Abstract

Background: Experimental studies support an important role for endothelial nitric oxide synthase (eNOS) in the regulation of angiogenesis. In humans, a common polymorphism exists in the eNOS gene that results in the conversion of glutamate to aspartate for codon 298. *In vitro* and *in vivo* studies have suggested a decreased NOS activity in patients with the Asp²⁹⁸ variant. We hypothesized that a genetic-mediated decreased eNOS activity may limit collateral development in patients with chronic coronary occlusions.

Methods: We selected 291 consecutive patients who underwent coronary angiography and who had at least one chronic (>15 days) total coronary occlusion. Collateral development was graded angiographically using two different methods: the collateral flow grade and the recipient filling grade. Genomic DNA was extracted from white blood cells and genotyping was performed using previously published techniques.

Results: Collateral development was lower in patients carrying the Asp²⁹⁸ variant than in Glu-Glu homozygotes (collateral flow grade: 2.64 ± 0.08 and 2.89 ± 0.08 , respectively, $p = 0.04$; recipient filling grade: 3.00 ± 0.08 and 3.24 ± 0.07 , respectively, $p = 0.04$). By multivariable analysis, three variables were independently associated with the collateral flow grade: female gender, smoking, and the Asp²⁹⁸ variant ($p = 0.03$) while the Asp²⁹⁸ variant was the sole variable independently associated with the recipient filling grade ($p = 0.03$).

Conclusion: Collateral development is lower in patients with the Asp²⁹⁸ variant. This may be explained by the decreased NOS activity in patients with the Asp²⁹⁸ variant. Further studies will have to determine whether increasing eNOS activity in humans is associated with coronary collateral development.

Background

In spite of recent advances in the techniques used for myocardial revascularization, chronic total coronary occlusions are frequently observed in patients with coronary artery disease. This could lead to symptoms of angina, quality of life impairment, left ventricular dysfunction, and prognosis worsening. In the case of severe stenosis or total occlusion of a coronary artery, the collateral circulation may be an alternative source of blood supply to the myocardium at risk [1,2]. Although some factors, such as the duration of myocardial ischemic symptoms, have been associated with the extent of collateralization, coronary collateral development remains difficult to anticipate and there is considerable inter-individual variability in this process [3]. One emerging concept in cardiovascular diseases, which could explain this variability, is the possible interaction between genetic determinants and the pathophysiological responses to cardiac injury.

Among candidate genes that may be implicated in collateral development is the endothelial nitric oxide synthase (eNOS) gene. Experimental studies support an important role for eNOS in the regulation of angiogenesis [4]: mice lacking eNOS gene have severely reduced angiogenesis in response to tissue ischemia [5,6] while eNOS overexpression enhances angiogenesis [7-9]. In humans, different common polymorphisms exist in the eNOS gene and among them one that results in the conversion of glutamate to aspartate for codon 298. *In vitro* studies have suggested that the Asp²⁹⁸ variant may be functional and associated with a decreased of eNOS activity [10]. *In vivo* studies have documented an increased reactivity to alpha-adrenergic stimulation in patients with the Asp²⁹⁸ variant suggesting a decreased NOS activity [11].

In the present study, we hypothesized that a genetic-mediated decreased eNOS activity may limit collateral development in patients with chronic coronary occlusions. We studied 291 patients with chronic coronary occlusions in whom collateral development was graded angiographically. We show that patients with the Asp²⁹⁸ variant have significantly less collateral vessel formation than Glu-Glu homozygotes.

Methods

Study population

Between May 2000 and October 2001, 2050 consecutive patients who underwent a coronary angiography at our institution were enrolled in a registry. All patients gave informed consent and had blood and serum samples that were stored at -80°C until further analysis. The baseline clinical and angiographic characteristics were prospectively recorded by trained physicians.

For the purpose of this study, we selected all patients who had at least one chronic (>15 days) total occlusion of a major coronary vessel. The patients with a history of coronary artery bypass graft were excluded. Two hundred and ninety one patients were thus selected to form the study population.

Angiography procedure and coronary collaterals grading

Selective coronary angiography was performed in multiple orthogonal projections using the Judkins technique. In case of significant lesion (stenosis or total occlusion), there was an intracoronary nitrates infusion. Collateral development was graded using two different methods by two independent observers. These methods have been previously validated [12].

The *collateral flow grade* evaluates the flow in the collateral: 0 = no flow in the collateral; 1 = the collateral is barely apparent; dye is not visible throughout the cardiac cycle but is present in at least 3 consecutive frames; 2 = the collateral is moderately opaque but is present throughout at 75% of the cardiac cycle; 3 = the collateral is well opacified and the column of dye is well defined but is < 0.7 mm wide throughout the majority of its length; 4 = the collateral is well opacified, fills antegrade, and is very large.

The second method was the *recipient filling grade*: 0 = no angiographically apparent collaterals; 1 = apparent collaterals extend into a region of myocardium with no angiographically apparent recipient vessel; 2 = minimal recipient filling by collaterals is manifested by minor side branch filling and no epicardial artery or epicardial side branch filling; 3 = Moderate recipient filling by collaterals is manifested by complete filling of epicardial side branches and partial filling of a major epicardial artery; 4 = there is complete filling of a major epicardial segment.

Genetic analysis

Blood samples were collected at the time of coronary angiography. Genomic DNA was extracted from white blood cells by a « salting out » procedure as previously described [13]. DNA fragment – including the G/T translation in the exon 7 – amplification was performed by Polymerase Chain Reaction (PCR). Primers and PCR conditions used for eNOS have been reported previously [14]. The products was digested by the Ban II enzyme for genotyping as previously described [14] and the results of the genotyping were tested for the Hardy-Weinberg equilibrium ($p > 0.05$).

Statistical analysis

Patients were grouped on the basis of the presence or absence of the Asp²⁹⁸ variant (Asp²⁹⁸ homozygotes and heterozygotes were combined and compared to the homozygotes Glu²⁹⁸) as previously reported [11,14-16].

For continuous variable, distributions were first tested before analyses. Since the distribution were normal, they were presented as mean \pm SEM and were compared with use of the bilateral unpaired Student' t test. Qualitative variables were compared with use of the Pearson chi-square test or the Fisher exact test when necessary. Multi-variable analysis was performed with use of a general linear model (GLM) adjusted for age, gender, smoking, hypertension, hypercholesterolemia and diabetes mellitus. Statistical analysis were performed with the SAS software, version 8 (SAS Institute Inc., Cary, NC, USA).

Results

The baseline characteristics of the study population are shown in table 1. There were no statistically significant differences between patients with the Asp²⁹⁸ variant and Glu-Glu homozygotes. Most patients were male with a mean age of 63 \pm 11 years and with a high prevalence of cardiovascular risk factors. Notably, 77% of the patients were current or past smokers and 36% were diabetics. Cardiovascular medications did not differ between the two groups. The angiographic severity of coronary atherosclerosis was similar in the two groups. In most of the cases, only one coronary artery was totally occluded.

Table 1: Demographics and medical therapy at baseline by genotype

	Asp ²⁹⁸ (n = 168)	Glu-Glu (n = 123)	All patients (n = 291)	p
Age, years	63 \pm 11	62 \pm 11	63 \pm 11	0.92

Data are presented as percent of patients or mean value \pm SD

CAD = coronary artery disease; MI, myocardial infarction

LAD = left anterior descending artery; Cx = circumflex; RCA = right coronary artery

ASA = acetylsalicylic acid; ACE = angiotensin-converting enzyme; ARB = angiotensin 2 receptor blockers.

Table 2: Predictors of collateral development: multivariable analysis

	Collateral flow grade		Recipient filling grade	
	β	<i>p</i>	β	<i>p</i>
Age \geq 63	- 0.04	0.72	+ 0.03	0.77
Female gender	- 0.49	0.009	- 0.22	0.23
Smoking	- 0.34	0.05	- 0.12	0.47
Hypertension	- 0.04	0.72	- 0.04	0.74
Hypercholesterolemia	- 0.01	1.00	- 0.16	0.23
Diabetes mellitus	- 0.23	0.06	- 0.20	0.09
Asp ²⁹⁸ variant	- 0.26	0.03	- 0.24	0.03

In the overall study population, the mean collateral flow grade was 2.75 ± 0.06 and the mean recipient filling grade was 3.10 ± 0.06 . By univariable analysis, angiographic evidence of collateral development was lower in patients carrying the Asp²⁹⁸ variant than in Glu-Glu homozygotes (collateral flow grade: 2.64 ± 0.08 and 2.89 ± 0.08 , respectively, $p = 0.04$; recipient filling grade: 3.00 ± 0.08 and 3.24 ± 0.07 , respectively, $p = 0.04$). When patients were classified into 3 groups (Glu-Glu homozygotes, Glu-Asp heterozygotes, Asp-Asp homozygotes), respective values for collateral flow grade were 2.84 ± 0.08 , 2.63 ± 0.09 , and 2.69 ± 0.23 , while respective values for recipient filling grade were 3.24 ± 0.07 , 3.01 ± 0.08 , and 2.94 ± 0.23 . Independent predictors of collateral development were then determined by multivariable analysis (table 2). When considering the collateral flow grade, three variables were independently associated with an impaired collateral development: female gender, smoking, and the Asp²⁹⁸ variant; there was also a strong trend for a deleterious effect of diabetes mellitus on collateral development. When considering the recipient filling grade, the Asp²⁹⁸ variant was the sole variable independently associated with an impaired collateral development; again, the presence of diabetes mellitus was associated with a trend for a deleterious effect. The presence of the Asp²⁹⁸ variant was therefore the sole independent predictor of both the collateral flow grade and the recipient filling grade.

Since collateral vessel development has been associated with a preserved left ventricular function in the case of total occlusion of a coronary artery [17], we compared the left ventricular ejection fraction in both groups. A recent evaluation of left ventricular ejection fraction was available in 162 (96%) of patients with the Asp²⁹⁸ variant and in 120 (98%) of Glu-Glu homozygotes. The mean (\pm SD) left ventricular ejection fraction was $53 \pm 16\%$ in the overall study population and was $50 \pm 16\%$ in patients with the Asp²⁹⁸ variant versus $54 \pm 16\%$ in Glu-Glu homozygotes ($p = 0.05$).

Discussion

In the present study, we found that patients carrying the Asp²⁹⁸ variant of eNOS gene had significantly less angiographic evidence of collateral vessel formation in response to total coronary occlusion. Multivariable analysis showed that this effect was independent of other factors that influence collateral vessel formation.

Nitric oxide (NO), constitutively produced by endothelial nitric oxide synthase (eNOS), plays critical roles in vascular biology, including regulation of vascular tone and blood pressure. In addition to its vasodilatory properties, NO has been implicated in the modulation of angiogenesis [4]. Ziche et al. suggested that NO may play a role in angiogenesis elicited by VEGF but not by FGF [18]. Murohara et al. demonstrated that angiogenesis developing in response to limb ischemia was severely reduced in mice lacking eNOS gene [5]. Moreover, eNOS over expression in transgenic mice [8] or using gene transfer strategies [7,9] enhances angiogenesis in response to tissue ischemia. There is thus strong experimental evidence to support an important role for eNOS in the regulation of angiogenesis in animal models, however the implication of eNOS activity in collateral vessel formation in response to myocardial ischemia in humans remains unknown

eNOS is encoded by a 26-exon gene located on chromosome 7 [19]. In view of the physiological and pathophysiological importance of NO, the potential role of eNOS in the pathogenesis of various human diseases has been examined using its polymorphic variants as potential disease markers. Different common polymorphisms exist and among them one in nucleotide 894 (G-T) that results in the conversion of glutamate to aspartate for codon 298. A study by Philip et al. has documented *in vivo* an increased reactivity to alpha-adrenergic stimulation in patients with the Asp²⁹⁸ variant suggesting a decreased NOS activity [11]. In recent clinical studies, the Asp²⁹⁸ variant has been implicated as a risk factor for coronary artery disease [20], hypertension [16], or has been associated with a poorer event-free survival in patients with congestive heart failure [14]. In a meta-analysis of 26 studies involving 23028 subjects, homozygosity for Asp²⁹⁸ was associated with increased risk of ischemic heart disease by 31% [15]. When taken together with the results of the present study, the above described literature suggests that a decreased NOS activity in coronary vessels of patients with the Asp²⁹⁸ variant may explain the decreased collateral vessel formation observed in this subgroup of patients. The mechanism by which the Asp²⁹⁸ variant could decrease the eNOS activity remains unclear. The Asp²⁹⁸ variant has been associated with an increased susceptibility to enzymatic cleavage [10] but it has been suggested that the increased susceptibility to proteolytic cleavage of NOS could result from sample preparation

[21]. In addition, other recent studies failed to find any association between the Asp298 variant and eNOS activity [22,23]. An other possible explanation is that the variant Asp298 may simply be a genetic marker. For example, the Asp298 variant is in linkage disequilibrium with an other polymorphism resulting in a nucleotide substitution in the promoter region (T/C -786) of the eNOS gene [24,25]. It has been shown that the rarer variant (C) suppresses eNOS transcription by approximately 50%. The Asp298 could be a marker of the occurrence of the unfavorable "C" allele in the promoter region, the latter responsible for the decreased of eNOS activity.

In the present study, collateral vessel formation was assessed using angiographic criteria. Angiographically visible collaterals represent only a fraction of the total collateral vessels because collaterals are angiographically demonstrable only when they reach 200 μm [12]. Several studies have shown that assessing the collateral circulation by intracoronary Doppler flow or pressure wires may be an interesting alternative to determine collateral blood flow in humans [26,27]; however, the invasive nature of this method which imply to cross the occlusion site by a guide wire would limit its interest in a genetic association study like the present one in which inclusion of consecutive and as much as possible unselected cases is mandatory to provide unbiased results. In an attempt to provide a rigorous, systematic analysis of human coronary angiogenesis by angiography, we used two criteria recently reviewed by Gibson et al. [12]. The collateral flow grade focuses on the development of the collateral network itself while the recipient filling grade is adapted from the Rentrop grade [28] and provides information on how the recipient vessel is filled by the collaterals. In the present study, the fact that the deleterious impact of the Asp²⁹⁸ variant was evident with both criteria reinforces our findings. An important question in the present study is to know whether the better angiographic criteria in Glu-Glu homozygotes are a result of the vasodilation properties of eNOS or are due to an increase in blood vessel growth. Such a question is beyond the scope of this clinical study but a direct effect of eNOS on angiogenesis has been documented in the above described experimental studies [7-9]. Moreover, the trend for higher left ventricular ejection fraction observed in Glu-Glu homozygotes suggests a beneficial effect of the collaterals on myocardial function. Finally, our analysis was based on a single time point; further assessment of collateral development by repeated angiographic follow-up would be of interest but was not performed due to the invasive nature of coronary angiography.

Conclusion

In conclusion, this investigation is the first study to show the relationship between the 894 (G-T) eNOS polymor-

phism and coronary collaterals in humans. It demonstrates that collateral development is poorer in patients with the Asp²⁹⁸ variant. This may be explained by a decreased NOS activity in patients with the Asp²⁹⁸ variant. Further studies will have to determine whether increasing eNOS activity in humans is associated with coronary collateral development.
