Edited by R. Michael Roberts, University of Missouri, Columbia, MO, and approved April 12, 2006 (received for review January 20, 2006)

**Experimental allergic encephalomyelitis (EAE), an autoimmune model of multiple sclerosis, is a complex disease influenced by genetic, intrinsic, and environmental factors. In this study, we questioned whether parent-of-origin effects influence EAE, using reciprocal F<sub>2</sub> intercross progeny generated between EAE-susceptible SJL/J (S) and EAE-resistant B10.S/SgMcdJ (B) mice. EAE susceptibility and severity were found to be different in female BS × BS intercross mice as compared with females from the three other birth crosses (BS × SB, SB × SB, and SB × BS), and in fact, both traits in female mice resembled those of their male siblings. This masculinization is associated with transmission of the SJL/J Y chromosome and an increased male-to-female sex ratio. Related studies using progeny of C57BL/6J Y-chromosome substitution strains demonstrate that the Y chromosome again influences EAE in both male and female mice, and that the disease course in females resembles that of their male littermates. Importantly, these data provide experimental evidence supporting the existence of a Y-chromosome polymorphism capable of modifying autoimmune disease susceptibility in both males and females.**

autoimmunity | sex chromosomes | disease susceptibility | parent-of-origin

**M**ultiple sclerosis (MS) is the major inflammatory demyelinating disease of the central nervous system (CNS) (1). The etiology of MS is unknown but is believed to have an immunopathologic basis arising in genetically predisposed individuals as a consequence of environmental insults (2). Evidence for the role of sociocultural, biological, environmental, physical, and parent-of-origin (POO) effects comes from epidemiological studies (3, 4). A recent study of half-siblings detected a significant maternal POO effect (2.35% for shared mother and 1.31% for shared father) in MS (5). The risk for siblings who share only a mother was similar to the risk in full siblings (2.34% vs. 3.11%,  $P = 0.1$ ), suggesting that the maternal POO effect could be the major component underlying familial aggregation (6). Moreover, findings from twin and half-sibling studies indicate that the gestational and/or neonatal environments influence the risk of MS later in life and that these effects are maternally related (7).

Experimental allergic encephalomyelitis (EAE) is an autoimmune (AI) model of MS induced by immunization with encephalitogenic antigens and adjuvants. Autoreactive T cells infiltrate the CNS and subsequently recruit additional lymphocytes and mononuclear cells, resulting in inflammation and demyelination (8). Susceptibility to EAE in mice is genetically controlled, with different inbred strains exhibiting various degrees of pathology and clinical disease (9). A spectrum of genetically controlled pathologies (10) and clinical (11) disease subtypes recapitulating those observed in MS (1, 12), including benign disease (CNS lesions in the absence of overt clinical signs), are seen in segregating populations. To date, >30 disease susceptibility and modifying loci have been mapped in mice.<sup>¶</sup> However, EAE, like MS, is also subject to intrinsic and extrinsic environmental factors (13–17). The present study was therefore undertaken to

determine whether the POO effect detected in MS could be documented and investigated in EAE.

Reciprocal F<sub>1</sub> hybrid and F<sub>2</sub> intercross mice between EAE-susceptible SJL/J (SJL or S) and -resistant B10.S/SgMcdJ (B10.S or B) mice were studied for EAE as described in refs. 10, 11, 18, and 19. Among male and female F<sub>2</sub> intercross mice a significant difference in disease susceptibility was observed only in females arising from matings in which the sires and grandsires possessed the SJL Y chromosome (BS × BS), indicating that the Y chromosome may indirectly influence EAE in females. We therefore studied progeny of Y-chromosome-substitution strains, and we found that the Y chromosome significantly affects the clinical disease course of both male and female mice.

## Results

EAE susceptibility was assessed in 71 F<sub>1</sub> hybrid and 1,152 F<sub>2</sub> intercross mice elicited by immunization with mouse spinal cord homogenate plus complete Freund's adjuvant (CFA). Birth cross and sex of the F<sub>2</sub> mice were distributed in approximately equal numbers (see Table 5, which is published as supporting information on the PNAS web site). No significant difference was detected in susceptibility to either clinical signs or EAE pathology among the male and female BS and SB F<sub>1</sub> hybrid parents of these F<sub>2</sub> progeny (see Table 6, which is published as supporting information on the PNAS web site).

The result of a simple logistic regression analysis of the F<sub>2</sub> progeny revealed that birth cross was not related to clinical disease (see Table 7, which is published as supporting information on the PNAS web site). A multiple logistic regression examining the effect of birth cross, stratified by sex, and controlling for age and season (17) also did not detect an association between birth cross and clinical EAE. Statistical analyses of POO effects on EAE pathology indicated that females overall were more likely to show CNS lesions (odds ratio = 2.04;  $P < 0.01$ ) when the dataset was corrected for age and season. Brain and spinal cord (SC) lesions were considered together (CNS lesions); although both showed the same significant trends separately. In addition, birth cross was significantly related to EAE pathology, with BS × SB, SB × SB, and SB × BS progeny more likely to exhibit lesions than BS × BS mice (Table 1). Birth cross was then shown to be significantly associated with CNS lesions in females but not in males. BS × SB, SB × SB, and SB ×

<sup>§</sup>Adjusted for age and season at immunization.

BS females were on average more than twice as likely to show CNS lesions (odds ratio = 2.58, 2.58, and 2.12, respectively) than BS × BS females.

The finding that BS × BS females are less likely to develop EAE pathology but nearly as likely to develop clinical signs may be due to differences in central function sensitivity to demyelinating lesions. An analysis of lesions (10), and a comparison of the pathology indices (PIs) for the SC, brain, and overall CNS, support this interpretation (Table 2). The SC, brain, and CNS PIs for BS × BS females are significantly less than those of the other three birth crosses, whereas no significant differences in the PI were detected among the males from the four birth crosses. Furthermore, the PI of the female BS × BS mice is not significantly different from the PI of the males. These results suggest that EAE in BS × BS females is organizationally masculinized and therefore functionally more sensitive to the consequences of AI demyelinating insults. This masculinization may be at the level of the immune system, CNS, or both.

The difference in susceptibility to CNS inflammation was only observed in females arising from matings in which the sires and grand-sires possessed the SJL Y chromosome (BS × BS). In theory the only Y-chromosome dependent mechanisms that can influence EAE in females are those originating in males during the prenatal and/or postnatal periods before weaning. To test this possibility directly, progeny of B6 females

× consomic male mice bearing different Y chromosomes [C57BL/6J (B6), B6.A-ChrY/NaJ (B6.Y<sup>A</sup>) and B6.SB-Yaa/J (B6.Yaa) mice] were studied for susceptibility to myelin oligodendrocyte glycoprotein peptide-(35–55) (MOG<sub>35–55</sub>)-induced EAE (Fig. 1). The clinical disease course in B6 (Fig. 1A) and B6.Yaa (Fig. 1C) progeny increased as a cubic function of time ( $P = 0.02$  and  $<0.01$ , respectively), whereas in B6.Y<sup>A</sup> (Fig. 1B) progeny it was consistent with a quadratic function ( $P < 0.01$ ). In all three strains, the clinical disease courses of male and female mice were not significantly different from one another and no significant sexual dimorphism in disease severity was detected.

Nevertheless, there was a clear influence of the Y chromosome on EAE in mice of both sexes. In male offspring (Fig. 2A), there were significant differences among the consomic lines (group differences,  $P < 0.01$ ), and across time ( $P < 0.01$ ). The interaction term was also significant ( $P < 0.01$ ), indicating that the clinical disease courses in the progeny of the three strains differed significantly. In female offspring (Fig. 2B), the main effect of group was also statistically significant ( $P < 0.01$ ), as were the clinical scores across time ( $P < 0.01$ ), and the interaction term ( $P < 0.01$ ). Last, because a significant sexual dimorphism was not detected for either disease course or severity of clinical signs in the offspring of the three strains, the data were pooled and reanalyzed (Fig. 3). A significant time effect ( $P < 0.01$ ), group effect ( $P \leq 0.01$ ), and interaction term ( $P \leq 0.01$ ) were obtained, indicating that the clinical disease courses differed significantly among the three Y-chromosome-substitution strains.

Given the dramatic nature of the differences observed, we repeated the study with a double-inoculation protocol (18, 19). Again, significant differences between male and female progeny within each of the Y-chromosome-substitution strains were not detected (see Fig. 7, which is published as supporting information on the PNAS web site), whereas among both male and female offspring (see Fig. 8, which is published as supporting information on the PNAS web site) the main effect of group was significant ( $\delta$  and  $\eta$ ;  $P < 0.01$ ), as were the differences in clinical

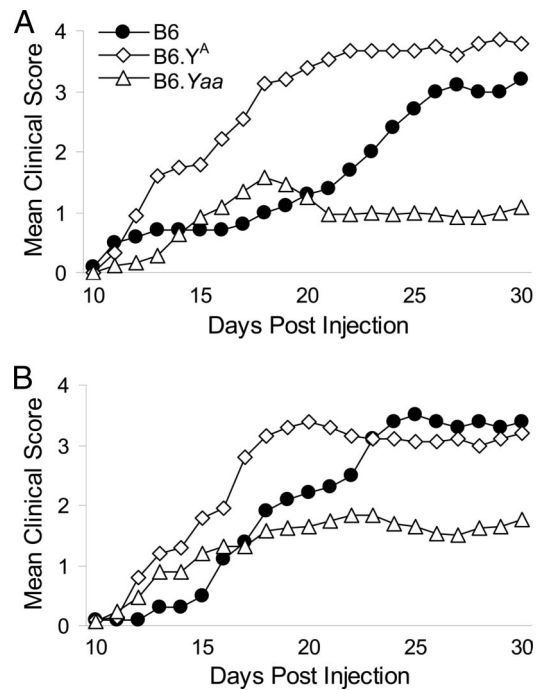

**Fig. 1.** Clinical EAE course in B6 ( $\delta = 10$ ,  $\eta = 10$ ) (A), B6.Y<sup>A</sup> ( $\delta = 15$ ,  $\eta = 26$ ) (B), and B6.Yaa ( $\delta = 24$ ,  $\eta = 24$ ) (C) progeny. Animals were injected with 100  $\mu$ g of MOG<sub>35-55</sub> emulsified in CFA containing 200  $\mu$ g of *Mycobacterium tuberculosis* H37Ra. Immediately thereafter, each animal received 200 ng of pertussis toxin (PTX) by i.v. injection. Mice were scored daily, starting at day 10 after injection.

scores across time ( $\delta$  and  $\eta$ ;  $P < 0.01$ ), and the interaction terms ( $\delta$  and  $\eta$ ;  $P < 0.01$ ). An analysis of the combined male and female data (Fig. 4) revealed a significant time effect ( $P < 0.01$ ), group effect ( $P < 0.01$ ), and interaction term ( $P < 0.01$ ), indicating that the clinical disease courses differently as a function of the Y chromosome.

Because the Yaa chromosome had the most profound effect on EAE, we compared the MOG<sub>35-55</sub>-specific immune responses of B6 and B6.Yaa mice. Serum levels of anti-MOG<sub>35-55</sub> IgG were lower in both male and female B6.Yaa mice compared with B6 males and females (Fig. 5A). Similarly, the *in vitro* proliferative responses (Fig. 5B) and secretion of IFN- $\gamma$  and IL-4 (Fig. 6) by T cells from male and female B6 mice were significantly greater than those of B6.Yaa male and female T cells.

## Discussion

In this study, BS  $\times$  BS F<sub>2</sub> females behaved more like their male siblings than like the female mice from the other three birth crosses in both lesion severity and clinical sensitivity to CNS damage. The origin of the POO effect eliciting this organizational masculinization is unknown, but possibilities include both

**Fig. 2.** Clinical EAE course in  $\delta$  (A) and  $\eta$  (B) B6, B6.Y<sup>A</sup>, and B6.Yaa progeny elicited by using the single MOG<sub>35-55</sub> plus CFA plus PTX induction protocol.

genetic and environmental (neonatal and/or prenatal). However, the mode of inheritance is inconsistent with classical X, Y, or mitochondrial inheritance and genomic imprinting because the observed effect requires a permanent mark in the BS F<sub>1</sub> hybrid females that selectively interacts with BS males and not SB males for transmission of the phenotype to the F<sub>2</sub> progeny. These interpretations are further supported by the lack of a significant difference in susceptibility to either clinical signs or EAE pathology among male and female bidirectional F<sub>1</sub> hybrid mice. This finding suggests that pre- and/or perinatal environmental effects underlie the organizational masculinization of EAE in female BS  $\times$  BS mice.

Litter composition can significantly influence female behavior during adulthood (20), and differences in maternal behavior generate long-term changes in offspring behavior and physiology (21). Neonatal manipulation of rodents can alter susceptibility to EAE (13), and exposure to testosterone suppresses diabetes and lupus in adult mice (22, 23). In litter-bearing mammals, fetuses

**Fig. 3.** Clinical EAE course in male and female B6, B6.Y<sup>A</sup>, and B6.Yaa progeny elicited by using the single MOG<sub>35-55</sub> plus CFA plus PTX induction protocol. As summarized in Table 3, no significant difference in the incidence of clinical disease was seen among the progeny of consomic lines; however, significant differences in the mean cumulative disease scores, mean peak scores, mean days affected, and mean severity indices were observed.

vical, thoracic, and lumbar segments of the SC, were selected for histopathological evaluation (see Figs. 9 and 10, which are published as supporting information on the PNAS web site) as previously described (10, 17). Animals exhibiting any CNS lesion were scored as affected in this study.

**Proliferation Assay and ELISA for IFN- $\gamma$ , IL-4, and MOG<sub>35-55</sub>-Specific Antibody.** Mice were immunized with 100  $\mu$ g of MOG<sub>35-55</sub> and 200  $\mu$ g of *M. tuberculosis* H37Ra, and draining lymph node cells prepared from these mice at day 10 after immunization. MOG<sub>35-55</sub>-specific T cell proliferative responses and quantification of IFN- $\gamma$  and IL-4 secretion were done as described in ref. 41. Sera were isolated from individual animals and frozen at  $-80^{\circ}\text{C}$  until assayed. Anti-MOG<sub>35-55</sub> IgG antibody levels were determined by ELISA using anti-mouse IgG conjugated to streptavidin-horseradish peroxidase. The specific details of each assay are published as *Supporting Materials and Methods* on the PNAS web site.

**Statistical Analyses.** A logistic regression analysis was used to examine the relationship between susceptibility to EAE or evidence of CNS inflammation, and cross and sex. This analysis was followed by multiple logistic regression analyses to examine the effects of these variables on disease susceptibility while controlling for each of the other selected variables, including sex

and season and age of the animal at the time of injection. The final multiple logistic regression analyses included adjustment for these two variables, with age (in weeks) being considered as a continuous variable. Analyses were performed by using SAS, Version 8.1 (SAS Institute, Cary, NC).

A repeated-measures analysis of variance was performed to examine the group changes in the mean clinical score across time, as well as time by group interactions. The time by group interaction term allows an examination of whether the changes in the mean clinical score across time differ among the various groups. Techniques relying on orthogonal polynomials were used to examine whether the mean clinical scores changed in a linear fashion with time, or whether these changes could be better described by some other polynomial function of time [i.e., increased as a multiple of time squared (quadratic function of time) or cubed (cubic function of time)]. Because the goal of this type of analysis is to fit the data with the polynomial of the smallest degree, polynomial functions higher than the cubic function were not considered. Analyses were performed by using BMDP statistical software (BMDP Statistical Software, Los Angeles; 1990).
