Edited by Leonard A. Herzenberg, Stanford University School of Medicine, Stanford, CA, and approved May 17, 2002 (received for review March 22, 2002)

To identify proteins undergoing glutathionylation (formation of protein-glutathione mixed disulfides) in human T cell blasts, we radiolabeled the glutathione pool with ³⁵S, exposed cells to the oxidant diamide, and analyzed cellular proteins by two-dimensional electrophoresis. One of the proteins undergoing glutathionylation was identified by molecular weight, isoelectric point, and immunoblotting as thioredoxin (Trx). Incubation of recombinant human Trx with glutathione disulfide or S-nitrosoglutathione led to the formation of glutathionylated Trx, identified by matrix-assisted laser desorption ionization–time-of-flight mass spectrometry. The glutathionylation site was identified as Cys-72. Glutathionylation of rhTrx abolished its enzymatic activity as insulin disulfide reductase in the presence of NADPH and Trx reductase. Activity was, however, regained with sigmoidal kinetics, indicating a process of autoactivation due to the ability of Trx to de-glutathionylate itself. These data suggest that the intracellular glutathione/glutathione disulfide ratio, an indicator of the redox state of the cell, can regulate Trx functions reversibly through thiol-disulfide exchange reactions.

Thioredoxin (Trx; ref. 1), a ubiquitous redox protein, is an essential cofactor electron donor for ribonucleotide reductase, but also has many other cellular functions, including regulation of transcription factors, apoptosis, and antioxidant activity and can act exogenously as a redox active growth factor (1, 2). The catalytic activity of Trx resides in its active site where the two redox active Cys (Cys-31 and Cys-34 in human Trx) undergo reversible oxidation/reduction. In addition to the conserved Cys residues in the active site, three additional structural Cys residues (Cys-61, Cys-68, and Cys-72) are present in the structure of human Trx.

The present paper describes the experiments that led us to the conclusion that Trx can undergo glutathionylation in T cells exposed to oxidative stress. Protein glutathionylation, the formation of a disulfide between a Cys in a protein and the Cys in the tripeptide glutathione (GSH), is a modification that can be induced in cells by oxidative stress. Glutathionylation can occur by direct oxidation of a protein and GSH, by a thiol-disulfide exchange between a protein Cys and oxidized glutathione (GSSG), and also with the intermediacy of S-nitrosoglutathione (GSNO; refs. 3 and 4). Glutathionylation of proteins is reversible, as those proteins can be reduced by glutaredoxins (5, 6), and the process serves to regulate protein functions by the redox state of the cell (i.e., by the GSSG/GSH ratio; refs. 7–9).

To demonstrate the glutathionylation of Trx, we first labeled the intracellular GSH pool of the T-cell blasts with [³⁵S]Cys and analyzed the cell lysate by two dimensional electrophoresis under nonreducing conditions. A spot was found in the autoradiographic protein map with IP/M_r corresponding to those of Trx. In the second part of the study, we incubated recombinant human Trx in the presence or absence of GSSG or GSNO to clarify the structural and functional properties of glutathionylated

Trx, then we analyzed the protein by matrix-assisted laser desorption ionization–time-of-flight (MALDI-TOF). Finally, we studied the effect of incubation with GSSG on the activity of Trx coupled to NADPH as a substrate for Trx reductase (TrxR). The results confirm that Trx can undergo glutathionylation, which is able to regulate its enzymatic activity and function.

Materials and Methods

Materials. GSH, GSSG, GSNO, N-ethylmaleimide (NEM), and diamide were from Sigma. TrxR was prepared from bovine liver as described (10).

T Cell Blasts. Human peripheral blood mononuclear cells (PBMC) were isolated by using standard Ficoll/Hypaque gradients from buffy coats of healthy donors (kindly provided by the Blood Center of the Hospital of Magenta, Magenta, Italy). PBMC were cultured at 1×10^6 cells per ml for 3 days in RPMI medium 1640 with 10% (vol/vol) FCS and 2 μ g/ml phytohemagglutinin (Sigma), then washed and cultured for 3 days with 50 units/ml human recombinant IL-2 (Chiron).

Cell Labeling and Exposure to Diamide. Cells were resuspended at 3.3×10^6 cells per ml and maintained throughout the experiment in Hanks' balanced salt solution (HBSS) containing 50 μ g/ml cycloheximide. After 20-min preincubation in HBSS/cycloheximide, the cells were incubated with 8 μ Ci/ml of L-[³⁵S]Cys [specific activity 1,000 Ci/mmol (1 Ci = 37 GBq); Amersham Pharmacia]. After 30 min, the cells were treated for 5 min with 1 mM diamide (Sigma), then collected by centrifugation and either processed for electrophoretic analysis as described below, or the proteins were precipitated with trichloroacetic acid (TCA) at a final concentration of 5%. After five washes with 5% TCA, the TCA-precipitable radioactivity was counted.

Protein Electrophoresis. The cell pellet (2×10^7 cells per sample) was extracted with chloroform/methanol, resuspended in 8 M urea + 0.5% carrier ampholytes, and run on immobilized pH gradients (IPG; ref. 11) covering, with an exponential course, the pH range 4–10 (12). IPG strips were embedded on 12% polyacrylamide gel slabs for the second-dimensional run in the discontinuous buffer system of Laemmli (13). Electrophoresis was carried out under nonreducing conditions. The slabs either

were stained with Coomassie blue and radioactivity was analyzed with a phosphor-imager after drying, or they were used for Western blot analysis.

Western Blot Analysis of Trx. The slabs were blotted onto a nitrocellulose membrane in the presence of 0.01% SDS. A goat polyclonal antibody against human Trx (14) was used at 1:200 dilution and revealed by enhanced chemiluminescence with a horseradish peroxidase-conjugated mouse anti-goat secondary antibody from Pierce.

Peptide Synthesis. Cys-containing Trx fragments were synthesized by solid-phase chemistry on an Applied Biosystems 433A synthesizer using *N*-(9-fluorenylmethoxycarbonyl) as a protective group for the aminic residues and *N*-[(1*H*-benzotriazol-1-yl)(dimethylamino)methylene]-*N*-methylmethanaminium tetrafluoroborate *N*-oxide and *N,N*-diisopropylethylamine as activators of carboxylic residues. Peptides were cleaved from the resin with trifluoroacetic acid/thioanisole/water/phenol/ethanedithiol in the ratio 82.5:5.5:5:2.5 (vol/vol), precipitated, and washed with diethylether.

Glutathionylation of Recombinant Trx. Recombinant human Trx was expressed in *E. coli* and purified as described (15). The numbering of amino acids is calculated without taking into account the *N*-terminal methionine, which is removed in rhTrx. Before the experiments, rhTrx was fully reduced as described below. Briefly, 500 μ l of the concentrated protein (2.5 mg/ml) were reacted under argon flow with a 20-fold molar excess of DTT in 50 mM Tris/1 mM EDTA, pH 7.4. The reaction was allowed to proceed for 30 min at 37°C. To remove the excess of DTT, samples were desalted on a NAP5-column (Amersham Pharmacia), and the exact concentration of the fully reduced rhTrx was established by measuring the absorbance at 280 nm using an extinction coefficient of 1.48 mg/ml (16). Full reduction of rhTrx was checked by titration of the free -SH groups, as described below.

To induce glutathionylation, rhTrx was incubated with the indicated concentration of GSSG for 2 h at room temperature. When indicated, rhTrx was incubated with 5 mM GSNO under the same experimental conditions.

Mass Spectrometric Analysis of Trx. Control or glutathionylated Trx was analyzed by a Bruker-Reflex III MALDI-TOF mass spectrometer. A few μ l of the sample were mixed with an equal volume of a saturated solution of sinapinic acid or α -ciano-4-hydroxycinnamic acid (Sigma) in acetonitrile/0.1% trifluoroacetic acid 1:3 (vol/vol); 1 μ l of the mixture was deposited on the MALDI mass spectrometry target.

Titration of Free -SH Groups with 5'-5'-Dithiobis-2-Nitrobenzoic Acid (DTNB). The number of free -SH groups of rhTrx was established spectrometrically with DTNB at 412 nm ($\epsilon_M = 13.6 \text{ M}^{-1}\text{cm}^{-1}$), as described (17).

Insulin Assay for Trx Enzyme Activity. The activity of human Trx was measured as its ability to reduce insulin disulfides in the presence of NADPH and calf thymus thioredoxin reductase (CT-TrxR; ref. 10). The reaction mixture containing 100 mM potassium phosphate buffer pH 7.0, 2 mM EDTA, 0.2 mM NADPH, and 0.16 mM insulin. The samples were prepared by mixing 500 μ l of the reaction mixture and different concentrations of Trx (2 or 4 μ M) in cuvettes. The reactions were started by the addition of 38 nM TrxR, and the absorbance of the samples were read at 340 nm against blank solution, which included all reagents except Trx.

The activity also was tested in the endpoint assay (10) by using a 20-min incubation to determine -SH groups formed in insulin

by breaking the reaction with 6 M guanidine-HCl, 1 mM DTNB, and reading at 412 nm.

Tryptic Digestion of rhTrx. Fully reduced rhTrx in water (8.6 μ M) was reacted with 5 mM GSSG for 2 h at room temperature as described above. Iodoacetamide was added to the reaction mixture to a final concentration of 2 mM to block residual Cys. The glutathionylated rhTrx was digested with trypsin (at a trypsin:Trx ratio of 1:10, wt/wt) in a solution containing 80% of acetonitrile and 50 mM ammonium bicarbonate (18). The reaction was allowed to proceed for 10 min at 37°C, and the tryptic peptides were analyzed by MALDI-TOF, as described above. Data were compared with the theoretical molecular weight of the rhTrx tryptic peptides, taking into consideration the possible glutathionylated Cys.

Results

Identification of Trx Among the Glutathionylated Protein in Oxidatively Stressed Lymphocytes. To identify proteins undergoing S-thiolation in human phytohemagglutinin blasts, cells were labeled with [³⁵S]Cys for 30 min in the presence of cycloheximide, washed, then incubated with 1 mM diamide for 5 min. Previous studies have shown that under these experimental conditions, diamide induces marked ³⁵S incorporation into proteins (19).

Cell extracts were analyzed by nonreducing two-dimensional gel electrophoresis. The Coomassie blue stain and the autoradiography of gels from diamide-treated cells are in Fig. 1 *Top* and *Middle*. Based on molecular weight and pI, we tentatively postulated that one of the radioactively labeled proteins, indicated by an arrow in the autoradiography shown in Fig. 1, might be Trx. To confirm the identity of this spot with Trx, we performed Western blot analysis by using an anti-human Trx antibody. As shown in Fig. 1 *Bottom*, immunoreactive Trx was identified, corresponding to the radioactive spot.

Glutathionylation of rhTrx by GSSG. To confirm the susceptibility of Trx to glutathionylation and to identify the modified Cys(s), we used pure rhTrx. The protein was treated with GSSG and then analyzed by MALDI-TOF. rhTrx had the expected molecular weight of $11,606.2 \pm 1.9$ ($n = 3$), and incubation with 5 mM GSSG induced the formation of a peak of $11,911.7 \pm 1.0$, compatible with the addition of one glutathione molecule (305.5 Da). A representative analysis of rhTrx and GSSG-treated rhTrx is shown in Fig. 2. Longer incubation times (overnight) with 5 mM GSSG induced the formation of two peaks compatible with the addition of one or two glutathione molecules (data not shown).

The fact that the extent of glutathionylation depends on the concentration of the oxidant also was seen in separate experiments where rhTrx was treated with 100 mM GSSG for 2 h and the free -SH groups were titrated with DTNB. Incubation of fully reduced rhTrx with GSSG decreased the free -SH groups from five to one.

When rhTrx was incubated with 5 mM GSNO, under the same experimental conditions used with GSSG treatment, only one peak was found, corresponding to the protein with one GSH (data not shown). We did not observe a peak corresponding to the molecular weight of an NO adduct, suggesting that under those experimental conditions, rhTrx is not S-nitrosylated by GSNO, unlike other proteins (20, 21).

Identification of Glutathionylation Sites of Trx. To identify the glutathionylation site(s), we performed tryptic digestion of fully reduced or GSSG-oxidized rhTrx, and analyzed the tryptic fragments by mass spectrometry. However, we could not use standard digestion protocols as they include a reduction of the disulfide bridges in the protein, which would also cleave the

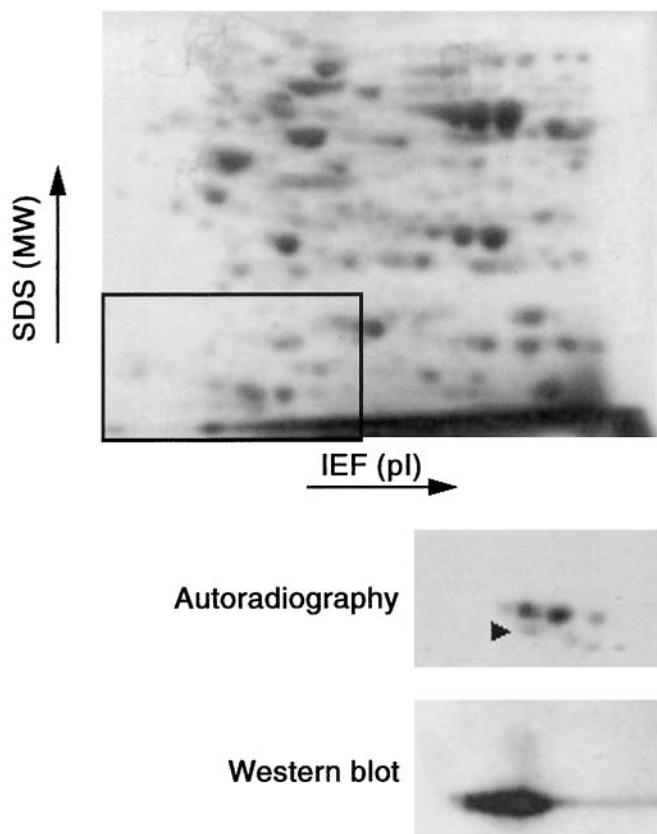

Fig. 1. Two-dimensional gel electrophoretic analysis of glutathionylated proteins. T cell blasts (106 per sample) were labeled with ^{35}S , then exposed to 1 mM diamide for 5 min; the proteins were separated by isoelectrofocusing (pH range 4–10, left to right) and then by SDS/10% PAGE (migration from top to bottom). All runs were done under nonreducing conditions. Figure shows the portion of the gel where Trx is migrating. (Top) Coomassie blue staining. (Inset) Portion of the gel for which autoradiography and Western blot are shown. (Middle) Autoradiography. (Bottom) Immunoblotting with anti-Trx.

mixed disulfide with GSH. Because preliminary experiments have shown that tryptic digestion under nonreducing conditions is not efficient, we used a modified protocol with digestion in organic-aqueous solvents (18) to ensure successful digestion of GSSG-treated rhTrx. The results are shown in Table 1. Two peptides of molecular mass of 1,452.6 Da and 1,580.8 Da are generated by digestion of GSSG-treated rhTrx that are not present in the spectrum of the untreated protein (shown in Fig. 3) and are compatible with glutathionylation of Cys-72.

To understand whether the susceptibility of Cys-72 was due to the presence of specific flanking amino acids or to the three-dimensional structure of the protein, we synthesized four peptides homologous to the corresponding rhTrx fragments, and that contained at least one Cys residue (Fig. 4). These four peptides were reacted with 5 mM GSSG and analyzed by mass spectrometry. The results, shown in Table 2, indicate that all of the Cys-residues can be glutathionylated when they are not involved in the three-dimensional structure of the protein. It is of interest to note that only one glutathione molecule is attached to the peptide 28–37 which comprises the two Cys of the active site of Trx.

Effect of Glutathionylation on Trx Activity. To investigate the effect of glutathionylation on the enzymatic activity of Trx, we incubated Trx with 5 mM GSSG, removed GSSG by desalting on a Sephadex G25 NAP5 column, and then evaluated disulfide

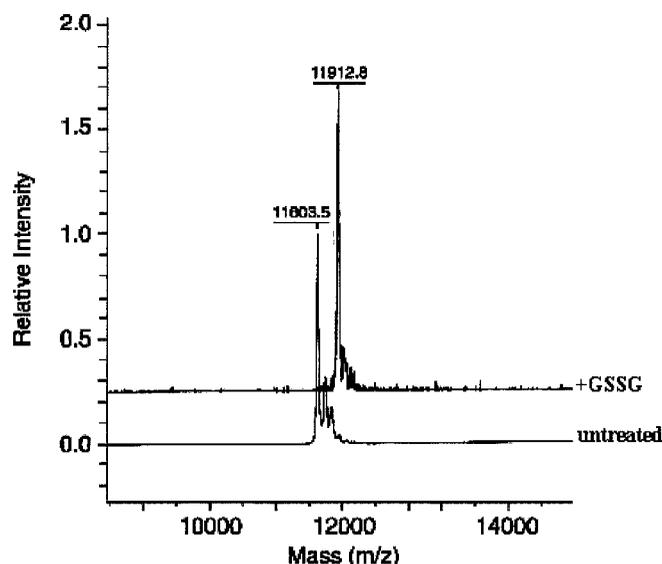

Fig. 2. MALDI identification of glutathionylated Trx. HrTrx (10 pmol) was incubated at room temperature without or with 5 mM GSSG and analyzed by MALDI-TOF MS.

reduction with insulin as a substrate. Glutathionylation reduced the activity of Trx to 63% of the control using an endpoint assay of formed -SH groups in insulin by a 20-min incubation. The attachment of a GSH residue on the -SH group of Cys-72, which is located in the active site surface of Trx, would be expected to abolish the activity of Trx-S₂ as a substrate for TrxR. To study this further, we used an assay where the kinetics of insulin disulfide reduction was followed in time as the oxidation of NADPH at 340 nm (Fig. 5). As can be seen from Fig. 5 A and B, the initial rate of the reaction with Trx-SG was almost zero, and the activity then was gradually regained. Thus, glutathionylation operated as a reversible regulatory device of the activity.

Discussion

This study shows that Trx can be glutathionylated under conditions of oxidative stress. Glutathionylation was confirmed by

Table 1. List of tryptic fragments of glutathionylated rhTrx

‡Fragment 1276.6 and + one GSH moiety.

The finding that Trx can be regulated by glutathionylation indicates the existence of crosstalk between the glutathione/glutaredoxin system and the Trx system through which Trx activity can be influenced by the GSH/GSSG ratio, an indicator of the redox state of the cell. The observation that GSNO also can induce glutathionylation of Trx with the same efficiency as GSSG suggests that, through the formation of GSNO, NO can influence Trx activity.

Although we demonstrate the occurrence of Trx glutathionylation in living cells exposed to an exogenous oxidant in the present work, other reports show that S-thiolation of enzymes, namely glyceraldehyde-3-phosphate dehydrogenase, with loss of enzyme activity, can take place during physiologic oxidative

stress such as that induced by monocyte activation (30). Therefore, it will be important to evaluate whether Trx is glutathionylated under pathological conditions resulting in oxidative stress.

It should be noted that although glutathionylation reduces the enzymatic activity of Trx, it could have more subtle effects on other activities of this protein, altering its affinity for interacting proteins or even generating new activities. For instance, in a protein related to Trx, sharing its insulin disulfide reducing activity, glycosylation inhibiting factor/macrophage migration inhibitory factor, S-thiolation caused conformational changes and generation of a growth factor like bioactivity (31). Trx has many biological activities, whose mechanisms are largely obscure: it acts extracellularly as a cytokine, chemokine, or growth factor (32–34) and intracellularly as a regulatory protein that influences several regulatory proteins such as NF- κ B (35) and ASK1 (36), and it is efficiently secreted through a still unknown mechanism. The relevance of the posttranslational modification of Trx reported here warrants further investigation.
