Ultrastructural Alterations in Allylamine Cardiovascular Toxicity

Late Myocardial and Vascular Lesions

PAUL J. BOOR, MD, and

The late myocardial and vascular ultrastructural changes in rat hearts following consumption of the cardiovascular toxin allylamine were studied. Rats were given 0.1% allylamine HCl in drinking water for 10–104 days. From 10 to 21 days, there was organization of acute myocardial necrosis by macrophages and scattered polymorphonuclear leukocytes with prominent interstitial-cell proliferation. Alterations at 21–104 days included extensive scarring with formation of dense mature collagen with scattered fibroblasts present, grossly evident left-ventricular aneurysm, and gross and microscopic changes similar to those observed in the secondary form of endocardial fibroelastosis. Areas of scar contained highly cellular foci of smooth-muscle cells, myofibroblasts, and abundant extracellular elastin. Cardiac myocytes frequently showed markedly disorganized myofilaments, bizarrely distorted mitochondria with condensed cristae, and other severe degenerative changes. Small vessels within and adjacent to scar showed proliferation of intimal smooth-muscle cells. Endothelial lesions or recent or organized thrombi were not seen. Focal endocardial metaplasia, consisting of both chondroid and osseous tissue, was found in areas of transmural scarring, or ventricular aneurysm. Chondrocytes had the overall nuclear and cellular morphology, abundant rough endoplasmic reticulum, and surrounding lacunae typical of mature fibrocartilage. In some areas, the collagen matrix was undergoing calcification with the typical cross-banded pattern of calcifying connective tissue. Osteocytes were located in a densely calcified bone matrix and displayed characteristic cellular extensions into surrounding canaliculi. These findings indicate a severe myocardial, small-vessel, and endocardial injury during the course of chronic allylamine intoxication. (Am J Pathol 1985, 121:39–54)

IN A PREVIOUS PAPER we characterized the early myocardial ultrastructural alterations which occur in rats given allylamine orally[1]; these alterations consist of acute myocardial necrosis without vascular occlusion, followed by a prompt inflammatory infiltrate composed predominantly of macrophages. Late cardiovascular lesions also occur in several species of animals following the repeated or long-term intravenous, intra-arterial, or oral administration of allylamine. These late alterations include aortic intimal hyperplasia and cartilaginous dysplasia,[2–4] coronary arterial intimal fibrous proliferation[4–7] and medial hyalinosis,[2] and smooth-muscle proliferation in smaller intramyocardial arteries.[8] Perhaps the most remarkable late allylamine-induced lesions, however, are the bizarre myocardial alterations, which include transmural scarring with ventricular aneurysm formation[2,3,9,10] and endocardial cartilaginous metaplasia with calcification, resembling osseous metaplasia.[10]

This study describes the ultrastructure of the late alterations which occur in rats after long-term allylamine administration.

Materials and Methods

Twenty male Sprague–Dawley rats (180–220 g) were allowed free access to 0.1% allylamine HCl as their only

Supported by Research Career Development Award HL00929 and Grant HL26189 from the National Heart, Lung, and Blood Institute.

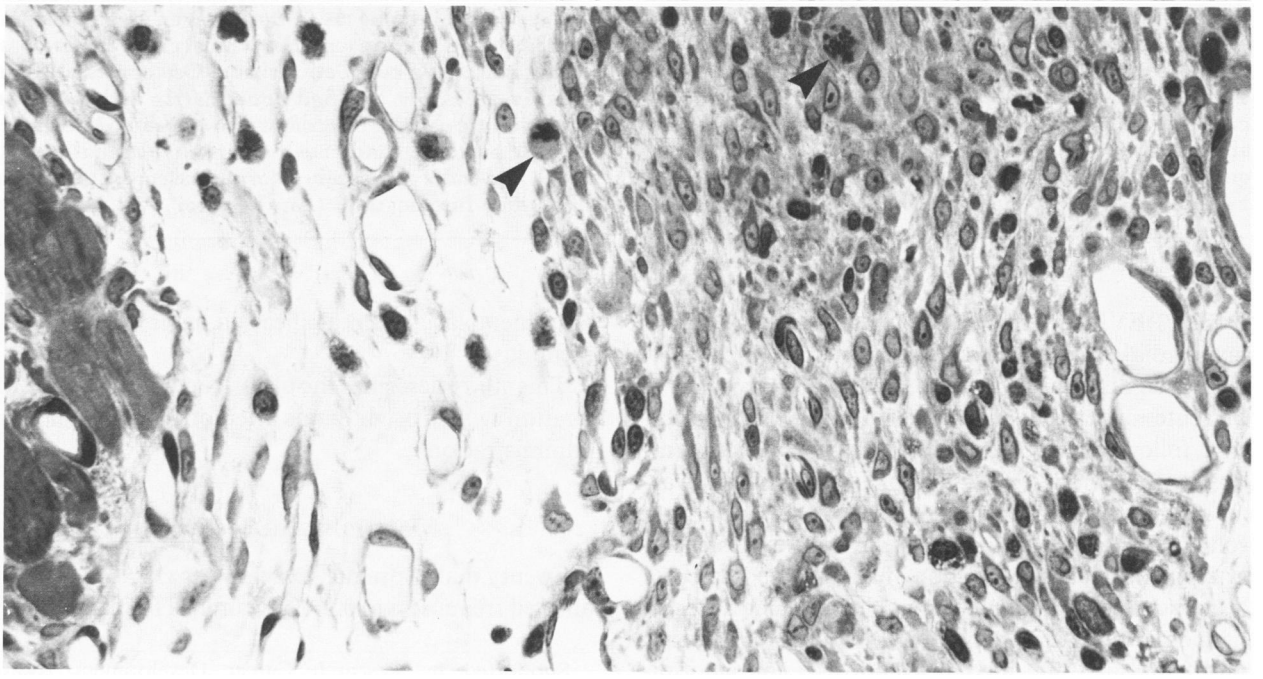

Figure 1—Light micrograph of 1-μ-thick section of rat left-ventricular endocardium shows the organizing myocardial necrosis seen at 10–21 days of allylamine consumption; a diffuse cellular infiltrate is present; necrotic myocytes are not evident. Note the sparing of a layer of myocytes, 2–5 cells thick; a similar spared layer of cells was also present in the epicardium. Ten days of allylamine consumption. (Toluidine blue, ×490) **Figure 2**—Light micrograph of areas of organizing myocardial necrosis shows inflammatory infiltrate of macrophages, a few polymorphonuclear leukocytes, prominent capillaries, and interstitial cells with frequent mitoses (*arrows*). Ten days of allylamine consumption. (Toluidine blue, ×500)

drinking fluid; details of this allylamine protocol have been previously described.[9] Allylamine was consumed for 10–17 days (7 rats), 21–28 days (7 rats), or 90–104 days (6 rats); 6 age-matched control rats were given plain tap water and were killed concurrently with experimental rats. As previously described,[1] rats were anesthetized and sacrificed by perfusion of the heart for 10 minutes with 2% glutaraldehyde in 0.1 M cacodylate buffer (430 mOsm). Grossly evident lesions, consisting of patchy white scars over the ventricles were graded on a severity scale of 1–4 as follows: grade 0, no gross lesions; grade 1, small patches of white scar tissue evident over ventricles; grade 2, multiple scarred areas; grade 3, multiple scarred areas, focally transmural; grade 4, bulging ventricular aneurysm evident.

Hearts were cut transversely into slices of 1–2 mm in thickness and allowed to remain in fixative for 1 hour. Slices were either cut into small 1-mm blocks or processed whole; selected blocks were cut with a jeweler's saw and flat-embedded. Tissue blocks (10–20 per rat) were selected predominantly from areas of myocardium with grossly evident scarring or from firm, white endocardial plaques. Hence, the apex and subendocardial left ventricle were most frequently sampled because these areas show the most extensive gross changes in allylamine-induced cardiomyopathy.[9,10] Tissue was postfixed in 1% osmium tetroxide, dehydrated, and embedded in Epon. One-micron-thick sections of all blocks were cut and stained with toluidene blue for study of the morphologic alterations; selected areas (2–6 blocks per experimental rat; 1 block for each control) were thin-sectioned for electron microscopy, stained with lead citrate and uranyl acetate, and observed in either a Philips EM 200 or a JEOL 100B electron microscope. Selected thin sections were stained by the electron-microscopic elastic tissue technique of Kajikawa et al.[11]

Additional hearts from 11 rats consuming allylamine for 21 or 104 days were fixed in 10% neutral buffered formalin, cut perpendicular to their long axis into 5–8 slices, and routinely dehydrated and embedded in paraffin. Sections were cut and stained by Masson's trichrome and Verhoeff-van Gieson elastic tissue techniques for assessment of scarred areas of myocardium. Also, for gross photography, the left ventricular free wall was dissected free from a heart which displayed characteristic scarring in a separate rat that consumed allylamine for 90 days.

Results

Evolving Necrosis

Areas of acute myocardial necrosis undergoing organization were characterized grossly by thinned, pur-

Figure 3—Left-ventricular free wall shows transmural scarring with markedly thinned ventricular wall (aneurysm) and a firm, white, glistening endocardial surface with a procelain-like appearance; such areas frequently contain abundant elastin and cartilaginous and osseous metaplasia. This and all subsequent micrographs are from rats consuming allylamine for 90 days. (Formalin fixation, ×12)

plish areas of myocardium and were seen in rats given allylamine for 10–17 days. By light and electron microscopy these areas consisted of remnants of necrotic myocytes associated with an inflammatory infiltrate of macrophages with scattered polymorphonuclear leukocytes, interstitial cells frequently undergoing mitosis, and prominent capillaries (Figures 1 and 2). A layer of myocytes, 2–5 cells thick, was generally spared in the immediate subendocardium and subepicardium in areas with transmural involvement (Figure 1). Individual myocytes and small groups of myocytes were occasionally noted to be undergoing acute myocardial necrosis at all times examined; necrosis was of the myofibrillar degeneration and contraction band type, as previously detailed.[1]

Mural Scarring

Rats given allylamine for 21–28 or 90–104 days showed grossly evident myocardial scarring which involved the left ventricular apex, free wall, and interventricular septum most frequently, but also was noted in the right ventricle. Scars were characterized by thinning of the ventricular wall with replacement of myo-

cardium by firm, white tissue; marked thinning of the apex resulted in apparent ventricular aneurysms. In transmural lesions, the adjacent endocardium was often white, firm, thickened, and glistening, with a "porcelain" appearance (Figure 3). The mean lesion grades for the three groups of rats were: 0.7 for 10–17 days of allylamine consumption (incidence, 2/7); 1.3 for 21–28 days (incidence, 4/7); and 3.0 for 90–104 days (incidence, 6/6). These gross lesion grades and the incidence of lesions following chronic allylamine administration are consistent with the degree of myocardial scarring observed and graded microscopially in our previous study.[9]

Light- and electron-microscopic study of scarred areas revealed predominantly dense mature collagen with scattered fibroblasts and capillaries. Occasional areas of scar were highly cellular; the cells in these areas contained irregularly shaped nuclei, prominent rough-surfaced endoplasmic reticulum, rare mitochondria, peripheral dense bodies similar to those seen in smooth-muscle cells,[12] bundles of thin filaments, prominent microtubules, and markedly irregular cell borders (Figures 4–6).

The intercellular matrix of these cellular areas was composed of mature collagen and occasional microfibrils associated with dense amorphous material consistent with elastin (Figures 5 and 7). Special staining of this material both in light- and electron-microscopic[11] preparations confirmed its identity as elastin (Figure 8).

Within areas of dense scar, occasional cardiac myocytes were completely surrounded by dense collagen. These myocytes were extemely degenerated, with markedly disoriented sarcomeres, distorted and condensed mitochondria, and fragments of intracellular desmosomes; intra- and extracellular spherical microparticles[13] were also present (Figures 9 and 10).

Small Vessel Alterations

Within and adjacent to scarred areas, small vessels with internal diameters of 15–30 μ displayed a promi-

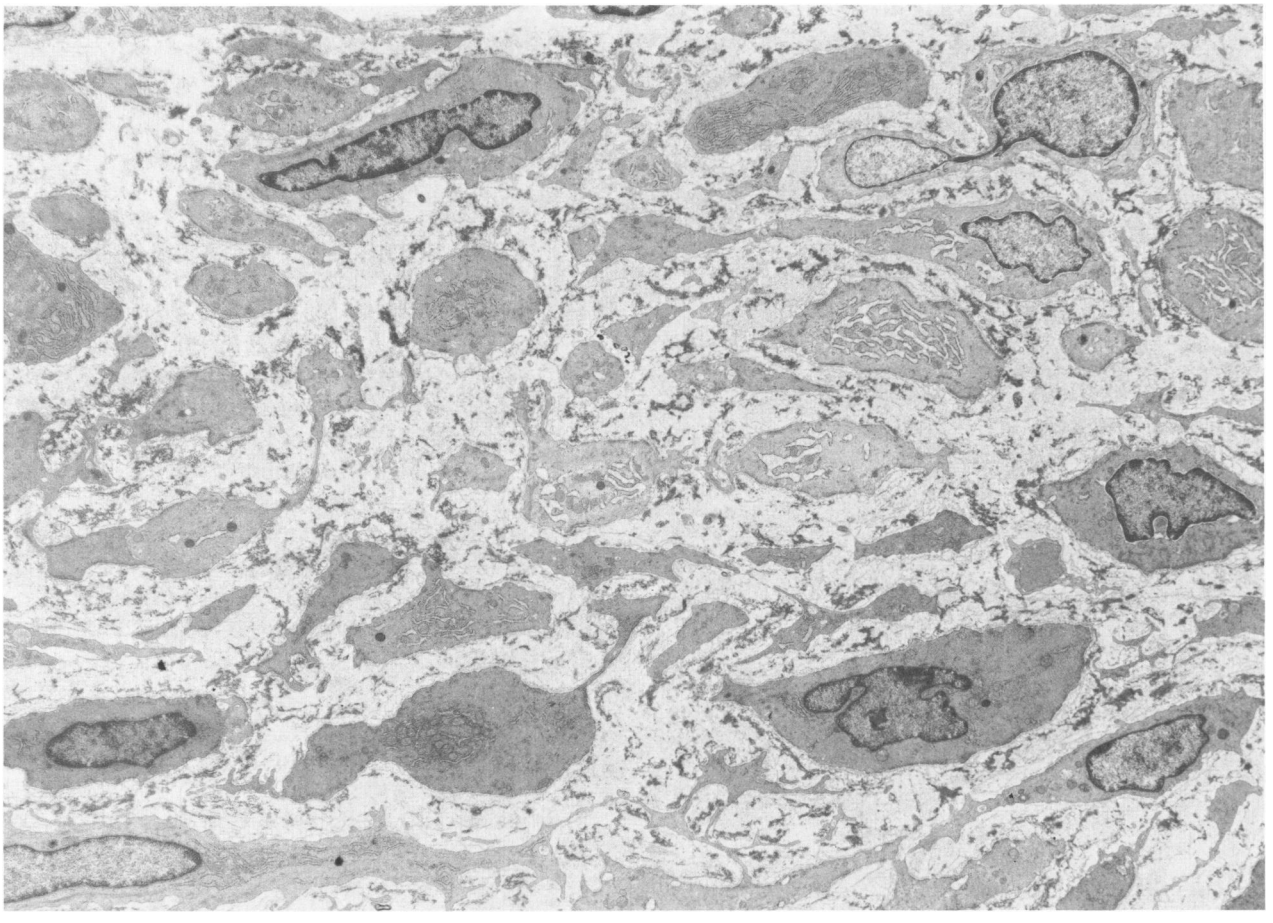

Figure 4—Low-power electron micrograph of a highly cellular area of scar containing numerous cells with irregularly shaped nuclei, irregular cell borders, abundant rough endoplasmic reticulum, and interstitium containing scattered patches of electron-dense elastin (see Figure 5). (×4400)

nent proliferation of cells between the vascular internal elastic lamina and the endothelial cells (Figure 11). The proliferating cells were smooth-muscle cells, as evidenced by peripheral dense bodies and prominent bundles of actinlike microfilaments. Endothelial cells remained intact, and no evidence of small-vessel thrombi was noted. Capillaries, small veins, and venules showed no lesions.

Endocardial Metaplasia

In areas of transmural fibrosis, focal endocardial cartilaginous and osseous metaplasia was found in two of the 6 animals receiving allylamine for 90–104 days (Figure 12). The metaplastic tissue was located near the endocardial surface, in strands of tissue which probably represented trabeculae carneae cordis of the left ventricle. Metaplasia was most frequently found in the left-ventricular endocardium but was also found in the right-ventricular endocardium.

The metaplastic cartilaginous areas were highly cellular. The chondrocytes in these areas (Figure 13) had uniform, oval or round nuclei and abundant rough endoplasmic reticulum and free ribosomes and were surrounded by lacunae containing microfibrils averaging 80 Å in diameter and scattered spicules that probably represented proteoglycan material. The intercellular matrix between chondrocytes consisted predominantly of dense collagen and scattered proteoglycan spicules. These features are ultrastructurally characteristic of fibrocartilage, rather than true hyaline cartilage.[14] In many areas, the collagen fibers within the matrix were undergoing calcification with a cross-banded pattern characteristic of calcifying connective tissue (Figures 14–16).

Areas of osseous metaplasia were characterized by osteocytes (Figure 17) which were morphologically similar to the chondrocytes but were located in lacunae surrounded by circular lamellae of densely calcified bone matrix. Canaliculi extended radially from the lacu-

nae and long, thin cellular extensions of the osteocytes were occasionally seen within canaliculi.

Discussion

Allylamine consumption causes progressive acute myocardial necrosis of areas which may vary in size from focal, individual cells to broader groups of myocytes. Therefore, at the earlier times examined in the present study (10–21 days), the major morphologic findings reflect organization of necrotic areas, predominantly in the subendocardium of the left ventricle. The progression of allylamine-induced myocardial injury results in extensive scarring which may resemble that seen in human left vetricular aneurysms.[2,3,9,10]

Microscopic scarring begins early in the course of allylamine-induced cardiac damage; in our previous study[9] we noted focal fibroblastic activity and fibrous tissue formation as early as 6 days after the start of allylamine consumption. By 21 days of consumption, the majority of rats in the present study showed grossly evident myocardial scarring. More prolonged consumption results in cumulatively greater scarring, as evidenced by progression of severity over a 36-day period in a previous study,[9] and by the continued occurrence of focal areas of myocardial necrosis and proliferation of fibroblasts throughout the entire period of consumption in the present study. The most noteworthy ultrastructural aspects of chronic allylamine-induced cardiac injury include 1) the extremely proliferative and fibroelastic nature of the mural scar; 2) the intimal proliferation of smooth-muscle cells in small myocardial arteries, and 3) the bizarre cartilaginous and osseous metaplasia observed in endocardium.

Nature of the Mural Scar

The major component of the scars observed in this study was dense, mature collagen. Focal areas of extensive elastin formation were also present. The proliferating cells observed within scars appeared to have many characteristics of both smooth-muscle cells and fibro-

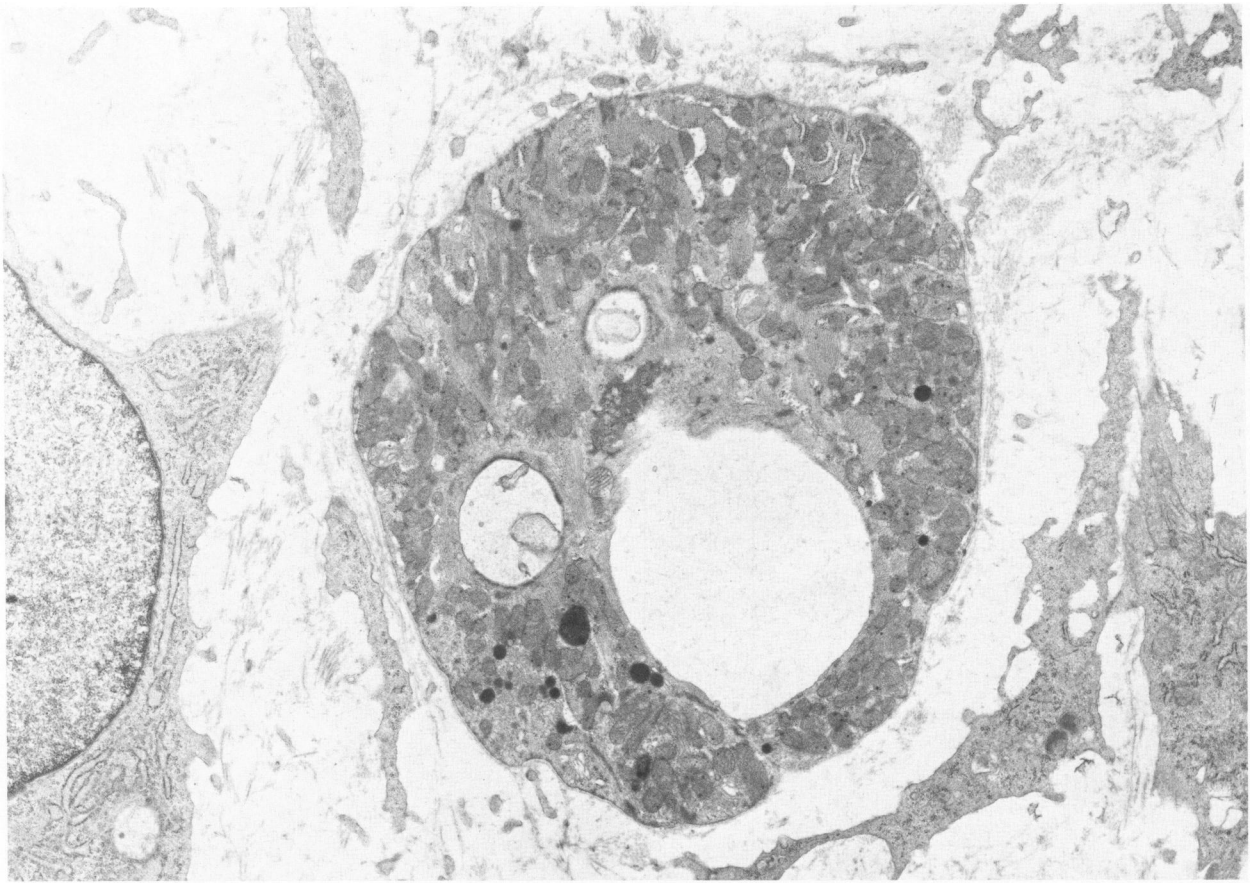

Figure 9—A markedly degenerated myocyte embedded in dense myocardial scar shows extremely deranged sarcomeres, and distorted, condensed mitochondria (see Figure 10). (×9580)

blasts, and therefore may be considered myofibroblasts.[15] These cells contain bundles of packed myofilaments resembling those found in smooth muscle.[12] These filaments may be related to a contractile function found in wound granulation tissue,[15-19] in the nodules of fibrous tissue involving the palmar aponeurosis in Dupuytren's contracture,[20] in the fibrous reaction to silicone prostheses,[21,22] and in the arterial media of human dysplastic renal arteries.[23] Cells in these diverse fibrotic conditions, and those found in the myocardial scars in the present study, also have convoluted nuclei with many folds and indentations, subsarcolemmal electron-dense areas which are characteristic of smooth-muscle cells,[19] microtubules,[24] and extracellular basement membrane material near the sarcolemma. A similar morphologic spectrum of cells, varying from fibroblasts to myofibroblasts and smooth-muscle cells, also has been described in the thickened endocardium found in human endocardial fibroelastosis.[25,26]

In our study, myofibroblasts were found in areas of collagen and elastin production, and the presence of scattered rough endoplasmic reticulum within these cells suggests that they are actively synthesizing the surrounding matrix. Smooth-muscle cells have been shown to produce both collagen and elastin in culture,[27,28] and although most reports concerning myofibroblasts do not associate them with elastin, it seems reasonable to assume that they are capable of elastin production.[15]

Another finding of this study is the gross (Figure 3) and microscopic similarity to endocardial fibroelastosis exhibited by the severely scarred hearts of allylamine-treated rats. Endocardial fibroelastosis occurs in a primary form[29,30] and in a secondary form which may be associated with a variety of congenital cardiac anomalies (see Schryer and Karnauchow[31] for a review). Endocardial fibroelastosis also can be secondary to a variety of pathologic processes which result in endomyocardial injury, including ischemic injury.[29,32]

Morphologically, both forms of endocardial fibroelastosis are characterized by diffuse thickening of the left ventricular endocardium by firm white tissue. In the primary form the elastic fibers are thick and large

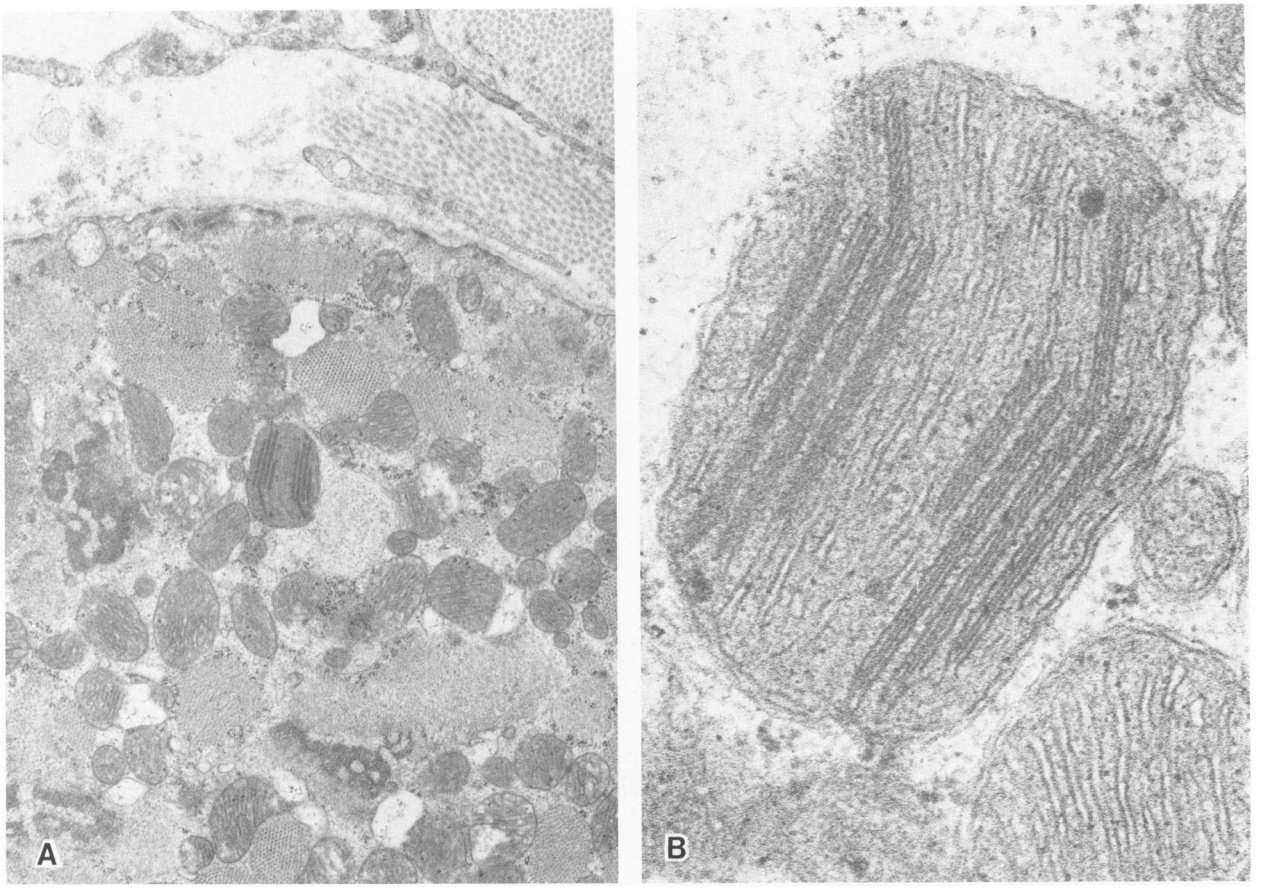

Figure 10A—A markedly degenerated myocyte shows markedly abnormal, condensed mitochondria of variable size and shape. (×12,000) **B**—High-power view of the abnormal mitochondrion seen in **A** shows cristae condensed into platelike membranous structures with a spiraling arrangement. (×75,000)

(1–2 μ in diameter), while in the secondary form they are smaller and less well oriented.[27] The small, irregularly arranged elastic fibers in the transmural scars induced by allylamine consumption (see Figures 4 and 8) are similar to those in the secondary form of endocardial fibroelastosis.

Many causes have been postulated for the development of endocardial fibroelastosis,[29,30,33] but in allylamine cardiotoxicity it seems likely that elastic tissue formation is a reactive phenomenon occurring in severely damaged, scarred areas in response to abnormal wall tension, hypoxia, or to late toxic effects of the chemical itself or its metabolites.

Small Vessel Alterations

In this study, we observed proliferation of smooth-muscle cells within the intima of small myocardial arteries. These vessels, which varied from 10 to 30 μ, correspond to small terminal arterioles or precapillary sphincters.[34] Previous studies of allylamine intoxication have described similar proliferative lesions in the larger coronary arteries[5–8] and also other systemic arteries[35] of the rat. Although other authors have suggested that these obstructive lesions may cause ischemia and, hence, may result in allylamine-induced myocardial necrosis, our previous light-microscopic studies[9,10] have shown that arterial lesions do not begin to occur until 21 days of allylamine consumption, when cardiac necrosis and scarring are already well established.

Obstructive small vessel lesions which are morphologically similar to those described in this study have been shown to occur in humans with hypertrophic cardiomyopathy,[36] scleroderma,[37] Friedreich's ataxia,[38,39] juvenile diabetes mellitus,[40] and in the cardiomyopathy of adult Africans in Rhodesia.[41] Morphologically similar proliferations of smooth-muscle cells have been experimentally induced in larger arteries by a variety of traumatic techniques[42–44]; such lesions also occur spontaneously in the chicken[45] and steelhead trout.[46] Few, if any, ultrastructural studies have been made of smooth-muscle cell proliferation in these pathologic sit-

uations, and the reasons for intimal smooth-muscle proliferation in those diverse experimental and natural situations are unknown.

Allylamine has been known to be a potent vascular toxin for many years, and a variety of investigators have used its toxicity to study vascular injury. Mellon et al,[47] in 1935, concluded that allylamine given intradermally caused a necrotizing arteriolitis which was independent of pH and seemed to initially affect the vascular wall. Their photomicrographs show extensive medial necrosis. Subsequent histochemical and biochemical studies of aortic and coronary arterial wall have demonstrated an allylamine-induced increase in glycogen,[48,49] accumulation of PAS-positive material presumed to be heterogeneous polysaccharides,[49] and alterations in phosphomonoesterase and dehydrogenase enzymes.[50] In addition, allylamine administered intravenously has been shown to be extremely toxic to endothelial cells, presumably causing rupture of the plasmalemma.[51] Recent *in vitro* studies[52,53] have shown that allylamine is actively metabolized to an extremely toxic aldehyde, acrolein, by cardiovascular tissues, especially by aorta and coronary arteries. Although the cellular localization of this metabolic process is unknown, we suspect that vascular smooth muscle may be involved. It seems reasonable to hypothesize that the toxin itself or its metabolite—acrolein—may have a toxic, stimulatory effect on smooth-muscle cells, resulting in the proliferation of these cells in certain vessels.

Endocardial Metaplasia

Hyaline cartilage occurs normally in the aortic ring in mammals and reptiles.[54–56] Aortic and mitral valve structures may undergo cartilaginous and bony metaplasia following degeneration secondary to chronic endocarditis with valvular aneurysm in the dog[57] or severe valvular stenosis with calcification and deposition of atherosclerotic material in the human,[58] as has been the personal observation of the author, Paul J. Boor. Metaplastic cartilage also occurs in the heart at sites of chronically implanted intravenous pacemakers[59] and

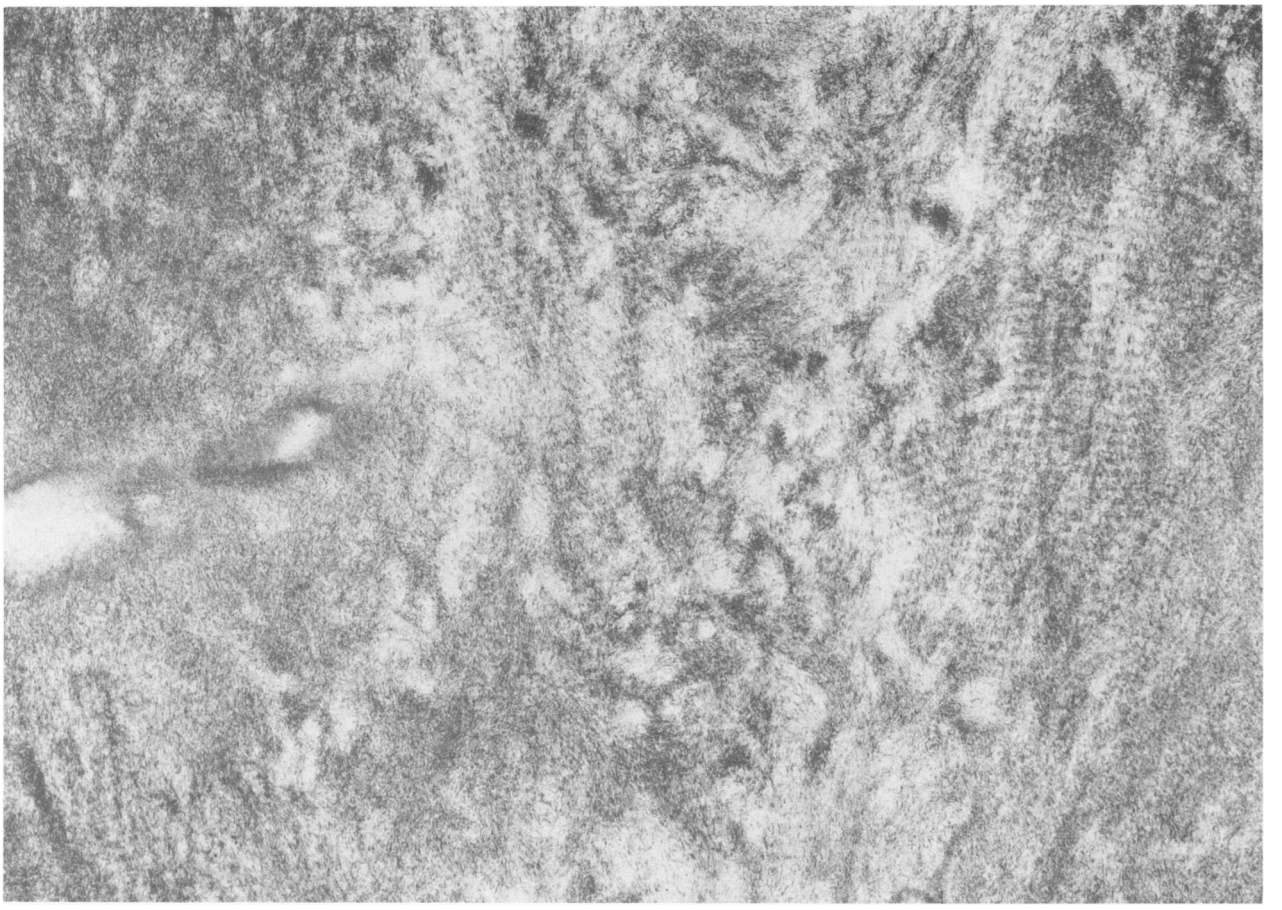

Figure 16—A high-power view of calcifying metaplastic tissue shows a cross-banded pattern with periodicity (~640 Å) characteristic of calcifying collagenous matrix. (×60,000)

automatic defibrillator leads,[60,61] in organizing atrial thrombi in the syndrome of arterial thrombosis in aging rodents,[62] and in the thickened endocardium of cats with restrictive cardiomyopathy.[63]

The metaplastic tissue which we observed beginning in rats after 21 days of allylamine consumption had the ultrastructural appearance of fibrocartilage, calcifying cartilage and connective tissue, and mature bone.[14] These metaplastic tissues were always found in endocardial trabeculae carneae near areas of extensive transmural myocardial scarring or ventricular aneurysms. It is unlikely that the cartilage observed actually formed in organized mural thrombi, because thrombi in this location were very rarely found in our previous study.[10]

The lesions in our model of allylamine-induced myocardial necrosis bear many similarities to the isoproterenol-induced lesions described by Rona and Kahn,[64] including not only the endocardial metaplasia, but also the inflammatory component of the necrosis and the exuberant proliferation in the scar. Rona and Kahn observed dense scar formation beginning at 8–12 weeks after isoproterenol administration but noted cartilaginous and bony metaplasia in the walls of ventricular aneurysms only after very prolonged periods (16 and 32 weeks). The metaplastic tissue observed in their study was apparently localized in endocardial structures—as was that described in our study—and they considered the metaplastic bony lamellae to be growing parallel to the endocardial surface.

Bone and cartilage have been induced experimentally in a variety of extraosseous sites by the implantation of devitalized tissues,[65] extracts of bone,[66] and formaldehyde injection.[59] Experimental aortic injury due to grafts or sutures results in cartilaginous metaplasia.[67] Rodbard suggested that abnormal mechanical properties, such as increased stiffness, resulted in aortic chondroid metaplasia[68]; still other workers have hypothesized a soluble chondrogenic factor.[69] McCandless and co-workers[70] induced cartilage formation in chicken aorta and myocardium by injections of the sulfated polysaccharide, carrageenan. Metaplastic changes have not been noted in experimental models of cardiac isch-

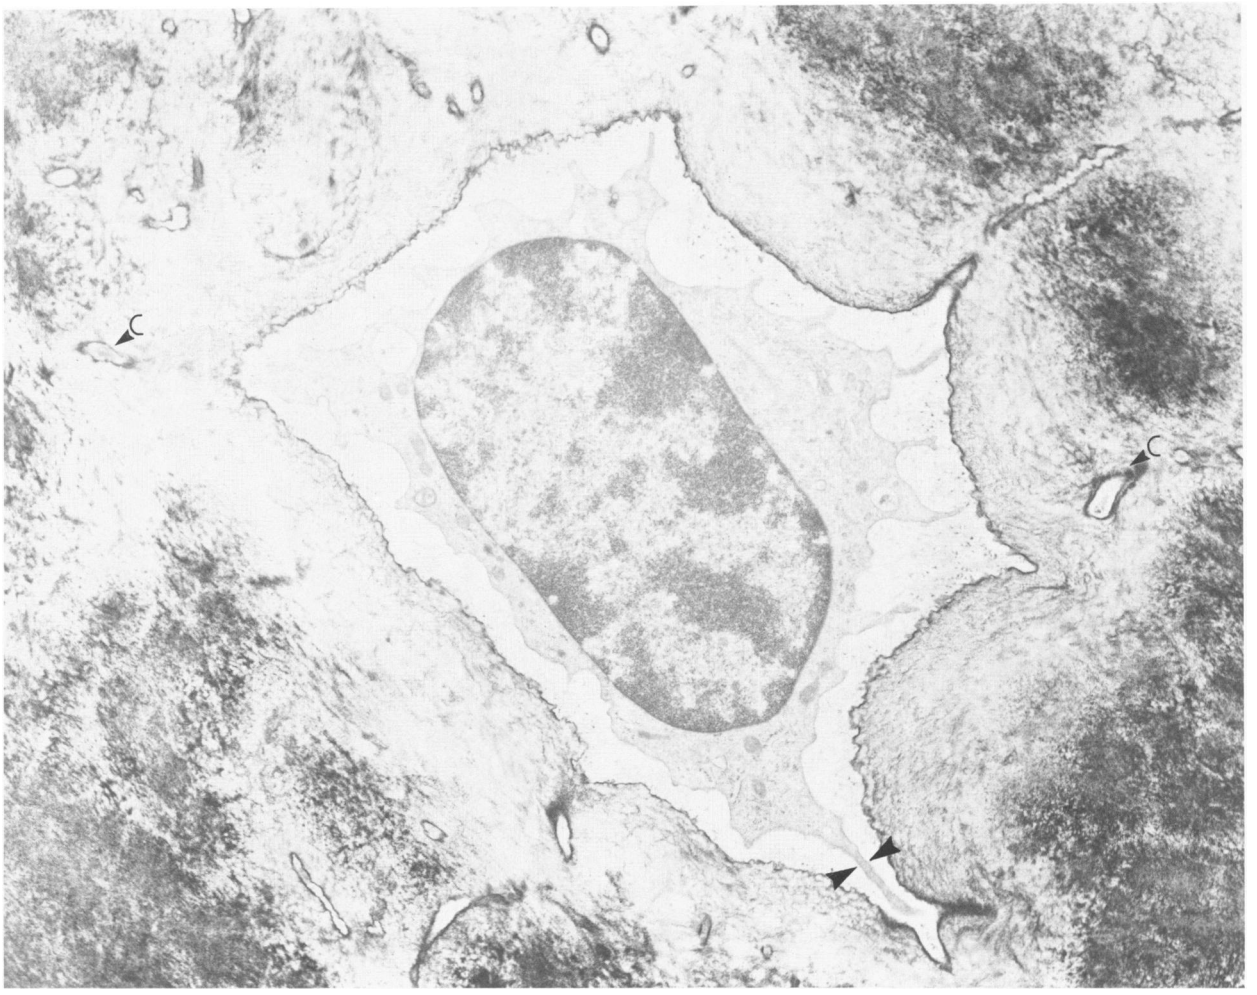

Figure 17—Within subendocardial metaplastic tissue, a mature osteocyte is surrounded by a lacunar space and dense, calcified bone matrix. Note numerous canaliculi (*C*) and a cytoplasmic process (*arrowheads*) extending toward a canaliculus. (×13,800)

emia[49,64,71]; however, Lehoczky-Mona and McCandless[72] found that prior coronary ligation increased the incidence of carrageenan-induced cartilage in myocardium, suggesting that tissue hypoxia can modulate myocardial chondrogenesis.

The concept that tissue ischemia or hypoxia favors cartilaginous or bony metaplasia is supported by recent studies of the initiating factors of tissue calcification in the epiphyseal growth plate. As proliferating chondrocytes begin to form calcified matrix along the normal growth plate, they release cellular calcium and phosphate ions.[73,74] The source of these ions is believed to be the chondrocyte mitochondria,[75] which have concentrated ions in the premineralized area of chondrocytes, and the stimulus for ion release is hypothesized to be low oxygen tension in the tissue[76] and a shift in the NADH/NAD^+ ratio to the reduced state.[77] Hence, localized anoxia and the consequent shift in tissue redox state may also favor formation of calcified cartilage and bone in certain damaged, anoxic soft tissues such as aorta. In fact, the concept that bone and cartilage formation is favored in areas of anoxia and poor vascular flow dates back to 1930, when Ham, in his study of fracture repair,[78] concluded that cartilage formation was favored in areas of ischemia.

No clear explanation is evident for the endocardial metaplasia that we have observed in allylamine-induced cardiomyopathy in the present study. It seems likely that an unknown combination of metabolic factors may result in the propensity of the endocardium to undergo metaplasia in this experimental model of allylamine-induced cardiomyopathy, as well as in the cardiac injury caused by large doses of isoproterenol.[64]

In conclusion, the ultrastructural features of chronic allylamine-induced cardiac lesions include 1) a dense collagenous scar with many active myofibroblasts, 2) areas of elastin formation with features resembling those in the secondary form of endocardial fibroelasto-

sis, 3) intimal proliferation of smooth-muscle cells in small intramyocardial arterioles and arteries, and 4) bizarre endocardial cartilaginous and bony metaplasia. Although there is no one unifying cause which can explain this variety of lesions, they clearly indicate severe chronic myocardial and endocardial injury during the course of long-term allylamine intoxication.

Acknowledgments

We are grateful for the technical assistance of Mr. Thomas J. Nelson, the secretarial assistance of Ms. Pam McBride and Ms. Avis Morgan, and the inspiration and guidance given by the late Dr. Edward S. Reynolds.
