Edited by Arthur Weiss, University of California School of Medicine, San Francisco, CA, and approved June 2, 2006 (received for review January 25, 2006)

**A longstanding paradox in the activation of cytotoxic T lymphocytes (CTL) arises from the observation that CTL recognize and rapidly destroy target cells with exquisite sensitivity despite the fact that cytokine production requires sustained signaling at the immunological synapse. Here we solve this paradox by showing that CTL establish sustained synapses with targets offering strong antigenic stimuli and that these synapses persist after target cell death. Simultaneously, CTL polarize lytic granules toward different cells without discrimination regarding antigenic potential. Our results show that spatiotemporal uncoupling of immunological synapse and lytic granule secretion allows multiple killing and sustained signaling by individual CTL. This unique mechanism of responding to multiple contacts provides remarkable efficiency to CTL function.**

confocal microscopy | immunological synapse | sustained signaling

An intriguing feature of CTL biology is that, although cytotoxicity is a rapid and low-threshold response, activation to interleukin production requires a prolonged time and an adequately strong antigenic stimulation (1, 2). We have previously shown that individual CTL interacting with cognate target cells exhibit a dual activation threshold reflecting the formation of two distinct immunological synapses (IS) at the CTL/target cell contact site: the lytic synapse and the stimulatory synapse (3). The term “lytic synapse” was used to refer to the polarization of the lytic machinery detectable at both low and high antigen concentrations, and the term “stimulatory synapse” was used to refer to the large-scale molecular segregation of surface molecules and signaling components characteristic of a mature IS and occurring only with target cells providing strong antigenic stimuli (3). The formation of a lytic synapse corresponded to full activation of CTL to cytotoxicity (whereas IFN- $\gamma$  production was marginal, and calcium mobilization was low and erratic). The formation of a stimulatory synapse corresponded to activation to cytokine production (3).

A large amount of information on the molecular dynamics occurring at the CTL/target cell contact site is now available; however, CTL activation to biological responses is still an enigmatic process because of three major unresolved questions.

The first question is how can CTL behave as efficient and rapid killers and at the same time gather the sustained signals required for cytokine production on the surface of their targets (2, 4)? Cytotoxicity is a very efficient phenomenon characterized by a high degree of sensitivity and rapidity. It has been previously estimated that target cells displaying as few as 1–10 specific peptide/MHC complexes on their surface can trigger cytotoxicity (5). In a recent study Purbhoo *et al.* (6) measured the number of peptide/MHC complexes present at the cell–cell contact site in living CTL/target cell conjugates. They showed that CTL could indeed be activated to lethal hit delivery by as few as two to three specific peptide/MHC complexes present at the cellular interface. Lethal hit delivery requires a very short time. Upon conjugation with cognate target cells, CTL rapidly

polarize their lytic machinery toward the opposing cells (7). Moreover, CTL can kill outnumbering target cells (8), indicating that they may rapidly detach and recycle from one target to another (9–12). How the process of CTL activation is compatible with rapid low-threshold cytotoxic responses and transient CTL/target interactions is still unknown.

The second unresolved question is how is the polarization of lytic machinery regulated in CTL interacting with multiple targets simultaneously? We have recently shown that CD4<sup>+</sup> helper T cells simultaneously interacting with different antigen-presenting cells (APC) rapidly polarize their secretory machinery toward the APC providing the strongest antigenic stimulus. This rapid polarization allows CD4<sup>+</sup> T cells to provide their help in a selective fashion (13). Although selective help delivery is instrumental for the development of adaptive immune responses, selective polarization of CTL lytic machinery toward the targets offering strong antigenic stimuli could be detrimental for indiscriminate immune surveillance against all potentially dangerous cells. Whether CTL selectively polarize against defined targets or conversely are able to behave as indiscriminate killers is still unknown.

A third question concerns the functional relation between the lytic and stimulatory synapses in individual CTL. The mature IS was originally described as a specialized signaling domain formed at the contact site between T cells and APC, characterized by large-scale molecular clustering and segregation of surface molecules and signaling components (7, 14, 15). Current research has led to an expansion of this term, where IS now indicates a multitude of structures that are mediators of intercellular communication (3). It has been suggested that in CTL the IS may have the role of polarizing secretion of lytic granules toward target cells (7). However, results from our laboratory and other laboratories have recently shown that polarization of CTL lytic machinery toward targets can occur in the absence of the large-scale molecular clustering and segregation characteristic of a mature IS (3, 6, 16). Together these results suggest that lethal hit delivery and molecular rearrangement at the synapse are rather independent events that may possibly take place separately in different areas of the cell and at different time points of interaction.

**Fig. 1.** The time kinetics of lethal hit delivery does not depend on the strength of antigenic stimulation. Sequences of snapshots depicting lytic granule polarization toward target cells pulsed with 10  $\mu$ M or 1 nM peptide concentration are shown. (A) A CTL loaded with LysoTracker red (red) is interacting with a target cell pulsed with 10  $\mu$ M peptide. Targets are loaded with calcein, a probe that is lost upon cell death (green). (B) A CTL loaded with LysoTracker red (red) is interacting with a target cell pulsed with 1 nM peptide and loaded with calcein (green). It should be noted that LysoTracker red is rapidly released into the culture medium and taken up to some extent by the target cells. The snapshot sequence in A corresponds to Movie 1, and the snapshot sequence in B corresponds to Movie 2. The numbers indicate the time points in minutes. (Scale bar: 10  $\mu$ m.) Data are from two representative experiments of 16 for the two concentrations of peptide.

In the present work we visualize molecular dynamics at the CTL/target cell contact site in CTL interacting with individual and multiple targets and provide time-lapse confocal microscopy records that shed light on the dynamics of CTL/target interaction. We show that CTL do not cycle between targets but rather remain attached to annihilated targets. Moreover, CTL adhere to strongly antigenic targets for a prolonged period even after disintegration of these cells and continue to undergo sustained signaling and IS formation. Meanwhile, CTL can kill multiple targets encountered simultaneously by polarizing lytic granules toward different targets with no discrimination of their antigenic potential.

Our results illustrate an unexpected intercellular dynamics that allows both multiple killing and sustained CTL activation. By means of this mechanism CTL rapidly administer lethal hits to various targets encountered simultaneously while establishing preferential liaisons with targets that are still offering activation stimuli even after death.

## Results

**Polarization of Lytic Machinery Is Intrinsically Very Rapid.** To define, in individual CTL, the dynamics of lethal hit delivery versus the formation of a stable IS, we initially studied the time kinetics of lytic synapse formation. CTL were loaded with LysoTracker red (to visualize lytic granules), and target cells were loaded with calcein, a dye that is lost upon cell death (17). The interaction between living CTL and target cells was studied by using time-lapse laser scanning confocal microscopy. Target cells were either unpulsed or pulsed with 1 nM (a peptide concentration sufficient to saturate cytotoxic response) or 10  $\mu$ M (a peptide concentration that saturates both cytotoxicity and cytokine production) antigenic peptide (3).

Fig. 1 shows that polarization of lytic granules toward target cells pulsed with antigenic peptide occurred within a few minutes after the initial contact between CTL and their targets. The polarization of CTL lytic granules was followed by the loss of calcein from target cells, showing that lytic synapse formation

leads to target death. The time kinetics of lytic granule polarization are better appreciated in Movies 1 and 2, which are published as supporting information on the PNAS web site, showing that lytic granule polarization was detectable within 3 min after cell–cell contact. Interestingly, the time kinetics of lytic machinery reorientation was independent of the strength of antigenic stimulation, because it was similar in CTL interacting with targets pulsed with 10  $\mu$ M or 1 nM peptide (a quantification of a statistically significant number of conjugates is shown Fig. 6, which is published as supporting information on the PNAS web site). The time kinetics of calcein loss was variable in the different CTL/target conjugates. This finding suggests that, although CTL deliver hits homogeneously rapid, the time required to trigger individual target cell death is variable.

CTL interacting with unpulsed target cells formed conjugates and crawled on target cell surface in the absence of calcein leakage and of any other evidence of target cell death (Movie 3, which is published as supporting information on the PNAS web site).

Together these results indicate that lytic granule polarization is intrinsically very rapid, allowing CTL to promptly attack targets with no distinction of their antigenic potential.

**Stimulatory Synapse and Sustained Signaling Keep Going After Target Cell Annihilation.** The above results support the notion that lytic synapse formation and target cell annihilation are rapid events occurring during the early steps of CTL/target interaction. This observation raises the question: how can a stimulatory synapse be formed and maintained for a prolonged time at the cellular interface while allowing for the sustained signaling that is required for CTL activation to cytokine production (2)?

To address this question, we studied the kinetics of stimulatory synapse formation in individual CTL interacting with their targets for a sustained time. Target cells were loaded with calcein to visualize cell death. CTL were stained with Cy5-labeled anti-CD3 Fab antibodies to detect the enrichment of T cell receptor (TCR)/CD3 complexes at the cell–cell contact site, a parameter of mature IS formation. Time-lapse video microscopy showed that initiation of calcein loss in the target cells precedes the clustering of TCR into the IS (Fig. 2A and Movies 4 and 5, which are published as supporting information on the PNAS web site).

To quantitatively evaluate the time kinetics of target cell death and of TCR/CD3 enrichment at the synapse we applied the LineScan function of METAMORPH software to series of snapshots depicting CTL/target cell interaction. This analysis resulted in sequential plots that are presented in Fig. 2B and Fig. 7, which is published as supporting information on the PNAS web site (Fig. 2B is animated in Movie 6, which is published as supporting information on the PNAS web site). This approach shows that, even though the time of enrichment of TCR into the IS varies in individual CTL/target cell conjugates, it is delayed compared with lethal hit delivery. In addition, TCR/CD3 clustering at the cell–cell contact site was sustained long after target annihilation (Fig. 2). When CTL were conjugated with targets pulsed with a 1 nM concentration the targets were readily killed in the absence of the TCR clustering typical of stimulatory IS (Movie 7, which is published as supporting information on the PNAS web site), in agreement with previously reported data (3, 6).

The unexpected observation that stimulatory synapse formation can be sustained even after target cell annihilation suggests that CTL could receive prolonged activatory signals while interacting with fragments of disintegrating targets. We therefore investigated whether CTL maintained sustained signaling for a prolonged time after the death of the opposing target cell.

CTL were loaded with Fluo-4 to detect the intracellular  $Ca^{2+}$  concentration ( $[Ca^{2+}]_i$ ) increase (3, 13), and CTL/target interactions were recorded for a sustained time. As shown in Fig. 3

**Fig. 4.** CTL polarize lytic granules toward different targets encountered simultaneously. Snapshots depict lytic granule polarization in CTL interacting simultaneously with target cells pulsed with 10  $\mu$ M (blue) or 1 nM (green) peptide concentration. Data are from one representative experiment of nine.

is published as supporting information on the PNAS web site, shows that the  $[Ca^{2+}]_i$  increase is significantly sustained after target cell death. These results show that CTL interacting with target cells providing strong antigenic stimulation do not rapidly disassemble stimulatory synapse upon target annihilation. Rather, they remain in contact with the dead targets and sustain active signal transduction for a long period.

**Individual CTL Kill Multiple Targets Simultaneously in a Nonselective Fashion.** The above results show that human CTL remain attached to their targets for a relatively prolonged time rather than rapidly recycling from one target to another. This observation raises the question of how CTL may kill outnumbering heterogeneous targets during an immune response. To address this question we investigated the possibility that CTL may be able to kill multiple targets encountered simultaneously regardless of their antigenic potential.

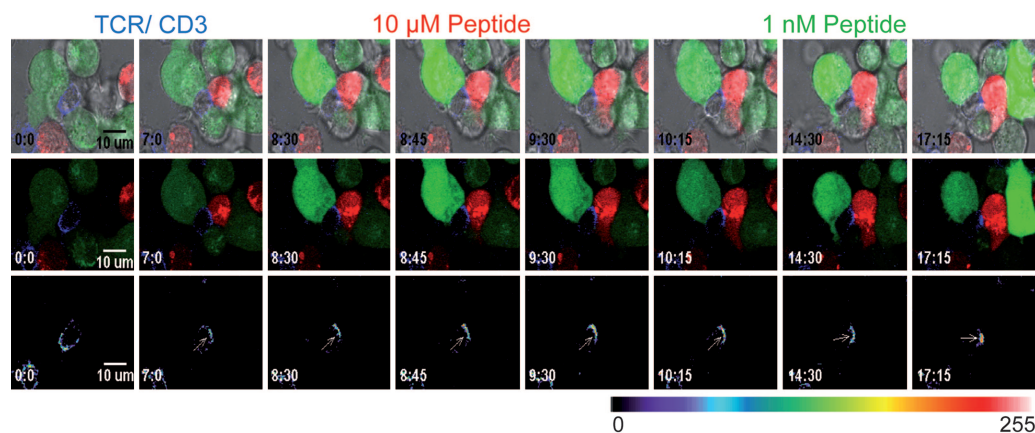

CTL simultaneous interaction with multiple targets was investigated by time-lapse confocal microscopy. Target cells were pulsed with a high (10  $\mu$ M) or a low (1 nM) antigenic peptide concentration and were loaded with different dyes to allow their

identification. We initially focused on lytic granule secretion. Movies 10 and 11 and Fig. 9, which are published as supporting information on the PNAS web site, and Fig. 4 show that CTL interacting with targets pulsed with different antigenic concentrations polarize their lytic granules toward both targets simultaneously.

To obtain quantitative information on polarization of lytic granules toward two different contact sites we took several snapshots of living cells by randomly changing the field during movie recording. A total of 136 snapshots depicting CTL in simultaneous contact with two targets were recorded in nine independent sessions. The polarization of lytic granule accumulation was scored by visual inspection in a blind study on registered images. T cells in simultaneous contact with two targets offering different antigenic stimuli were initially scored. Eighty-four triplicates were scored: 44% of CTL exhibited a double polarization, 29% exhibited lytic granule accumulation toward one target cell, and 27% showed an uncertain phenotype. More precisely, they showed a tendency to relocate lytic granules toward the two contact sites without clearly focused polarization of lytic granules. A simultaneous polarization of lytic granules in CTL interacting with two targets offering the same antigenic stimulation was also observed. 52 triplicates were scored: 46% of CTL exhibited a double polarization, 17% exhibited lytic granule accumulation toward one target cell, and 37% showed an uncertain phenotype.

Taken together the above results directly illustrate that individual CTL are indeed killers of multiple targets encountered simultaneously. A recent study showed that, in the case of CTL conjugated with two targets offering similar densities of antigenic ligands, the tubulin cytoskeleton oscillates between the two targets (18). In that study, the dynamics of lytic granule polarization in CTL conjugated with targets offering different densities of antigenic ligands was not investigated. Therefore, our results extend these described findings.

We next focused on TCR/CD3 dynamics on the surface of CTL interacting with different targets. CTL were stained with Cy5-labeled anti-CD3 Fab antibodies, and their interaction with targets pulsed with low (1 nM) or high (10  $\mu$ M) antigenic concentration was visualized. Target cells were loaded with Fluo-4 to have a rapid evidence of lethal hit delivery in parallel with TCR/CD3 dynamics (10, 19). Fig. 5 and Movies 12 and 13, which are published as supporting information on the PNAS web site, show that, although TCR/CD3 was enriched in the contact

**Fig. 5.** Lytic and stimulatory synapses can be uncoupled in individual CTL. Sequences of snapshots depicting TCR/CD3 staining (blue) in CTL interacting simultaneously with target cells pulsed with a high (10  $\mu$ M; red) or a low (1 nM; green) peptide concentration. To rapidly detect lethal hit delivery in target cells, targets pulsed with 1 nM peptide were loaded with Fluo-4 AM. (Top) Overlapping of differential interference contrast microscopy images and fluorescence staining. (Middle) Only fluorescence staining is shown. (Bottom) TCR staining intensity using a pseudocolor scale. The white arrows in Bottom indicate the TCR/CD3 enrichment at the CTL/target contact site. At the end of the time recording a second target cell receives the lethal hit by a CTL not visible in the movie and undergoes  $[Ca^{2+}]_i$  increase. The snapshot sequence corresponds to Movies 12 and 13. Data are from one representative experiment of three.

## Materials and Methods

**T Cells and Target Cells.** An HLA-A2-restricted T cell line (CM-Vpp65) specific for the peptide NLVPMVATV of human cytomegalovirus protein pp65 was used (3). HLA-A2-matched Epstein-Barr virus (EBV)-transformed B cells (JY) were used as target cells (3). T cell line and EBV-B cell lines were generated and maintained as described (2).

**Dynamics of Lytic Granules and TCR/CD3 in Living Cells.** To visualize lethal hit delivery T cells were loaded with LysoTracker Red (Molecular Probes) for 45 min at 37°C in RPMI medium 1640/5% FCS. To visualize TCR/CD3 dynamics, T lymphocytes were labeled with Cy5 TR66 Fab at 20  $\mu\text{g}/\text{ml}$  in RPMI medium 1640/5% FCS at 4°C for 30 min as described (13).

Target cells were labeled with either 1  $\mu\text{M}$  calcein (Molecular Probes) in RPMI medium 1640/5% FCS for 30 min at room temperature or 0.5  $\mu\text{M}$  Orange CMTMR or 0.5  $\mu\text{M}$  Bodipy 630 (both from Molecular Probes) at 37°C for 15 min. Target cells were previously pulsed with 1 nM or 10  $\mu\text{M}$  peptide for 2 h at 37°C.

Target cells were seeded into microchambers (Lab-Tek Cham-

ber coverglass, Nalge Nunc) previously coated with poly-D-lysine (Sigma). Fluorescence measurements were done on a Zeiss LSM-510 confocal microscope at 37°C and 5% CO<sub>2</sub>. Image sequences of the time-lapse recording were processed with METAMORPH software (13).

To have a quantitative evaluation of the time kinetics of target cell death and of TCR/CD3 fluorescence at the synapse we applied the LineScan function of METAMORPH software to series of snapshots depicting CTL/target cell interaction. This analysis resulted in sequential plots that are presented in Figs. 2B and 7 and are animated in Movie 6.

In additional experiments either CTL (to detect TCR-mediated signaling) or target cells [to detect early cellular damage (10, 19)] were loaded with 1  $\mu\text{M}$  Fluo-4 AM for 30 min at 37°C. The green fluorescence emission of Fluo-4 reflecting the [Ca<sup>2+</sup>]<sub>i</sub> was monitored by time-lapse confocal microscopy as described (3).
