Abstract

Although primary and memory responses against bacteria and viruses have been studied extensively, T helper type 2 (T_H2) effector mechanisms leading to host protection against helminthic parasites remain elusive¹. Examination of the intestinal epithelial submucosa of mice after primary and secondary infections by a natural gastrointestinal parasite revealed a distinct immune-cell infiltrate after challenge, featuring interleukin-4–expressing memory CD4⁺ T cells that induced IL-4 receptor^{hi} (IL-4R^{hi}) CD206⁺ alternatively activated macrophages². In turn, these alternatively activated macrophages (AAMacs) functioned as important effector cells of the protective memory response contributing to parasite elimination, demonstrating a previously unknown mechanism for host protection against intestinal helminths.

Productive adaptive immune responses result in CD4⁺ T-cell polarization into effector phenotypes defined by differing cytokine milieus³. Helminth parasites and allergens induce T_H2 responses, including CD4⁺ T-cell interleukin (IL)-4 production promoting arginase-1 expression by alternatively activated macrophages (AAMacs)⁴. Although it is known that these AAMacs accumulate during asthmatic inflammation⁵ and helminth parasite infections^{2,4,6,7}, and downregulate type 1 inflammation^{2,4,6}, a protective role for them remains undefined.

Infection of mice with the natural mouse gastrointestinal helminth parasite *Heligmosomoides polygyrus* triggers a highly polarized T_H2 response¹. *H. polygyrus* infection is chronic with established adult worms; if parasites are cleared from the host's intestinal lumen, a rapid, protective T_H2 memory response operates against challenge infections⁸. Our studies examined early events in this memory response to *H. polygyrus* larvae developing in the intestinal submucosa and indicated that AAMacs have an important role in parasite expulsion.

H. polygyrus progresses through distinct environmental niches during infection (Supplementary Fig. 1 online), with tissue-invading larvae developing into adults and migrating into the lumen at day 8 after inoculation (Supplementary Fig. 1). To examine which stages of the protective memory response required CD4⁺ T cells, we administered CD4-specific antibody to mice to deplete CD4⁺ cells at specific intervals after secondary infection (Fig. 1a). Administration at early time points (days 0 and 7) resulted in increased worm burden (Fig. 1b), day 7 treatment had intermediate effects, and later treatments (days 9 or 11) had marginal effects, indicating that CD4⁺ T cells are required at early stages of a secondary infection for effective parasite expulsion. This implicated the adaptive immune response during larval development in the intestinal tissue as crucial for host protection. To further confirm that the memory response affects invasive larvae, we recovered muscularis-residing larvae from infected small intestines by using a Baermann apparatus⁹, which provokes premature larval evacuation of the tissue, as an indicator of health and mobility. Significantly fewer larvae were recovered from the tissues of mice with secondary infections than from those with primary infections (**P* < 0.001, Fig. 1c).

Previous studies described a distinct immune cell architecture and increased CD4-dependent T_H2 cytokine gene expression at the host-parasite interface, with Gr-1⁺ neutrophils accumulating adjacent to the parasite surrounded by a band of CD4⁺ T cells, and increased CD4-dependent T_H2 cytokine gene expression observed as early as 4 d after challenge but not primary inoculation (Fig. 1d)^{10,11}. These localized immune cells represent a fraction of the diverse immune cell phenotypes in the intestine, necessitating further analyses of the host-parasite interface through the combined use of immunofluorescence and laser-capture microdissection (IF-LCM). Increased mRNA encoding IL-4 and IL-13 (but not interferon (IFN)- γ) were detected in CD4⁺ and Gr-1⁺ populations (Fig. 1e and data not shown). We developed a new approach as described in Methods, for direct detection of IL-4 protein *in situ* and showed its expression within the band of CD4⁺ T cells 4 d after challenge (Fig. 1f). Isotype control antibodies showed minimal nonspecific staining (Fig. 1g); IL-4 protein was not detected at the host-parasite interface 4 d after primary infection, nor was it detected in challenged IL-4-deficient (*Il4*^{-/-}) mice or untreated tissues (data not shown). This implies that memory CD4⁺ T cells secrete IL-4 protein at the host-parasite interface, although it is possible that other leukocytes also express IL-4 in a CD4-dependent manner, as in *Nippostrongylus brasiliensis* infection¹².

Although IL-4R α ^{hi} cells surrounding developing *H. polygyrus* larvae 4 d after challenge did not express a variety of leukocyte markers (Fig. 1d and data not shown), infiltrating macrophages (Fig. 1h,i) upregulated the IL-4R α chain, a required component of IL-4Rs (Fig. 1h) and the mannose receptor (CD206; Fig. 1i), characteristic of AAMacs². CD4⁺ T cells (Fig. 2a), IL-4R α , macrophages and CD206 (Fig. 2b) at the interface 4 d after primary infection were markedly reduced. Similar results were observed in C57BL/6 mice (data not shown), indicating that these findings were not strain specific. Decreases in AAMacs were also observed in challenged *Il4*^{-/-} (Supplementary Fig. 2 online) and CD4-depleted mice (Supplementary Fig. 2), indicating that IL-4 and memory CD4⁺ T cells were required for the *in vivo* accumulation of AAMacs. F4/80⁺ macrophages 4 d after challenge showed elevated expression of arginase-1 (Fig. 2c), Fizz1 (Fig. 2c) Ym1 and acidic mammalian chitinase (AMCase) and no detectable inducible nitric oxide synthase (iNOS; Fig. 2c), further confirming their alternatively activated state.

To examine whether IL-4R signaling triggered alternative macrophage activation *in vivo*, we transferred CD4⁺ T cells from *H. polygyrus*-cured mice to naive wild-type or *Stat6*^{-/-} (IL-4R defective) recipients. Four days after inoculation, both wild-type and *Stat6*^{-/-} recipients showed similar Gr-1⁺ neutrophil and CD4⁺ T cell infiltrates at the host-parasite interface (Fig. 2d,f). At day 4 after infection, macrophages in wild-type, but not *Stat6*^{-/-}, recipients showed marked

upregulation of CD206, as indicated by the yellow cell population (Fig. 2e,g), and had lower parasite and egg burdens (Supplementary Fig. 3 online), as compared to wild type. Arginase-1 expression results in proline production, fibroblast recruitment and subsequent collagen deposition, which are characteristics of T_{H2} inflammation¹³. Collagen deposition was detected at 12 d, but not 4 d, after challenge (Supplementary Fig. 4 online), consistent with inflammation mediated by AAMacs in this microenvironment.

To examine directly whether macrophages mediate protective immunity, we depleted them *in vivo* by treating mice with clodronate(Cl₂MDP)-loaded liposomes¹⁴. Effective worm expulsion was observed in *H. polygyrus*-challenged mice treated with control PBS-loaded liposomes but not in those treated with Cl₂MDP-loaded liposomes (Fig. 3a); similar results were obtained in BL/6 mice (data not shown). Notably, egg burdens remained decreased in Cl₂MDP liposome-treated mice. Challenged mice treated with PBS liposomes yielded significantly fewer recoverable larvae, as determined with the Baermann apparatus, than macrophage-depleted mice at days 4 and 7 after infection ($P < 0.01$, Fig. 3b). Examination of the host-parasite interface 4 d after challenge showed that F4/80⁺ macrophages were selectively depleted from Cl₂MDP liposome-treated mice (Fig. 3c–f) and that other infiltrating leukocytes were unaffected by either treatment. No significant changes in cytokine gene expression were detected in the draining mesenteric lymph nodes or proximal small intestines of challenged mice receiving either liposome treatment (Fig. 3g), indicating that CD4⁺ T cells were appropriately activated.

To further confirm a role for AAMacs in host protection, we administered an arginase inhibitor, *S*-(2-boronoethyl)-l-cysteine (BEC)¹⁵, to the challenged mice, yielding high parasite burdens, reduced egg burdens at day 14 (Fig. 4a) and enhanced larval recovery at both 4 and 7 d after challenge (Fig. 4b). To examine the effect of arginase on the parasites directly *in situ*, we stained parasite cross-sections for cytochrome oxidase (COX) activity, which has been used as an indicator of stress¹⁶ and observed in several helminths^{17,18}. COX staining was markedly increased 7 d after challenge as compared to that in mice with primary infection or in challenged mice administered BEC (Fig. 4c–f).

Macrophages are usually associated with responses against intracellular pathogens, as their activation via Toll-like receptors and IFN- γ results in iNOS expression and microbicidal NO production^{19,20}. Exposure to type 2 cytokines promotes arginase-1 expression and production of polyamines and proline, essential for cellular proliferation and collagen production, respectively^{19,21}. Protective arginase-1 expression has not been described in infectious diseases; previous studies have shown that arginase blockade *in vivo* promotes intracellular parasite killing by enhancing classical macrophage activation, increasing iNOS activity^{15, 21,22}. Our studies show that arginase also mediates host protective responses, in this case against intestinal nematode parasites. Taken together with the macrophage depletion studies, this indicates that—as in T_{H1} responses—macrophages activated by CD4⁺ T cells, are an essential effector population in protective T_{H2} responses, and their accumulation during the secondary response is required for parasite clearance, thus providing an evolutionary role for their alternatively activated state. AAMacs have also been found to be protective in schistosomiasis through a quite distinct mechanism, reducing pathology through downregulation of a harmful T_{H1} inflammatory response⁶.

Mechanisms contributing to helminth parasite clearance have remained elusive, although studies have suggested that T_{H2} responses enhance gut contractility and luminal fluid secretion, leading to worm expulsion^{23–25}. Also, increased gut epithelial cell turnover promotes expulsion of *Trichuris muris*²⁶, and increased mastocytosis is associated with helminth trickle infection^{27,28}. These mechanisms may also be important for *H. polygyrus*, which passes through multiple sites during the course of infection, as the remaining adult parasites in

challenged mice depleted of macrophages or treated with BEC showed reduced fecundity, suggesting that additional macrophage-independent mechanisms remained intact. Collagen was detected only at later stages of the response, and thus is unlikely to be protective. Although chitinases have been proposed as potential effector molecules in resistance to other parasites²⁹, they are probably not important in this system, as neither larval nor adult stages express chitin. Future studies should examine the arginase-dependent protective mechanisms, including potential anti-parasitic factors produced by AAMacs, such as urea and superoxide radicals²².

The studies described here suggest a new model for the development of a protective T_H2 memory response. Memory CD4⁺ T cells rapidly accumulate at the host-parasite interface and secrete IL-4, inducing localized development of AAMacs recruited to this site. These macrophages impair larval parasite health and mobility through an arginase-dependent pathway, contributing to eventual expulsion of adult worms. These findings could provide insights into protective mechanisms against human tissue-dwelling nematodes that may trigger polarized type 2 inflammation associated with AAMacs, including hepatic *Ascaris lumbricoides*, lymphatic *Filaria (Brugia malayi)*, *Trichuris trichiura* and *Anisakis simplex*.

Methods

Mice, parasites and injections

Female BALB/c (Small Animal Division, National Cancer Institute–Frederick), *Il4*^{-/-} and *Stat6*^{-/-} mice (Jackson Laboratories) were kept under specific pathogen-free conditions in filter top cages in the animal facility at the Beltsville Human Nutrition Research Center, Agricultural Research Service, US Department of Agriculture, and experiments were performed under the principles set forth in the Guide for the Care and Use of Laboratory Animals, Institute of Animal Resources, National Research Council, Department of Health, Education and Welfare (US National Institutes of Health). We inoculated 200 infective third-stage *H. polygyrus* larvae orally (1'Hp) into mice as previously described⁸. We treated infected mice with pyrantel pamoate 14 d after inoculation, to clear the parasites, and shelved them for at least 5 weeks, allowing for the development of resting memory cells. We then reinfected mice (2'Hp) or used them as donors for memory CD4⁺ T cells (Hp cured). We treated some mice with 1 mg of antibody to CD4 (GK1.5) or with liposomes, all of which were injected intravenously. We administered liposomes on days 0, 1, 3, 5, 7 and 9. For experiments involving BEC, we gave mice 0.2% BEC in their drinking water on days 2–11 after challenge¹⁵.

Immunohistochemistry

We prepared small-intestine tissue sections using a Swiss roll method¹⁰ and stained them as previously described¹⁰. We used antibodies to the following: Gr-1–FITC, IL-4R α –PE (M1), CD11c–FITC (BD PharMingen), CD4–Alexa647, F4/80–Alexa647 (Caltag), and CD206–FITC (MR5D3; Serotek). We took images ($\times 200$) on a Zeiss Axiovert 200M microscope (Zeiss), controlled by a TILLVISTRAC imaging system (TILLVISION 4.0 software, TILL Photonics). Some images were taken using a Leica DM6000B microscope with automated stage and Leica DFC350FX camera and were tiled together using Image-Pro stitching software (Media Cybernetics). We normalized exposure times and fluorescence intensities to appropriate control images. We photographed fluorescent channels separately, merged them together and overlaid them atop the corresponding Nomarski images.

For IL-4 *in situ* staining, we used 20 $\mu\text{g}/\text{ml}$ of 11B11–Alexa488 (BD PharMingen) and 10 $\mu\text{g}/\text{ml}$ BDV6-24G2–Alexa488 (Caltag) in tandem, and normalized results to serial sections stained with 30 $\mu\text{g}/\text{ml}$ of rat IgG1–Alexa488 isotype control (BD PharMingen). We added two additional wash steps with 0.5% Tween-20 in PBS for this procedure. We performed H&E,

picrosirius red and cytochrome oxidase staining as previously described^{16,21}. Cytochrome oxidase scoring was done by an investigator blinded to the study conditions, by assigning a score of 1–4 (lightest to darkest) to parasite cross-sections.

Immunofluorescent laser capture microdissection (IF-LCM)

We performed IF-LCM with modifications to previously described methods³⁰. Briefly, we stored freshly cut 4- μ m tissue sections on dry ice until use. We fixed sections in 75% ethanol for 30 s, air dried them, washed them in PBS, stained them with antibody cocktail (5 μ g/ml F4/80–Alexa647 or 5 μ g/ml anti-Gr-1–FITC, plus 20 μ g/ml anti-CD4–Alexa647 and 400 units/ml RNasin (Promega)) for 30 s, rinsed them in PBS, incubated them in 75% ethanol for 30 s and 100% ethanol for 30 s, and desiccated them by two 1-min xylene incubations. Slides were dissected using PixCell II and CapSure™ LCM Caps (Arcturus Engineering) or LMD6000 (Leica Microsystems) and dissected samples were analyzed by real-time RT-PCR as previously described. Arginase-1 and iNOS primers and probes were provided by H. Dawson (US Department of Agriculture). Fizz1, Ym1 and AMCcase primers were previously described²¹.

Parasite and egg quantification

For adult parasite burdens, we collected the contents of the small intestines 14 d after infection, and counted parasites using a dissecting microscope. For egg burdens, we collected fecal contents, loosened them in PBS and counted number of eggs under a light microscope. For larval parasite counts, we collected small intestines, opened them longitudinally and incubated them in PBS at 37 °C for 3 h in a Baermann apparatus as previously described⁹. Briefly, intestines collected 4 or 7 d after infection were placed in a sieve suspended atop a pilsner glass, and parasites that collected at the bottom of the glass were counted.

Liposome-mediated macrophage depletion

We administered Cl₂MDP- or control PBS-loaded liposomes (0.2 ml) during macrophage-depletion experiments¹⁴. We generated liposomes as previously described¹⁴ using phosphatidylcholine (LIPOID E PC; Lipoid GmbH) and cholesterol (Sigma). Cl₂MDP was a gift of Roche Diagnostics GmbH. We collected mesenteric lymph node (MLN) and proximal small-intestine samples from liposome-treated mice 7 d after infection, homogenized them in Trizol (Invitrogen) and prepared them for real-time RT-PCR as previously described²⁷.

Cell preparations and adoptive transfers

We isolated CD4⁺ T cells from MLNs of *H. polygyrus*-cured mice as previously described with modifications. We generated single-cell suspensions in RPMI containing 2.5% FCS and washed them multiple times. We enriched CD4⁺ cells using MACS CD4⁺ beads (Miltenyi Biotech); we injected 5 \times 10⁵ cells intravenously into sex- and age-matched recipients, which were infected 2 d after transfer.

Statistical analysis

Statistical analyses were performed using SigmaStat 3.0 (SyStat Software), using Student *t*-tests to compare two groups, ANOVA followed by Tukey *post hoc* test or Kruskal-Wallis test followed by Dunn *post hoc* tests to compare multiple groups.

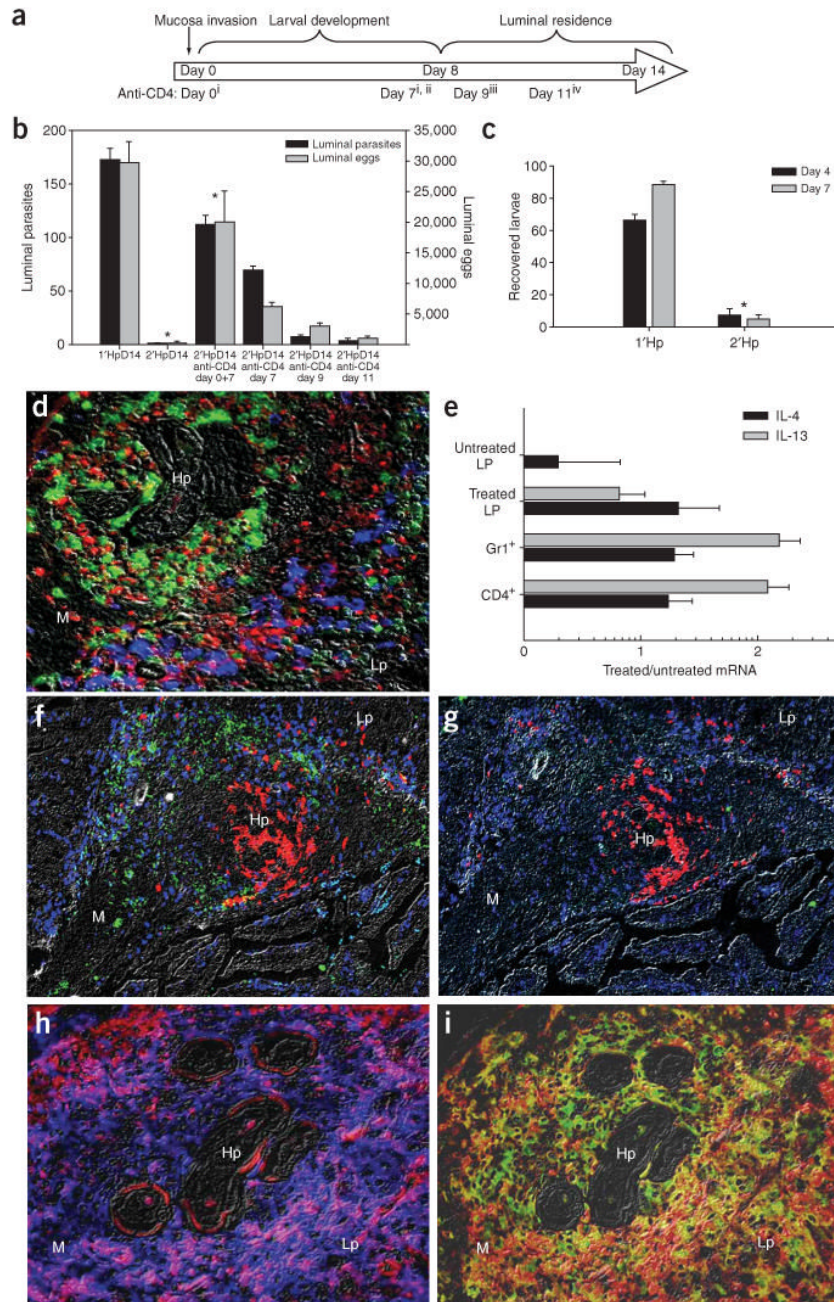

Figure 1. CD4⁺ T cell-dependent protective mechanisms occur at early stages after Hp challenge inoculation. **(a)** Anti-CD4 was administered to challenged mice at days 0 and 7⁽ⁱ⁾, 7⁽ⁱⁱ⁾, 9⁽ⁱⁱⁱ⁾ or 11^(iv) after inoculation. Treatment group number indicated in parentheses. **(b)** Worm and egg burdens determined 14 d after challenge in mice receiving anti-CD4 treatments. Mean and s.e.m. of five mice per treatment group are shown and are representative of three separate experiments. **P* < 0.05 by Kruskal-Wallis test followed by Dunn *post hoc* test. **(c)** Parasite larvae recovered from the small intestines of primed or challenged mice using a Baermann apparatus 4 (black bars) and 7 d (gray bars) after infection. Mean and s.e.m. of four or five mice per treatment group are shown and are representative of three separate experiments. *

$P < 0.001$ by Student *t*-test. **(d)** Fluorescence immunohistochemistry of the host-parasite interface 4 d after challenge, showing IL-4R α^{hi} (red) cells encircling the parasite, Gr-1 $^{+}$ (green) cells accumulating adjacent to the parasite and CD4 $^{+}$ T (blue) cells surrounding both the parasite and the Gr-1 $^{+}$ population (M, muscularis; Lp, lamina propria; Hp, *H. polygyrus*). **(e)** Cytokine mRNA expression levels determined by real-time RT-PCR for CD4 $^{+}$, Gr-1 $^{+}$ and treated lamina propria (CD4 $^{-}$ Gr-1 $^{-}$) samples obtained from the host-parasite interface using IF-LCM. Mean and s.e.m. from five mice per treatment group are plotted on a log scale and are representative of two independent experiments. **(f)** IL-4 protein (green) was detected *in situ* in the region occupied by CD4 $^{+}$ T cells (blue), which surround Gr-1 $^{+}$ neutrophils (red). **(g)** Rat IgG1–Alexa488 isotype control antibody showed minimal nonspecific binding in a serial section of the tissue shown in **f**. **(h)** F4/80 $^{+}$ macrophages (blue) costained for the IL-4R α (red), as demonstrated by the ring of purple cells around the parasite. **(i)** F4/80 $^{+}$ macrophages (red) accumulating at the host-parasite interface expressed CD206 (green), resulting in a yellow-orange stain indicative of their alternatively activated state.

Figure 2.

AAMac accumulation 4 d after *H. polygyrus* challenge is Stat6 dependent. **(a,b)** Four days after primary infection, Gr-1⁺ neutrophils (green) accumulated adjacent to the parasite, with substantially fewer CD4⁺ T cells (blue), IL-4R^{hi} cells (red), F4/80⁺ macrophages **(b)**, red and CD206⁺ cells (green) compared to what is seen after secondary infection (see Fig. 1d). **(c)** F4/80⁺ cells dissected from the host-parasite interface by IF-LCM 4 d after challenge showed gene expression profiles characteristic of AAMacs, including undetectable iNOS (left) and high levels of arginase, Fizz1 (right), Ym1 and AMCase. Mean and s.e.m. of four or five mice per treatment group is plotted on log scales. **(d–g)** CD4⁺ T cells transferred from *H. polygyrus*-primed mice induced alternatively activated macrophages in wild-type **(d,e)** but not *Stat6*^{-/-} recipients **(f,g)**. Gr-1⁺ neutrophils (red) and CD4⁺ T cells (blue) accumulated around the parasite 4 d after infection following adoptive transfer of T_H2 memory cells into wild-type **(d)** and *Stat6*^{-/-} recipients **(f)**. Serial tissue sections show staining for macrophages (F4/80, red) and macrophage mannose receptor (CD206, green), showing that wild-type recipients **(e)** developed alternatively activated macrophages (yellow), whereas *Stat6*^{-/-} recipients **(g)** did not. Lp, lamina propria; m, muscularis; Hp, *H. polygyrus*.

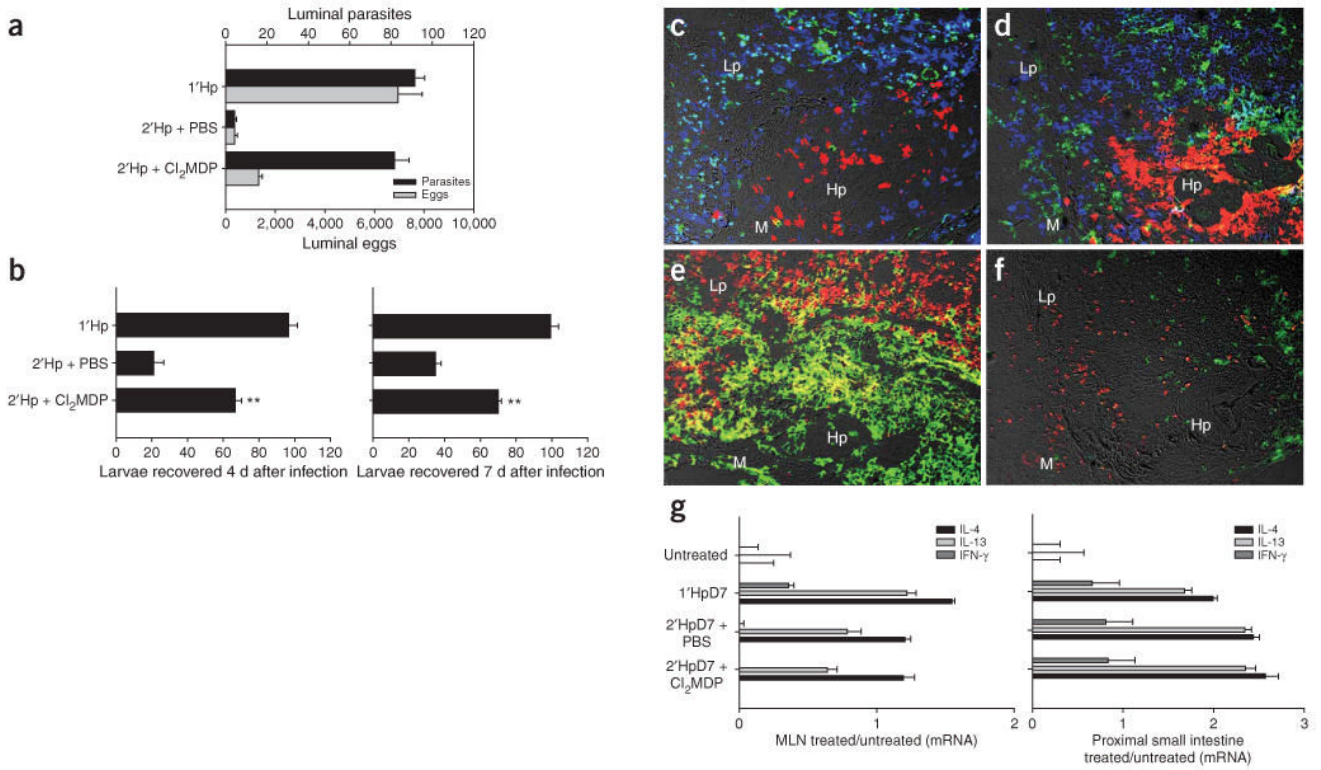

Figure 3. Macrophage depletion abrogates a protective T_H2 memory response. **(a)** Parasite and egg burdens determined 14 d after challenge in mice treated with Cl₂MDP or PBS liposomes. **(b)** Larvae collected using a Baermann apparatus from intestines of challenged mice receiving clodronate or PBS liposome treatment at day 4 and 7 after inoculation. Mean and s.e.m. of five mice per groups are shown; results are representative of three separate experiments. * $P < 0.01$ by ANOVA followed by Tukey *post hoc* test. **(c–f)** Immunofluorescence of the host-parasite interface 4 d after challenge showed that neither clodronate **(d)** nor PBS liposome **(c)** treatment affected infiltration of Gr-1⁺ (red), CD4⁺ (blue) or CD11c⁺ (green) cells at the host-parasite interface. F4/80⁺CD206⁺ macrophages were specifically depleted in the CL₂MDP liposome-treated **(f)** as compared to the PBS liposome-treated group **(e)**. Cytokine gene expression in mesenteric lymph node (MLN; **g**, left) and proximal small intestine (right) samples were collected 7 d after infection, as determined by real-time RT-PCR and plotted on log scales. Lp, lamina propria; m, muscularis; Hp, *H. polygyrus*.

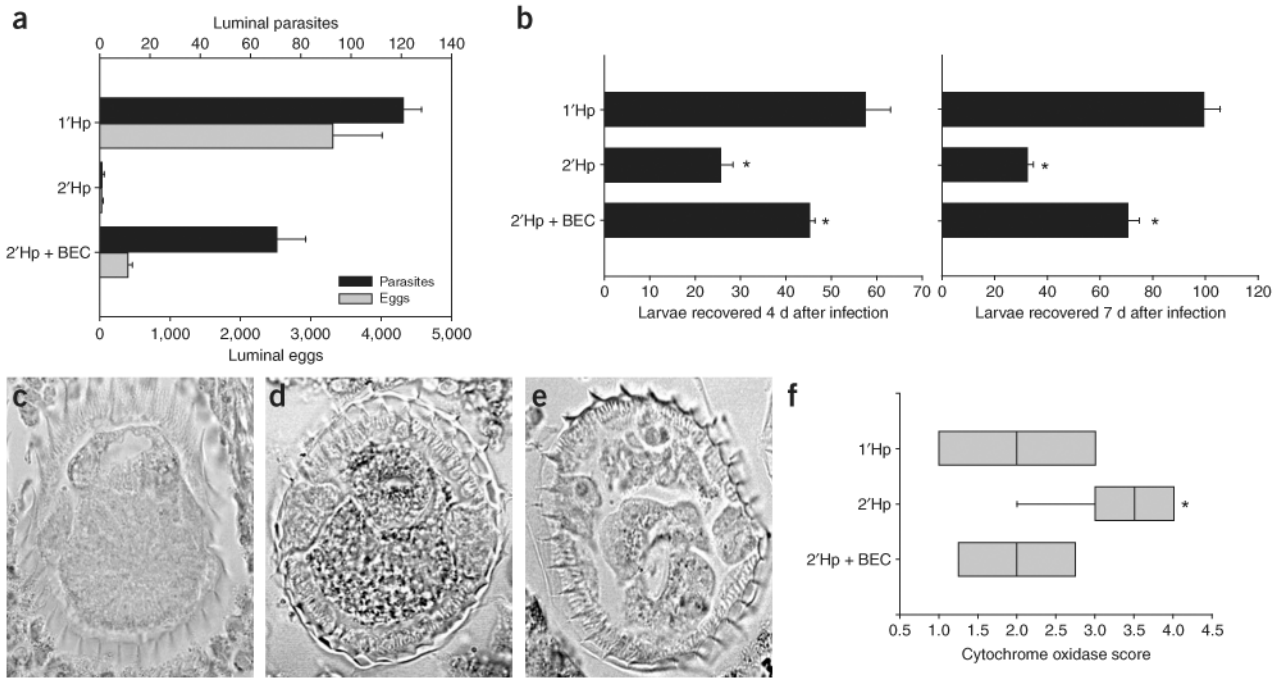

Figure 4. Arginase inhibition abrogates protective memory response to *H. polygyrus*. **(a,b)** Shown are parasite and egg burdens determined 14 d after inoculation **(a)**, and larvae recovered from infected small intestines 4 **(b, left)** or 7 d **(right)** after infection using a Baermann apparatus, in challenged mice that were given 0.2% BEC (2'HpD14 + BEC) in their drinking water. Bars represent mean and s.e.m. of five mice per group. **** $P < 0.001$** and *** $P < 0.01$** by ANOVA followed by Tukey *post hoc* test. **(c–e)** Cytochrome oxidase (black granules) staining of parasite cross-sections 7 d after primary infection **(c)**, secondary infection **(d)** and secondary infection with BEC treatment **(e)**. Staining intensity within parasite cross-sections was scored blindly (1–4, lightest to darkest). **(f)** Box plots of scores from four mice per treatment group are plotted. *** $P < 0.05$** by Kruskal-Wallis test followed by Dunn *post hoc* test.
