contacts, however, yielded 12 patients with the disease, of whom eight were children, which underlines the efficiency of the service if properly applied.

The public reaction to the articles in local papers was interesting, and evidently there are still many misconceptions about tuberculosis. Most of the people who submitted themselves for x ray examination were totally ignorant of the implications of the disease and reacted in a way more reminiscent of the plague or smallpox. This shows again how powerful an influence the media may be in medical matters. The unjustified loss of trade to the public house must also be a matter of some concern and reflects to some extent the public attitude to the disease.

In conclusion, this epidemic serves to emphasise two long established but probably forgotten truths about tuberculosis. Firstly, tuberculosis still exists in this country and is not merely a disease of immigrants, social outcasts, and alcoholics; in non-vaccinated people it remains a highly contagious disease of young adulthood. The BCG vaccination, however, is safe, free from systemic side effects, and of proved efficacy when given at the age of maximum susceptibility to the disease. Every effort should be made to pursue the schools vaccination programme, particularly in children who initially default. Secondly,

the public should be made aware that tuberculosis in all forms can be cured completely with drugs at little personal inconvenience.

We thank the Bradford chest physicians for access to their patients.

Clinical range of neonatal rotavirus gastroenteritis

J DEARLOVE,   P LATHAM,   B DEARLOVE,   K PEARL,   A THOMSON,   I G LEWIS

Abstract

A baby admitted to a special care baby unit with profuse watery diarrhoea was found to have a rotavirus infection. A total of 196 babies were admitted to the unit over the next year. Routine stool samples were taken weekly from all babies and additional samples were taken from all babies who developed clinical signs suggesting sepsis. A total of 76 babies excreted rotavirus; 32 of these developed a diarrhoeal illness, 12 of whom were severely ill with bloody diarrhoea and abdominal distension; and two had perforations. The smaller, sicker babies who stayed in hospital longer were more likely to acquire infection; colostrum did not confer protection against rotavirus or symptomatic infection. The outbreak of rotavirus declined independently of the measures taken to eradicate it.

Our findings suggest that neonatal rotavirus infection may occasionally cause severe gastrointestinal problems.

Introduction

In December 1980 an infant was admitted to the special care baby unit at Charing Cross Hospital. He developed a profuse watery diarrhoea. Rotavirus was isolated from his stools and also from his mother's faeces. Over the next year we treated a large number of infected babies with a very high morbidity. Although neonatal rotavirus infections are generally regarded as relatively benign,[1] our experience was very different.[2]

Materials and methods

All babies admitted to the special care baby unit in the year after the index case—that is, from 18 December 1980 to 18 December 1981—were studied. Cases arising after 18 December 1981 were excluded from the study. All the babies studied were seen by at least two of the authors. Later in the study period, we attempted a similar surveillance of asymptomatic babies in the postnatal wards, but those results are not included here.

An initial stool sample was taken from all babies; thereafter stool samples were taken weekly and cultured for bacterial pathogens. Stools were also examined for the presence of rotavirus. In addition, any baby who appeared ill and was being investigated for a septic condition had a stool sample examined for the presence of rotavirus. Initially, the stool specimens were examined by electron microscopy. After three months, this technique was replaced by semiquantitative enzyme linked immunoassay (Rotazyme), which is of comparable sensitivity,[3] as we found when using both techniques at the beginning of our study. The Rotazyme test may give negative results or be graded optically as positive from one (weakly positive) to six (very strongly positive). We regarded a result of grade two, as indicative of rotavirus infection. The date that the first stool with positive results was taken from the patient was assumed to be the date that the baby acquired rotavirus. The date in the baby's notes indicating a clear change in clinical state as defined by our criteria was taken to be the date that the baby became ill.

The babies who excreted rotavirus appeared to have a wide range of gastrointestinal symptoms varying in severity from those resembling necrotising enterocolitis to mild diarrhoea. The babies were classified

TABLE IV—*Distribution of physical signs in 196 babies admitted to the special care unit. Figures are numbers of patients*

	With rotavirus (n = 76)	Without rotavirus (n = 120)
Babies with severe diarrhoea*		
Total	12	4
Perforation	2	0
Pneumatosis	3	1
Abnormal bowel pattern	10	4
Bloody diarrhoea	11	4
Abdominal distension	12	4
Signs suggestive of sepsis	12	4
Babies with mild diarrhoea†		
Total	20	2
Needing intravenous fluids	5	1
Needing oral rehydration	11	1
Needing no treatment	4	0

* Babies with rotavirus v those without; $p < 0.01$.
† Babies with rotavirus v those without; $p < 0.001$.

diarrhoea, compared with 32 from the original sample of 76). The babies who were reinfected were also more likely to have stayed on the unit longer, about 65 days, compared with only 34 days for babies who had only one infection.

Discussion

There are two aspects to our study. It is, firstly, a description of a rotavirus epidemic, pointing out that smaller, sicker babies get infected and that the longer the baby stays in an infected unit the more likely it is to get a second infection. The second, and more difficult, aspect to the study is linking the clinical signs to the acquisition of rotavirus. In December 1980 we noticed two clinical problems affecting our babies; a diarrhoeal illness and slow weight gain. It became clear that slow weight gain could not be attributed to rotavirus. Rotavirus is, however, a common cause of acute infantile diarrhoea and it has been described in neonates.[4] About half of the babies who had rotavirus in their stools also had symptoms and onset of symptoms often coincided with acquisition of infection. Obviously we cannot say that rotavirus was the prime cause of illness in the sick babies, despite the rather compelling circumstantial evidence.

Our study could be criticised on several points. For example, we did not examine every sample by electron microscopy as well as Rotazyme assay and may, therefore, have missed other viruses.[5] When we used the combined technique at the outset of this study, however, we could not identify other viruses in the stools of these babies. We learnt several practical lessons. Fumigation of the unit performed in August and September appeared to have little effect on rates of infection, as did strict hand washing and wearing disposable aprons. Giving the first feed as fresh maternal colostrum offered no protection against gastroenteritis or rotavirus. We thought that the weighing scales, the sterilising solution, or the ventilators could have been contaminated with rotavirus but we could not detect antigens or isolate rotavirus from these sources. We did notice, however, that the symptomatic cases clustered around the times when we were busiest with new admissions. Curiously, the rotavirus epidemic waned over the first half of 1982, despite admission rates similar to those of 1981: this bore no obvious relation to our measures to control infection.

Finally, when we originally described our experience,[2] we thought that some of our babies who had a rotavirus infection also appeared to have necrotising enterocolitis. This diagnosis was based on the British Paediatric Association's surveillance criteria, which recognises two grades of severity of necrotising enterocolitis. Grade I needs two of our five criteria (excluding perforation) for severe diarrhoea. Although our cases of severe diarrhoea might fulfil these criteria, all but the three with pneumatosis could also be diagnosed as gastroenteritis. Because of this lack of specificity, we decided that only the cases with all five clinical signs and with radiological evidence of pneumatosis intestinalis had necrotising enterocolitis. This would mean that three out of 76 babies who excreted rotavirus had necrotising enterocolitis around the same time, compared with one out of 120 babies with no rotavirus. Although this is a significant difference ($p < 0.02$), the numbers are very small indeed. This finding does, however, underline the suggestion that neonatal rotavirus infections may occasionally cause severe gastrointestinal problems.

REPELLING MEDICINES—Repelling medicines are of contrary operation to these three last mentioned, viz attenuating, drawing, and discussive medicines: It is true, there is but little difference between these three, some hold none at all: and if you will be so nice, you may oppose them thus. And so medicines making thick, correspond to attenuating medicines, or such as make thin, repelling medicines are opposed to such as draw, and such as retain the humours and make them tough, are opposite to such as discuss, some hold this niceness needless. 2. The sentence of authors about repulsive medicines is various. For seeing an influxion may be caused many ways, a repulsive hath got as many definitions. For such things as cool, bind, stop, and make thick, stay influxions, and therefore repulsives are by authors opposed, not only to attractives, but also to attenuating, and discussing medicines. But properly such things are called repulsives, which do not only stay influxions (for so do such medicines which stop and make thick) but such as drive the humours flowing to, or inherit in the place, to some other place. The truth is, binding is inherent to repulsives, so is not coldness nor making thick: Yet such as are binding, cold and thin in operation, are most effectual. Your taste will find repulsives to be, tart, or sharp, or austere, with a certain binding which contracts the tongue. Their use is manifold, as in hot tumours, head-aches, or the like. By these in fevers are the vapours driven from the head, Vinegar or Roses is notable. They are most commodious in the beginning and encrease of a disease, for then influxions most prevail. But seeing that in the cure of tumours there are two scopes, 1. That that which flows to it may be repelled. 2. That that which is already in it may be discussed; repulsives are most commodiously used in the beginning, discussives in the latter end. In the middle you may mix them, with this proviso, that repulsives exceed in the beginning, discussives in the latter end. *Caution* 1. If the matter offending be of a venomous quality, either abstain from repulsives altogether, or use purging first, lest the matter fly to the bowels and prove dangerous, especially if the bowels be weak. 2. Also forbear repulsives, if the pain be great. 3. Lastly, Have a care lest by repulsives you contract the pores so much, that the matter cannot be removed by discussives. (Nicholas Culpeper (1616-54) *The Complete Herbal*, 1850.)
