other reviews (6, 34, 66).

Functional effects of HI mutations

Mutations in 5 different genes can produce HI: the K_{ATP} channel subunits *SUR1* (6, 35) and Kir6.2 (*KCNJ11*) (36, 37), and the metabolic enzymes glucokinase (*GCK*) (66, 67), glutamate dehydrogenase (*GLUD1*) (68), and short-chain L-3-hydroxyacyl-CoA dehydrogenase (*SCHAD*) (69). However, in about half of patients the genetic basis of HI has not yet been determined.

Mutations in *SUR1* (*ABCC8*) are the most common cause of HI, accounting for almost 50% of cases (6, 34). More than 100 mutations have been described, distributed throughout the gene. They comprise 2 functional classes: those in which the protein is not present in the surface membrane (class I), and those in which the channel is present in the plasma membrane but is always closed, independent of the metabolic state of the cell (class II). Class I mutations are characterized by loss of K_{ATP} channels in the plasma membrane, which may result from impaired *SUR1* synthesis, abnormal *SUR1* maturation, defective channel assembly, or faulty surface membrane trafficking (6, 70–72) (since *SUR1* is required for surface expression of Kir6.2 [ref. 73], Kir6.2 is also absent). Class II mutations impair the

ability of MgADP to stimulate channel activity (6, 39, 57), so that ATP inhibition becomes dominant and the K_{ATP} channel is permanently closed even at low glucose concentrations. Many, but not all, class II mutations reside in the nucleotide-binding domains of SUR1. In general, class I mutations produce more severe disease, whereas some class II mutations cause a milder phenotype because a residual response to MgADP remains (39, 40). However, there is no precise genotype-phenotype correlation, and the same mutation can produce HI with differing degrees of severity in different people.

Mutations in Kir6.2 (*KCNJ11*) that cause HI are much rarer than those in SUR1 (Table 1) (36–38). They also act by reducing, or abolishing, K_{ATP} channel activity in the surface membrane. Because the K_{ATP} channel sets the β cell membrane potential, decreased channel activity produces a persistent membrane depolarization and continuous insulin secretion, irrespective of the blood glucose level (Figure 1).

The glycolytic enzyme glucokinase (GCK) and the mitochondrial enzyme glutamate dehydrogenase (GDH) play key roles in β cell metabolism. It is therefore reasonable to postulate that the gain-of-function mutations in these genes produce HI by increasing ATP synthesis and shifting the K_{ATP} channel inhibition curve to lower glucose concentrations. As a result, K_{ATP} channel activity would decrease, stimulating insulin secretion. Mutations in GDH cause an additional hyperammonemia and an enhanced insulin response to a protein meal or the amino acid leucine (68). The latter may be explained by allosteric stimulation of GDH by leucine, leading to enhanced ATP generation. With one exception (74), the mutations in *GCK* and *GLUD1* (encoding GDH) reported to date produce a mild form of HI that does not require pancreatectomy. It is still unclear how mutations in *SCHAD*, which is involved in mitochondrial fatty acid oxidation, cause HI.

Certain mutations in SUR1, for example R1353H, produce familial leucine-sensitive HI, in which hypoglycemia is provoked by leucine (40). The phenotype is less severe, consistent with the fact that

mutant K_{ATP} channels show a partial response to MgADP. As leucine stimulates β cell ATP production, it seems possible that some SUR1 (and GDH) mutations cause a partial β cell depolarization, which is insufficient to elicit electrical activity and insulin release in the resting state. However, further K_{ATP} channel closure as a result of leucine-stimulated ATP production enhances membrane depolarization, thus eliciting insulin secretion. This hypothesis is supported by the fact that leucine can trigger insulin secretion in normal subjects, although not enough to provoke hypoglycemia, and that enhanced leucine sensitivity is produced by prior treatment with tolbutamide, which closes K_{ATP} channels (75).

Although HI is often associated with neurological problems, it is difficult to assess whether these result from hypoglycemia prior to diagnosis and treatment, or are a direct consequence of the mutation itself. In many extrapancreatic tissues, K_{ATP} channels are closed at rest, so loss-of-function mutations might be expected to have little effect. Furthermore, sulfonylurea therapy in type 2 diabetic patients has few side effects (though it is not clear whether these drugs access brain K_{ATP} channels).

Implications for therapy

In general, mutations in SUR1 and Kir6.2 cause a severe form of HI that is refractory to diazoxide (6, 38) and requires subtotal pancreatectomy. This arises because K_{ATP} channels are either absent or drug-resistant. In contrast, HI caused by mutations in *GCK*, *GLUD1*, or *SCHAD* responds well to diazoxide (6), as K_{ATP} channel properties are normal. In these patients, opening of K_{ATP} channels by diazoxide hyperpolarizes the β cell and so reduces electrical activity and insulin secretion despite high plasma glucose levels. Patients with *GCK* mutations may even be able to control their symptoms by eating regularly (76). This is because *GCK* mutations merely reset the threshold for glucose-stimulated insulin secretion, so that insulin release is still regulated, although the amount is abnormally high for the blood glucose level. Thus, genotyping HI patients may help determine correct therapy.

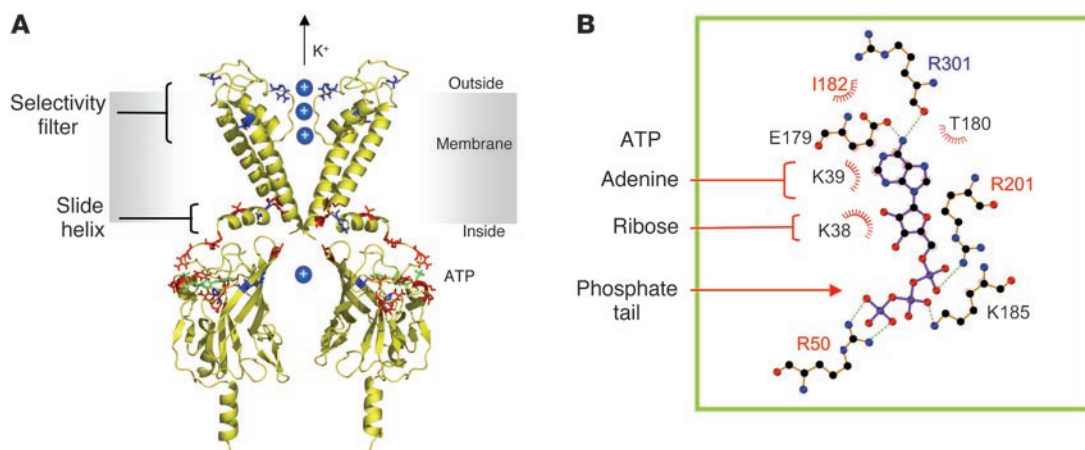

Figure 3

Location of disease-causing mutations in Kir6.2. **(A)** Structural model of Kir6.2 (116) viewed from the side. For clarity, only 2 transmembrane domains, and 2 separate cytosolic domains, are shown. Residues mutated in neonatal diabetes are shown in red, and those that cause hyperinsulinism of infancy in blue. ATP (green) is docked into its binding site. Of the residues implicated in neonatal diabetes, R50, R201, Y330C, and F333I lie close to the ATP-binding site; F35, C42, and E332K at the interface between Kir6.2 subunits; Q52 and G53 in a region postulated to interface with SUR1; and V59, C166, and I296L within regions of the channel involved in gating. **(B)** Close-up of the putative ATP-binding site with residues lying within 3.5 Å of ATP indicated. Residues mutated in neonatal diabetes are shown in red. Part **B** is adapted with permission from *The EMBO Journal* (116).

Table 2
Disease severity correlates with extent of MgATP block

Mutation	Phenotype	Fraction unblocked I-K _{ATP} at 1 mM MgATP	Reference
WT	None	2.4%	33
G53S	TNDM	6%	33
G53R	TNDM	11%	33
I182V	TNDM	12%	33
R201H	PNDM	22%	33
I296L	DEND syndrome	36%	84

Fraction of unblocked K_{ATP} current measured in the heterozygous state in the presence of 1 mM ATP for WT (Kir6.2/SUR1) and Kir6.2 mutant channels.

Both sulfonylureas and K channel openers can act as chemical chaperones and correct surface trafficking defects associated with some SUR1 mutations (71, 72). As the resulting K_{ATP} channels have normal nucleotide sensitivity, drugs with similar chaperone activity that do not block the channel could potentially be useful for treating HI. However, not all mutations can be rescued in this way, and the pharmacology varies with the mutation. Thus, the K channel opener diazoxide corrected trafficking of SUR-R1349H (an effect reversed by glibenclamide) (71), whereas the sulfonylureas glibenclamide and tolbutamide, but not diazoxide, restored surface expression of SUR1-A116P and SUR1-V187D (72). It may not be simple, therefore, to develop drugs that correct surface trafficking generically.

HI and diabetes

There is accumulating evidence that HI caused by some SUR1 mutations can progress to type 2 diabetes in later life (39, 40). This is hypothesized to occur because continuous β cell membrane depolarization, due to reduced K_{ATP} channel activity, causes a maintained influx of Ca²⁺ that activates apoptosis, thereby reducing β cell mass and insulin secretion. Studies on Kir6.2 knockout mice support this idea (4, 77). Except where no surgery has been carried out (39), it is difficult to distinguish whether SUR1 mutations predispose human patients to type 2 diabetes, or whether the diabetes results from early pancreatectomy. It is also uncertain whether HI mutations in other genes enhance susceptibility to diabetes.

Permanent neonatal diabetes

Neonatal diabetes mellitus is characterized by hyperglycemia requiring insulin therapy that develops within the first 6 months of life. It is a rare disorder affecting 1 in 400,000 live births (78), and it may be either transient (TNDM) or permanent (PNDM). Approximately 50% of PNDM cases result from heterozygous gain-of-function mutations in Kir6.2 (7, 28–33). Homozygous loss-of-function mutations in GCK are a rare cause of the disease (66, 79, 80) and are thought to act by impairing K_{ATP} channel closure indirectly, via reduced metabolic generation of ATP. Transient neonatal diabetes (TNDM), which resolves with a median of 3 months, is usually associated with an abnormality of imprinting in chromosome 6q24 (81). However, heterozygous mutations in Kir6.2 can produce a remitting relapsing form of neonatal diabetes that resembles TNDM (33).

To date, 20 mutations in 14 different residues have been reported to cause neonatal diabetes (Table 1). Their location in a struc-

tural model of Kir6.2 is shown in Figure 3. They form striking clusters in the putative ATP-binding site, at the inner end of the transmembrane domains (where the second transmembrane helices come together to form the inner mouth of the channel), and in cytosolic loops that link these 2 regions. This suggests that the PNDM mutations may provide clues to how ATP binding is translated into closure of the Kir6.2 pore. Two residues, V59 and R201, are mutated more commonly than others.

A range of phenotypes

Gain-of-function mutations in Kir6.2 cause a range of phenotypes, distinguished by increasing severity (Table 1). The most common class of mutation produces PNDM alone. These patients show minimal insulin secretion in response to i.v. glucose but may secrete insulin in response to sulfonylureas (7, 28, 32, 82, 83). Other classes of mutation cause more severe phenotypes. Some patients have delayed speech and walking and may show muscle weakness in addition to neonatal diabetes (7, 29, 30). A third class of mutations cause DEND syndrome, which is characterized by marked developmental delay, muscle weakness, epilepsy, dysmorphic features, and neonatal diabetes (7, 83–85). Mutations that cause less severe phenotypes than PNDM are also found. Thus, some mutations cause TNDM (33) and 1 mutation has been identified that causes diabetes of variable severity, ranging from TNDM to diabetes of adult onset (age 22–26) that resembles maturity-onset diabetes of the young (86).

Functional effects of the mutations

All PNDM mutations studied to date are gain-of-function mutations that act by reducing the ability of ATP to block the K_{ATP} channel and thereby increasing the K_{ATP} current amplitude under resting conditions (7, 33, 83, 84). There is a reasonable correlation between the clinical phenotype and the extent to which MgATP inhibition is reduced, when the heterozygous state is simulated in heterologous expression systems. Table 2 shows that, at physiologically relevant concentrations of MgATP (1–5 mM), mutations that cause small increases in K_{ATP} current result in TNDM, while larger increases in current cause PNDM alone, and an even greater increase is associated with DEND syndrome. It will be important to determine whether this correlation between K_{ATP} current and disease severity is a consistent feature.

In β cells, an increase in K_{ATP} current leads to a smaller depolarization in response to increased metabolism. Consequently, electrical activity and insulin secretion will be diminished, and the greater the increase in K_{ATP} current, the more severely insulin secretion will be impaired. The β cell may be especially sensitive to gain-of-function mutations in Kir6.2 as its resting potential is largely determined by the K_{ATP} channel, and its metabolism is very sensitive to blood glucose levels.

Kir6.2 is also expressed in skeletal muscle, cardiac muscle, and neurons throughout the brain (52, 53), a distribution consistent with the neurological symptoms found in severe forms of the disease. Based on the functional data, it seems likely that in these tissues a greater reduction in ATP sensitivity is required to increase the K_{ATP} current sufficiently to influence electrical activity. This might arise because K_{ATP} channels contribute less to the electrical activity of these cells, perhaps because of a low density of K_{ATP} channels; or because of contributions to membrane current from other ion channels; or because Kir6.2 associates with SUR2 (which may reduce the response to metabolism [ref. 22]);

or because of differences in cell metabolism or other channel regulators. It is worth noting that K_{ATP} channels are normally closed in many of these tissues and open only under conditions of metabolic stress (25, 27, 87, 88).

Precisely how severe mutations in Kir6.2 lead to epilepsy, developmental delay, muscle weakness, and dysmorphic features remains to be established, and sorting it out is likely to require animal models. At first sight, it appears paradoxical that epileptic symptoms can be caused by a *gain-of-function* mutation in a potassium channel. However, this is easily explained by overactivity of K_{ATP} channels in *inhibitory* neurons, which would decrease inhibitory tone and enhance excitability of target neurons. Consistent with this idea, K_{ATP} channels are expressed in most GABAergic inhibitory interneurons in the hippocampus, but only in a minority of excitatory pyramidal neurons (24); and diazoxide inhibits firing of interneurons but not pyramidal cells (25). Furthermore, K_{ATP} channel openers prevent GABA release in slices of substantia nigra (26, 27). The muscle weakness could be of neural or muscle origin, as both skeletal muscle (53) and nerve terminals (89) express Kir6.2. Interestingly, the electrocardiogram of patients with PNDM mutations is superficially normal (7, 28), as observed for transgenic mice overexpressing a cardiac-targeted gain-of-function mutation in Kir6.2 (90).

Although gain-of-function Kir6.2 mutations cause epilepsy in humans, transgenic mice overexpressing WT Kir6.2 or SUR1 in forebrain are *protected* against seizure and ischemic injury (15, 16), and knockout of Kir6.2 enhances susceptibility to generalized seizure (14). This suggests that K_{ATP} current magnitude may be critical for brain function, and that too little current as well as too much can predispose to seizure: this might reflect the relative amounts of K_{ATP} current in inhibitory and excitatory neurons. Alternatively, the transgenic mice may not provide a perfect model of the human disease.

Molecular basis of reduced ATP sensitivity

As discussed above, ATP has 2 effects on the K_{ATP} channel: ATP binding to Kir6.2, in a process that does not require Mg^{2+} , blocks the channel, whereas binding of $MgATP$ to SUR1 stimulates channel activity (49). It is therefore essential to analyze the molecular mechanism of ATP block both in Mg^{2+} -free solution (to avoid the complicating effects of $MgATP$ stimulation), and in the presence of Mg^{2+} to determine whether coupling of SUR1 to Kir6.2 is affected.

Studies in Mg -free solution have shown that although all PNDM mutations reduce the ability of ATP to block the K_{ATP} channel, they do so by a variety of molecular mechanisms (83, 84). To date, mutations that cause neonatal diabetes alone (e.g., R201H/C, I182V) impair ATP binding directly (7, 33, 83, 91), consistent with their location within the predicted ATP-binding site (Figures 3 and 4). In contrast, mutations that cause DEND syndrome (e.g., V59G, Q52R, I296L) affect ATP inhibition indirectly. They bias the channel toward the open state and impair its ability to close (83, 84) (Figure 5). Consequently, the fraction of time the channel spends open in the absence of ATP (the intrinsic open probability, P_o) is increased. Because the affinity of the open state for ATP is less than that of the closed state, mutant channels are less inhibited by ATP (92). These mutations lie in regions predicted to be involved in channel gating (Figure 3). Finally, some mutations (V59G, I296L) appear to influence both intrinsic gating and ATP binding (or the mechanism by which binding is translated into channel closure) (83, 84).

In the presence of Mg^{2+} , the ATP sensitivity of the channel is reduced (49). This effect appears to be greater for several PNDM mutant channels (33, 84), suggesting that $MgATP$ activation via SUR1 may be enhanced. However, studies to date are limited, and this area requires more work.

The importance of heterozygosity

All PNDM patients identified to date are heterozygotes. Because Kir6.2 is a tetramer (50, 51), their cells will express a mixed pop-

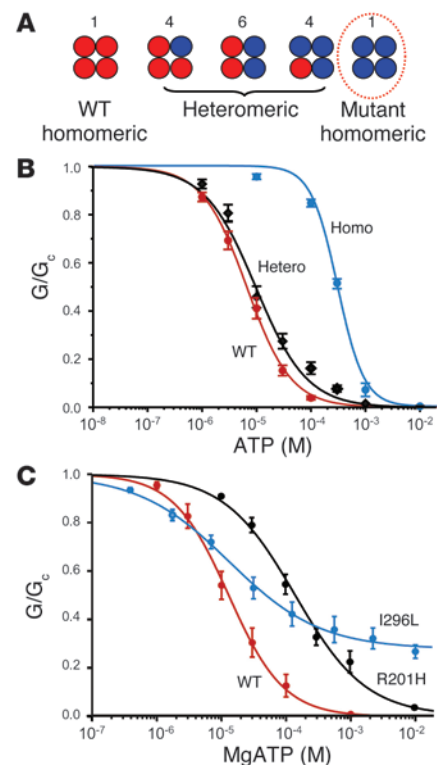

Figure 4

PNDM mutations reduce channel inhibition by ATP. (A) Schematic of the mixture of channels with different subunit compositions expected when WT and mutant Kir6.2 are coexpressed (as in the heterozygous state). The relative numbers of the channel types expected if WT and mutant subunits segregate independently (i.e., follow a binomial distribution) are indicated above the figure. The circle indicates the only channel type predicted to show a substantial change in ATP sensitivity if the mutation affects ATP binding (see text). (B) Mean relationship between [ATP] and K_{ATP} current (G), expressed relative to the conductance in the absence of nucleotide (G_o) for Kir6.2/SUR1 (red, $n = 6$) and heterozygous (black, $n = 6$) and homomeric (blue, $n = 6$) Kir6.2-R201H/SUR1 channels. The smooth curves are the best fit to the Hill equation. The IC_{50} was 7 μ M, 12 μ M, and 300 μ M for WT, heterozygous R201H, and homomeric R201H channels, respectively. Data were obtained in the absence of Mg^{2+} . Part B reproduced with permission from *Proceedings of the National Academy of Sciences of the United States of America* (83). (C) Mean relationship between [MgATP] and K_{ATP} current, expressed relative to the conductance in the absence of nucleotide for Kir6.2/SUR1 (red, $n = 6$) and heterozygous Kir6.2-R201H (black, $n = 5$) and heterozygous Kir6.2-I296L/SUR1 (blue, $n = 5$) channels. The smooth curves are the best fit to the Hill equation. The IC_{50} was 13 μ M, 140 μ M, and 50 μ M for WT, heterozygous R201H, and heterozygous I296L channels, respectively. Data in C are from refs. 33 and 84.

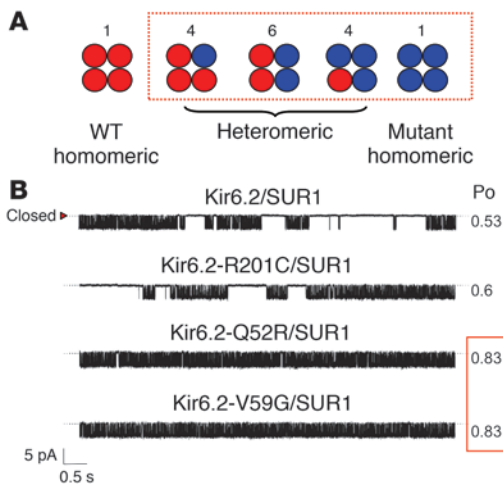

Figure 5 Effects of Kir6.2 mutations on channel gating. **(A)** Schematic of the different channel types expected when WT and mutant Kir6.2 are coexpressed (as in the heterozygous state). The box indicates channel types expected to have altered ATP sensitivity if the mutation affects channel gating (see text). **(B)** Single K_{ATP} channel currents recorded at -60 mV from inside-out patches from oocytes coinjected with mRNAs encoding SUR1 plus either WT or mutant Kir6.2 as indicated. Reproduced with permission from *Proceedings of the National Academy of Sciences of the United States of America* (83).

ulation of channels, each containing between 0 and 4 mutant subunits (Figure 4A). The ATP sensitivity of each of these 5 channel types will be determined by the extent to which each subunit (WT or mutant) contributes to the overall ATP sensitivity, and by the number of mutant subunits. In turn, the contribution of the mutant subunit will depend on whether it primarily affects ATP binding or intrinsic gating. For this reason, it is essential to study the effect of a mutation on the heterozygous channel population, whose behavior is not easily predicted from studies of homomeric mutant channels.

Because binding of a single ATP molecule closes the K_{ATP} channel (93), a mutation that reduces ATP binding will substantially impair ATP block only when all 4 subunits are mutant. If WT and mutant Kir6.2 subunits distribute randomly (51, 93), only one-sixteenth of channels in the heterozygous population will contain 4 mutant subunits (Figure 4). Thus the shift in the ATP sensitivity of the mean channel population will be small, precisely as seen for heterozygous R201C and R201H channels (7, 33, 83).

Mutations that affect intrinsic gating cause larger shifts in the ATP sensitivity of the heterozygous channel population. This can be explained if the energy of the open state scales with the number of mutant subunits (83); in this case, the ATP sensitivity of more than 90% of channels in the heterozygous population will be affected (Figure 5A). This explains why mutations that affect the intrinsic P_o (such as Q52R, V59G, and I296L) cause a greater shift in the ATP sensitivity of heterozygous channels. The ATP sensitivity of heterozygous Q52R channels is well fit by assuming that the entire shift in ATP sensitivity results from the observed change in channel gating (83). However, other mutations (V5G, I296L) cause even greater shifts in the ATP sensitivity of both homomeric and heterozygous channels and appear to have additional effects on ATP binding and/or transduction (83, 84).

The importance of heterozygosity in determining the severity of a mutation appears to be a novel feature of gain-of-function K_{ATP} channelopathies. Accordingly, we may expect to find similar phenotypic variability in other tetrameric ion channels where channel function can be influenced differentially by the presence of 1, or more, mutant subunits. It is also worth noting that if mutant and WT subunits were to express at different levels, the composition of the heterozygous population might deviate from a binomial distribution and thus influence the channel ATP sensitivity in a less quantitatively predictable fashion.

Implications for therapy

Prior to the discovery that PNDM could be caused by mutations in Kir6.2, it was supposed that patients with this disorder suffered from early-onset, type 1 diabetes, and they were treated with insulin. Recent studies, however, demonstrate that patients with mutations that cause PNDM alone can be managed on sulfonylureas (7, 28, 82). It remains to be seen whether sulfonylurea therapy is effective in the long term. However, it is important to remember that while insulin therapy may control the diabetes, it does not mitigate the effects of enhanced K_{ATP} channel activity in nonpancreatic tissue: this requires drugs that close K_{ATP} channels. Whether sulfonylurea therapy will be as suitable for patients with mutations that increase the intrinsic P_o of the channel remains unclear, because these channels are less sensitive to the drugs (83). This is expected, as mutations that stabilize the channel in the open state impair sulfonylurea inhibition (92). However, it may be possible to manage such patients, on a combination of insulin, to control their diabetes, and sulfonylureas, to control the extrapancreatic effects. A key question is whether sulfonylureas will be effective at treating CNS symptoms, as the extent to which they cross the blood/brain barrier is unclear. Drugs that enter the brain and selectively block K_{ATP} channels might be beneficial in this respect.

The efficacy of sulfonylurea therapy in PNDM will also depend on the particular gene that is mutated. Loss-of-function mutations in metabolic genes, such as *GCK*, reduce ATP production and enhance K_{ATP} channel activity indirectly. Blocking the K_{ATP} channel with sulfonylureas will restore Ca^{2+} influx but, as ATP is also required for the secretory process, may not be sufficient to reinstate insulin secretion fully.

Impaired metabolic regulation and early-onset diabetes

Impaired metabolic regulation of K_{ATP} channels, resulting from mutations in genes that influence β cell metabolism, can cause both monogenic HI and diabetes. As described above, mutations in *GCK* and *GLUD1* cause HI, probably by enhancing metabolic ATP generation and decreasing K_{ATP} channel activity. Conversely, mutations that reduce ATP synthesis, and thus the extent of K_{ATP} channel inhibition in response to glucose metabolism, may be expected to give rise to diabetes.

Maturity-onset diabetes of the young (MODY) is characterized by early onset, autosomal dominant inheritance, and pancreatic β cell dysfunction (66, 94). It is caused by mutations in at least 7 different genes. Heterozygous loss-of-function mutations in *GCK* cause MODY2, which is associated with moderate hyperglycemia and is often asymptomatic and detected only during routine screening; as described above, homozygous inactivating mutations in *GCK* impair β cell metabolism more severely and cause permanent neonatal diabetes. Five other MODY genes encode the transcription factors HNF4 α , HNF1 α , IPF1, HNF1 β , and NEUROD,

which are not only important for β cell development but can also regulate expression of genes critical for glucose metabolism. For example, knockout of HNF1 α , which causes MODY3, impairs β cell glucose metabolism and thereby K_{ATP} channel closure in mice (95). Whether other transcription factors influence K_{ATP} channel function has yet to be established. Finally, as described above, mutations in Kir6.2 itself can also give rise to MODY (86).

Defective mitochondrial metabolism can also produce diabetes, as in maternally inherited diabetes with deafness (MIDD), which results from a mutation in the mitochondrial DNA that encodes a leucine transfer RNA (96, 97). It seems plausible to speculate that enhanced K_{ATP} channel activity, due to reduced ATP production, contributes to the impaired insulin secretion.

Implications for type 2 diabetes

Given that mutations in Kir6.2 cause neonatal diabetes and MODY, and that mutations in genes that regulate K_{ATP} channel activity lead to MODY and MIDD, which present in childhood or early adult life, it is natural to conjecture that common genetic variations in the same genes, which produce smaller functional effects, might predispose to type 2 diabetes in later life. Accumulating evidence supports this view.

Large-scale association studies indicate that a common variant (E23K) in Kir6.2 is strongly associated with an enhanced susceptibility to type 2 diabetes (98–100). Although the effect is statistically small (the odds ratio associated with the K allele is only ~ 1.2), the high prevalence of the K allele (34%) makes this a significant population risk. Precisely how the E23K polymorphism enhances diabetes susceptibility remains unclear. Data obtained by expressing recombinant K_{ATP} channels in heterologous systems are conflicting. Some studies demonstrate an increase in intrinsic P_o , with a consequent reduction in ATP sensitivity, and enhanced activation by Mg nucleotides (101, 102), whereas others report no effect on ATP sensitivity but enhanced sensitivity to the stimulatory action of long-chain acyl-CoAs (103). It is also possible that the E23K variant may cause a greater reduction in ATP block of the K_{ATP} channel in pancreatic β cells than in heterologous systems. Interestingly, in mice, a 4-fold reduction in K_{ATP} channel ATP sensitivity is enough to cause neonatal diabetes (3). Furthermore, large-scale studies in humans have shown that the E23K variant is associated with reduced insulin secretion in glucose-tolerant subjects (104, 105). It is also worth remembering that because Kir6.2 is expressed in multiple tissues, diabetes susceptibility may involve tissues other

than the β cell: for example, glucagon secretion is increased in individuals carrying 2 K alleles (106).

Polymorphisms in HNF1 α , HNF4 α , and GCK (107–109), and in genes involved in mitochondrial metabolism (110, 111), have also been associated with an increased risk of type 2 diabetes. They probably influence disease susceptibility by impairing metabolic regulation of K_{ATP} channel activity.

This leads to the conclusion that good candidate genes for polygenic disease (in this case, type 2 diabetes) are those that cause monogenic disease (PNDM, MODY). As they manifest only in later life, the functional effects of individual gene variants associated with polygenic disease are likely to be small. It also suggests that the increased risk of diabetes with age may reflect a deteriorating β cell metabolism, leading to enhanced K_{ATP} channel activity and reduced insulin secretion (62). This idea is supported by the fact that insulin secretion is critically dependent on mitochondrial metabolism (112), which is known to decline with age (113) and has been implicated in age-related disease (112–114).

Conclusions

K_{ATP} channel activity in the β cell is finely balanced, reflecting its physiological role as a key regulator of insulin release. Increased activity leads to reduced insulin secretion, and, conversely, reduced K_{ATP} channel activity decreases insulin release. Consequently, mutations that either directly or indirectly alter β cell K_{ATP} channel activity produce a spectrum of diseases that ranges from severe HI to DEND syndrome (Figure 6).

In general, there is a good correlation between the magnitude of the K_{ATP} current and disease severity. Thus mutations that cause a total loss of K_{ATP} channel in the surface membrane produce severe HI, whereas those that impair channel function only partially produce a milder phenotype that can be treated with diazoxide or results in leucine-sensitive HI. Likewise, the extent to which the ATP sensitivity of Kir6.2 is decreased determines the severity of the diabetes phenotype. Mutations that cause the greatest reduction in ATP inhibition, and the largest increase in K_{ATP} channel activity, manifest effects in multiple tissues and lead to developmental delay, epilepsy, muscle weakness, and neonatal diabetes. Lesser shifts in ATP sensitivity give rise to neonatal diabetes with developmental delay, while even smaller changes manifest primarily in the β cell and cause neonatal diabetes alone.

The range of phenotypes associated with monogenic K_{ATP} channelopathies, which present at birth, suggests a similar spectrum

Figure 6

Schematic illustrating the relationship between K_{ATP} channel activity and insulin secretion. T2DM, type 2 diabetes mellitus.

of K_{ATP} channel polymorphisms that have less severe effects on channel function and predispose to late-onset, polygenic, disease. The association of the E23K polymorphism in Kir6.2 with susceptibility to type 2 diabetes supports this idea. Because of a gradual decline in β cell function with age, polymorphisms that cause a small decrease in K_{ATP} channel activity are unlikely to predispose to late development of HI but rather may help to protect against type 2 diabetes.

It is noteworthy that mutations in Kir6.2 cause both diabetes and HI, whereas mutations in SUR1 are, to date, entirely associated with hyperinsulinism. This is not unexpected, however. A total loss of protein (Kir6.2 or SUR1) will necessarily result in loss of K_{ATP} channel activity and thus HI. Loss of metabolic regulation, however, will have different effects in Kir6.2 and SUR1. For SUR1, impaired binding/hydrolysis and/or transduction of Mg nucleotides will decrease K_{ATP} channel activity, producing HI. Mutations that enhance Mg-nucleotide activation seem inherently far less likely. Thus, diabetes due to SUR1 mutations will be rare. Mutations that impair ATP binding to Kir6.2, on the other hand, will enhance K_{ATP} channel activity and cause diabetes. It is not understood why mutations that affect Kir6.2 gating invariably increase channel opening (thereby lowering ATP sensitivity), but this may suggest that the channel is most stable in the open state.

Finally, a similar spectrum of insulin secretory disorders can be expected from mutations in genes that regulate K_{ATP} channel activity, with mutations that indirectly enhance K_{ATP} currents mediating diabetes and those that reduce channel activity producing HI. As expected, loss-of-function mutations in metabolic genes cause

PNDM or MODY depending on the extent to which they impair β cell metabolism, while gain-of-function mutations cause HI of varying severity. Naturally occurring polymorphisms in genes that cause minor variations in metabolic regulation, or density, of K_{ATP} channels can be predicted to produce small differences in K_{ATP} channel activity and insulin secretion, so influencing diabetes susceptibility. Some such polymorphisms have been identified, and more are likely to follow.

In conclusion, individuals may be predisposed to either HI or diabetes according to the magnitude of their β cell K_{ATP} current under resting conditions, with their position on this delicate K_{ATP} channel see-saw being determined by their unique combination of polymorphisms in multiple genes.

Acknowledgments

The author wishes to thank those working in the field who have contributed greatly to the ideas expressed in this review, especially Jennifer Antcliff, Christophe Girard, Peter Proks, and Paolo Tammaro in the author's group, and colleagues Roger Cox, Anna Gloyn, Fiona Gribble, Andrew Hattersley, and Patrik Rorsman. The author also thanks the Wellcome Trust, Diabetes UK, Grow-Beta, and the Royal Society for support. F.M. Ashcroft is the Royal Society GlaxoSmithKline Research Professor.
