Summary

Drosophila expresses several muscle myosin isoforms from a single gene by alternatively splicing six of the nineteen exons. Here we investigate exon 7, which codes for a region in the upper 50k domain near the nucleotide binding pocket. This region is of interest because it is also the place where a large insert is found in myosin VI and where several cardiomyopathy mutations have been identified in human cardiac myosin. We expressed and purified chimeric muscle myosins from *Drosophila*, each varying at exon 7. Two chimerics exchanged the entire exon 7 domain between the indirect flight muscle (IFI, normally containing exon 7d) and embryonic (EMB, normally containing exon 7a) isoforms to create IFI-7a and EMB-7d. The second two chimerics replaced each half of the exon 7a domain in EMB with the corresponding portion of exon 7d to create EMB-7a/7d and EMB-7d/7a. Transient kinetic studies of the motor domain from these myosin isoforms revealed changes in several kinetic parameters between the IFI or EMB isoforms and the chimeras. Of significance were changes in nucleotide binding, which differed in the presence and absence of actin – consistent with a model in which the exon 7 domain is part of the communication pathway between the nucleotide and actin binding sites. Homology models of the structures suggest how the exon 7 domain might modulate this pathway.

Introduction

The conventional myosin II mechanoenzyme uses the energy from ATP hydrolysis to power muscle contraction. Myosin II, the main component of the muscle thick filament, is a hexameric protein formed by two myosin heavy chains (MHC), two essential light chains and two regulatory light chains. The catalytic myosin heads protrude from the surface of the thick

filament and form strong transient interactions with the actin-containing thin filament. Summation of the interactions by many myosin heads with the thin filament generates force and motion that result in muscle fiber shortening.

Striated muscle fibers, which include skeletal and cardiac, exhibit a range of shortening velocities. A large body of evidence supports the hypothesis that variation in myosin heavy and light chain isoforms accounts for the diversity in contraction velocities of these fibers (see reviews: [1, 2]). Early studies described a relationship between the steady-state ATPase activity of myosin isoforms and contraction velocity of muscle fibers expressing the same myosin isoforms suggesting that biochemical changes in MHC contribute to the observed diversity [3, 4]. Numerous subsequent analyses established a correlation between myosin isoform kinetic properties and their actin filament *in vitro* motilities or *in vivo* muscle shortening velocities. Recent crystallographic and cryo-electron microscopy observations have revealed a conserved structural mechanism (see reviews: [5, 6]) for these myosin isoforms further supporting the proposal that differences in the kinetic properties rather than mechanical properties of the myosin isoforms govern the contraction velocities of striated muscle fibers.

Recent investigations using an invertebrate model, *Drosophila melanogaster*, assessed whether a similar kinetic mechanism exists for muscle myosin isoforms in this organism. The studies focused on two of the fifteen known myosin isoforms [7-9], the embryonic body wall muscle isoform (EMB) and the indirect flight muscle isoform (IFI). Kinetic analyses of these isoforms using myosin or myosin subfragment 1 (S1) revealed less than a two-fold difference in nearly all measured steady-state and transient kinetic parameters [10, 11]. These small kinetic differences are in clear contrast to the results from measuring *in vitro* actin filament velocities and the frequency of maximum power generation and the rate of tension redevelopment in fibers, which together show that IFI supports substantially faster actin filament and fiber contraction velocities than the EMB isoform [10-13]. A recent study of the effects of ATP, ADP and Pi concentration on IFI and EMB fiber kinetics may shed some light on this lack of correlation. The results from this study show that the IFI and EMB-containing fibers respond very differently to ATP, ADP and Pi; the authors concluded that the rate-limiting step for the IFI isoform is Pi release while the EMB isoform rate-limiting step is the isomerization step prior to ADP release[14].

To better understand the relationship between myosin kinetics and *in vivo* fiber shortening velocities in *Drosophila*, analyses have focused on the regions that vary between the IFI and EMB isoform. Myosin isoform diversity in *Drosophila* is generated by alternatively splicing six of the nineteen exons from a single *Mhc* gene [7, 9, 15]; the IFI and EMB isoforms differ in all six regions. To address the function of each variable region, chimeric myosin isoforms were created by sequentially exchanging each variable domain between the IFI and EMB isoforms. Subsequent generation of transgenic flies expressing these chimeric isoforms allowed for assessment of the changes to muscle function *in vivo* and MHC function *in vitro* [10, 11, 13, 16-19].

The exon 7 domain (colored red in Fig. 1) forms the upper lip of the ATP-binding site (residues 319 – 335) and a portion of the adjacent external surface (residues 301 - 318). IFI and EMB spliced transcripts include exon 7d and 7a, respectively, which are two of four isovariants in this exon cassette. Previously, exons 7d and 7a were exchanged between the IFI and EMB transcripts to produce chimeric myosin isoforms IFI-7a and EMB-7d. Initial i*n vitro* and *in vivo* results suggested the exon 7 domain modulates myosin isoform function by affecting the lifetime of a state where myosin is detached or weakly attached to actin [16]. A second study of the indirect flight muscle (IFM) mechanical properties of IFI-7a and EMB-7d transgenic flies showed that the exon 7d domain also affects the duration of a strongly bound state that influences fiber speed and flight performance [17].

Here we used transient kinetic analyses to perform a detailed investigation of the modulatory role of the exon 7 domain on *Drosophila* myosin isoform biochemical kinetics. Four chimeric isoforms were used; two were the IFI-7a and EMB-7d isoforms previously created [16]. The other two isoforms were designed to independently test the influence of the residues that vary between the exon 7a and 7d domains on EMB isoform kinetic properties. We created these by replacing separately each sub-domain (lip or surface domain) of exon 7a in EMB by the same region of exon 7d, thus producing the EMB-7d/7a (includes 7d surface domain residues 301-318) and EMB-7a/7d (includes 7d lip domain residues 319-335) isoforms (Fig. 1B). Using these four isoforms, we measured several biochemical transitions in the myosin cross-bridge cycle.

We found that substitution of the entire exon 7a domain in the EMB isoform with exon 7d (EMB-7d) slightly reduced the ATP-induced dissociation rate of acto-S1 and significantly enhanced the rate of coumarin-ADP (eda-deac ADP) release but had no influence on the ADP affinity for acto-S1. Exchanging the entire exon 7d domain of IFI with exon 7a (IFI-7a) reduced the ATP-induced dissociation rate and the rate of eda-deac ADP release from IFI but enhanced the ADP affinity for acto-S1. When exchanging either the exon 7d lip or surface domain, we observed no change in the steady-state ATPase rate as seen with EMB-7d, but there were changes in both the eda-deac ADP release rate from S1 and in the affinity of ADP for acto-S1. Collectively, the kinetic differences measured in these four isoforms indicate that exchanging or splitting the exon 7 domain produced novel biochemical interactions governing *Drosophila* myosin kinetic transitions. Homology models derived for the IFI, EMB and four chimeric isoforms suggest a structural mechanism by which sequence changes in the exon 7 domain influence *Drosophila* myosin kinetics. Together the kinetic perturbations and modeling data reveal the exon 7 domain is part of the communication pathway between the nucleotide and actin-binding sites.

Results

Generation of transgenic flies

To address which nonconserved residues between exon 7a and 7d contribute to the functional differences in myosin isoforms EMB and EMB-7d [16], we generated two constructs, *EMB-7a/7d* and *EMB-7d/7a*. Both chimeric myosin isoforms substituted exon 7d residues in place of the exon 7a residues normally present in the EMB isoform (Fig. 1). In EMB-7a/7d residues 319-335 (lip sub-domain) were exchanged and in EMB-7d/7a residues 301-318 (surface sub-domain) were exchanged. To mediate germline transformation of *Drosophila*, each *P* element construct was injected separately into *yw* embryos along with a helper plasmid, Δ2-3, containing a transposase source required for insertion of the *P* element into chromosomal DNA [20, 21]. Transformed flies with appropriate insertion events were crossed into a Mhc^{10} background. Mhc^{10} is null for MHC in the indirect flight and jump muscles [22]. This genetic background eliminates myosin isoform expression only in these muscle types and allows for assessment of *in vivo* function and purification of transgenic myosin without contamination from endogenous myosin. These techniques yielded three independent fly lines for the EMB-7a/7d isoform and five independent fly lines for the EMB-7d/7a isoform. A single fly line expressing the greatest amount of MHC for each mutant was used for myosin purification. Each myosin preparation yielded 300-400 μg from approximately 150-180 flies.

Steady-state Mg^{2+}ATPase assays of chimeric myosin isoforms

A previous study showed an increase in the basal and actin-activated Mg^{2+}ATPase activity when the exon 7d domain was exchanged for exon 7a in the EMB background (Table 1, EMB-7d isoform) [16]. We determined the Mg^{2+}ATPase activity for the chimeric myosin isoforms EMB-7a/7d and EMB-7d/7a. The basal and maximal (V_{max}) actin-activated activities

for both isoforms were similar to the EMB isoform and did not show any increase in activity as seen with the EMB-7d isoform (Fig. 2 and Table 1). The elevation of the ATPase activity therefore requires the whole exon 7 exchange, i.e., neither half of the exon can produce the effect on its own. However, the K_M for actin with either isoform showed a 3-4 fold decrease relative to the EMB isoform and a 1.5-2 fold decrease relative to the EMB-7d isoform. The decrease of the K_M is not simple to interpret but could reflect an increased affinity of these myosin isoforms for actin.

Production of *Drosophila* S1 isoforms

In order to measure the transient kinetic parameters, each myosin isoform was digested with α-chymotrypsin to produce S1, the catalytic globular domain. Chymotryptic digestion eliminates the α-helical rod domain and the regulatory light chain, but leaves the essential light chain intact. The S1 is soluble at low salt and produces minimal aggregation. The samples contain relatively pure S1 (~100-200 μg) with minor contamination resulting from over-digestion of the myosin [11].

Dissociation of coumarin ADP (eda-deac ADP) from S1 (k_{-D})

To estimate the rate constant of ADP dissociation from S1 in the absence of actin, the change in fluorescence of a coumarin labelled ADP (eda-deac ADP[42]) was measured upon displacement of eda-deac ADP by ATP-binding to S1 [23]. Previously it was shown that this coumarin-labeled analog has very similar kinetic properties compared to ADP. When using edadeac ADP the ADP release rate (k_{-D}) was unchanged for rabbit fast-skeletal myosin S1, the *Dictyostelium* myosin head fragment (M765-1R) and rat EDL myosin S1 [23].

A single laser flash released 15-20 μM ATP from cATP (100 μM) and the fluorescence change resulting from eda-deac ADP release was well described by a single exponential function. Exchange of the full exon 7a or exon 7d domain into the IFI or EMB isoform, respectively, resulted in an alteration of the rate constant for eda-deac ADP release (k_{-D}) in the direction of the donor domain; the eda-deac ADP release rate constant from IFI-7a (4.7 ± 0.8 s^{-1}) and EMB-7d (4.3 ± 0.7 s^{-1}) were very similar and the values lie between those of IFI (7.5 ± 1.3 s^{-1}) and EMB S1 (1.8 ± 0.4 s^{-1}; Table 2 and Fig. 3).

The eda-deac ADP release rate constants for EMB-7a/7d and EMB-7d/7a S1 were 2.6 ± 0.4 s^{-1} and 6.1 ± 0.8 s^{-1}, respectively (Table 2). Including the IFI exon 7d lip domain (EMB-7a/7d) results in a rate close to the IFI S1 rate (7.5 ± 1.3 s^{-1}). On the other hand, including the exon 7d surface domain (EMB-7d/7a) yields a rate closer to the EMB S1 rate [11]. With EMB-7a/7d the eda-deac ADP fluorescence decreased on displacement, in the same direction as for the IFI, EMB and EMB-7d isoforms (Fig. 3A and C). There was no correlation between the direction of the fluorescence change and the affinity of the analogue for S1. Surprisingly, the results with EMB-7d/7a showed a fluorescence increase as did IFI-7a (Fig. 3B and D). Similar variation in the direction of fluorescence changes has been observed previously with vertebrate and *Dictyostelium* S1 isoforms [23] and reflects differences in the local environment of the protein bound fluorophore.

Determination of the ATP-induced dissociation rate (K_1k_{+2}) of acto-S1

To determine the second order rate constant governing the dissociation of acto-S1 by ATP (K_1k_{+2}: see Scheme 1), 1 μM actin and 1-3 μM S1 were preincubated and then dissociated by ATP released from cATP. A single sample was subjected to a series of laser flashes decreasing in intensity to release varying concentrations of ATP. The rate of change in light scattering (k_{obs}) was recorded for each laser flash and could be well described by a single exponential at each ATP concentration (data not shown). The linear slope of a graph of k_{obs} vs. ATP concentration determines the apparent second-order rate constant for the dissociation of acto-

S1 by ATP (Fig. 4). Both the values for IFI-7a acto-S1 (0.33 ± 0.07 μM^{-1} s^{-1}) and EMB-7d acto-S1 (0.64 ± 0.05 μM^{-1} s^{-1}) showed decreases relative to the previously reported values for IFI (0.75 ± 0.08 μM^{-1} s^{-1}) and EMB acto-S1 (0.91 ± 0.13 μM^{-1} s^{-1}), respectively[11] (Table 2). The kinetic rates for the ATP-induced dissociation of EMB-7a/7d (0.67 ± 0.18 μM^{-1} s^{-1}) and EMB-7d/7a (0.66 ± 0.14 μM^{-1} s^{-1}) acto-S1 (Fig. 4B) were similar to the dissociation rate observed for EMB-7d, but lower than the dissociation rate for EMB acto-S1 (Table 2).

Determination of ADP affinity (K_{AD}) for acto-S1

The equilibrium dissociation constant for ADP (K_{AD}) from acto-S1 provides a measure of the ADP affinity for S1 in the presence of actin. Competition between ADP and ATP binding to acto-S1 allows the measurement of K_{AD}; for details see Weiss et al. [24]. To determine the ADP affinity in a single S1 sample, the ATP-induced rate of acto-S1 dissociation was measured repeatedly as the concentration of ADP increased. The change in the light scattering measured for each ADP concentration was fit with a single exponential to determine k_{obs}. The K_{AD} values for the isoforms (except for EMB-7a/7d S1, see below) determined from the applied hyperbolic fits (equation 1) to the graph of k_{rel} vs. ADP concentration (Fig. 5) are presented in Table 2. The K_{AD} for EMB-7d is not different from EMB [11] but the IFI-7a K_{AD} is 1.5-2 fold lower than that of IFI [11]. Unexpectedly, the K_{AD} for EMB-7d/7a S1 showed a 3-fold decrease (tighter ADP affinity) relative to EMB-7d and EMB S1 K_{AD} values and a 2-fold decrease relative to the K_{AD} for IFI S1 (409 ± 26 μM) [11]. The significance of these K_{AD} changes was confirmed by running a Student's t-test for all the mutants, as compared to IFI and EMB (see Table 2). Interestingly, the plot of the k_{rel} vs. ADP concentration for EMB-7a/7d exhibited a sigmoidal shape; this behavior was consistent in each of the preparations for this isoform. As a result, the curve could not be fit with equation 1; instead an apparent K_{AD} was determined by calculating the ADP concentration at which 50% inhibition was observed. This yielded a value of 191 ± 59 μM for EMB-7a/7d actoS1 ADP affinity. Again the K_{AD} for this isoform was 2-3 fold lower (tighter acto-S1 ADP affinity) than the values determined for the IFI, EMB and EMB-7d S1 isoforms.

Homology Models

Both *Drosophila* IFI and EMB myosin head sequences showed significant sequence identity with various other myosin super family members. A sequence identity of 60 % (± 1%) was found when aligning IFI and EMB myosin head sequences with class II scallop myosin, thus enabling us to build well-resolved homology models. SWISS-MODEL generates reliable models for target-template pairs sharing > 40 % sequence identity. When the sequence identity is as high as 60% then the quality of target-template pairs is generally very good, with the majority of the models deviating between 0.5 – 1.0 Å from the template [25]. Crystal structures are available of the various states of scallop myosin during the cross-bridge cycle and these were chosen to generate 3D homology models of the IFI and EMB myosin heads and also of the chimeras obtained after swapping exon 7 completely (IFI-7a and EMB-7d) or after swapping a part of exon 7 (EMB-7a/7d and EMB-7d/7a). Three of the scallop myosin structures used here contain a nucleotide in the binding pocket and they represent various conformational states of myosin during the cross-bridge cycle: the actin-detached state (ExPDB 1kk8) contains ADP-BeF_x, the pre-powerstroke state (ExPDB 1qvi) contains ADP-VO_4 and a novel conformation contains partially-bound $ADPSO_4$ (ExPDB 1s5g). The other scallop myosin structure does not have a nucleotide in the binding pocket (ExPDB 1sr6) and this one represents the near-rigor state of myosin. The generated models have Ramachandran Z-scores of −0.475 (± 0.182) and average packing Z-scores of −1.069 (±0.064), which were within the expected range for well-refined structures. The overall topology of the models was similar to that of the scallop myosin II templates (average rmsd of the backbone is 0.45 ± 0.25 Å). Overlaying the two wild-type models for *Drosophila* IFI and EMB and their respective exon 7 chimeras revealed a high degree of similarity in backbone structure, apart from the region in the converter

area (exon 11). The kinetic properties of this region have been described in detail elsewhere [11] and therefore will not be discussed here.

General description of the exon 7 area

In the exon 7 area, the rmsd of the myosin backbone between IFI and EMB was < 0.05 Å and followed the same topology for both isoforms. For descriptive purposes, we use the same nomenclature for secondary structure elements as described previously [26]. A small helix (helix J) at the N-terminus of the exon 7 domain is followed by a longer loop and then another longer helix (helix K: 327-341). The N-terminus (327-335) of helix K is the C-terminal part of the exon 7 area. Figure 6 shows the structure of the exon 7 region (colored red) for both IFI and EMB using the scallop structure, ExPDB 1qvi, as a template. The residues that vary between the IFI and EMB isoform are indicated in Figure 1B. In the N-terminal part of exon 7, residue 304 is located before helix J and residues 313 and 314 immediately after this helix. The loop region between the two helices contains variable residues 323 and 324 while helix K in the C-terminal part of exon 7 has three variable sites: 328, 332 and 334.

Exon 7 area: highly conserved interactions.

Sequence alignments (Fig. 7) showed that only two exon 7 residues are highly conserved: G^{318} and D^{327}. Inspection of the homology models revealed that D^{327}, located at the N-terminus of helix K, is involved in a strong salt-bridge toward R^{283} (Fig. 6). This salt-bridge was present in all homology models and has also been found in crystal structures of other myosins, including skeletal and smooth chicken myosin II (ExPDB 2MYS and 1BR4) and *Dictyostelium* myosin II (1FMV), in addition to members of other myosin classes, such as myosin I (myosin-1E, 1LKX), myosin V (1OE9) and myosin VI (2BKH). Sequence alignments also showed that R^{283} and its neighboring residues are highly conserved. These residues interact with the well conserved switch 1 region, in particular K^{236}, or with residues that are located around G^{318} in the exon 7 domain. Together, these residues around R^{283} form the 'relay area' and provide a mechanism by which the exon 7 domain is able to 'sense' the conformation of switch 1. The location of G^{318} in the middle of the loop between helix J and K may function to orient the interacting residues properly toward the relay area (Fig. 6). No variable residues in exon 7 are involved in direct contacts with either switch I or this 'relay area', indicating this switch I sensitivity is a conserved feature of both isoforms.

Exon 7 area: Non-conserved interactions

Careful inspection of the exon 7 area in the homology models revealed close interactions between the ribose oxygen and the side-chain of the non-conserved residue 324 in all three states containing a nucleotide. Measurements of the hydrogen-bond distances between the H-donor (either asparagine in IFI or serine in EMB) and the H-acceptor of the nucleotide indicated that the asparagine (N^{324}) side-chain is closer to the ribose moiety than the serine (S^{324}) side-chain. This difference was most pronounced in the pre-powerstroke state, with the N^{324} hydrogen donor almost 1 Å closer to the ribose oxygen than the S^{324} hydrogen donor (Fig. 8). Comparison of the conformations with a partially-bound nucleotide showed the N^{324} H-donor is about 0.5 Å closer than the S^{324} side-chain (not shown). Lastly, in the actin-detached state only the N^{324} side-chain was able to form a hydrogen bond toward the nucleotide (not shown). All these observations indicate that an asparagine at position 324 allows a greater number of direct contacts with the bound nucleotide than a serine.

Other non-conserved residues in the exon 7 area were found to make contacts with nearby regions, in particular helix L (yellow in Fig. 6: 345-361), which follows the exon 7 region (Fig. 6). The N-terminus of the exon 7 area makes contacts with the C-terminus of helix L whereas the C-terminus of the exon 7 region makes contacts with the N-terminus of helix L. It is worth noting that the variable residues at position 313 and 314 ($H^{313}I^{314}$ in EMB or $Y^{313}N^{314}$ in IFI)

are interacting with helix L (Fig. 6) and that these contacts vary between myosin conformational states. In the near-rigor state, i.e. the myosin conformational state without a nucleotide in the binding pocket (ExPDB 1sr6), residues 313 and 314 make very weak contacts toward residues 355-360 of helix L and only the side-chain of N^{314} is involved in the formation of hydrogen bonds towards helix L. In the three states containing a nucleotide (actin-detached, pre-powerstroke and a novel conformation with the partially-bound ADP-SO_4), however, the contacts between helix L and these residues become much stronger thereby allowing the side-chain hydroxyl of Y^{313} to form a hydrogen bond toward helix L (K^{365}). These results indicate that the exon 7d domain, which contains both Y^{313} and N^{314} (Fig. 1B), is able to form more contacts toward helix L than does the exon 7a domain. In addition, the homology models that used the actin-detached state (ExPDB 1kk8) and the pre-powerstroke state (ExPDB 1qvi) showed that the variable residue at position 304 (L/F) interacts with residue 357 on helix L (not shown).

Discussion

Previously, exchange of the exon 7 domain between the IFI and EMB isoforms was found to increase steady-state Mg^{2+}ATPase rates in the resulting IFI-7a and EMB-7d chimeric isoforms, but not to alter actin filament velocities generated by these isoforms compared to IFI and EMB, respectively. Expression of the IFI-7a and EMB-7d chimeric isoforms in the IFM (in place of the IFI) resulted in minimal effects on locomotion when compared to IFI and EMB, respectively. The EMB-7d transgenic flies showed improved stability of the muscle structure (uniformity of length and packing of actin and myosin filaments in the muscle fiber) compared to EMB transgenic flies, which show significant deterioration of muscle structure within a few days after eclosion [27]. Collectively, these data led to the conclusion that the exon 7 domain modulates kinetic transitions that govern the attachment of myosin to actin [16]. A follow up study investigated the influence of the exon 7 region on IFM fiber mechanical properties and found the IFI-7a exchange produced minimal alterations to IFM function [17]. The only observed difference was a slight decrement in flight ability at 15°C. Exchanging EMB-7d, however, produced significant increases in the frequency of maximum power generation and the rate of tension redevelopment and higher active stiffness in these fibers compared to the EMB fibers. In order to produce these effects, myosin must be strongly bound to actin. Therefore the EMB-7d exchange must additionally influence the lifetime of a strongly bound state of the EMB cross-bridge cycle that does not limit actin filament velocity [17]. In this study we used a detailed kinetic analysis to understand how sequence variation in the exon 7 domain influenced biochemical transitions in *Drosophila* myosin isoforms to clarify the modulatory role of this domain.

Steady-state kinetics of *Drosophila* exon 7 chimeric isoforms

We sought to determine if either of two distinct areas of the IFI exon 7d domain might be responsible for driving the kinetic properties of myosin isoforms. Interestingly, exchanging only a part of the exon 7d domain in creating the EMB-7a/7d and EMB-7d/7a isoforms had little effect on the maximal actin-activated Mg^{2+}ATPase activity but decreased the K_M 2-3 fold as compared to the EMB isoform. This was in contrast to the EMB-7d isoform, which showed a 30% increase in maximal actin-activated ATPase activity but no effect on the K_M as compared to the EMB isoform [10, 16]. Overall, these data suggest that variable residues in either half of the exon 7d domain mediate an increase in actin affinity but both halves of the exon 7d domain coordinate to produce the increase in ATPase activity observed with the EMB-7d isoform.

Transient kinetics of *Drosophila* exon 7 chimeric isoforms

In general, the differences observed in the transient kinetic experiments of EMB-7d, EMB-7a/7d and EMB-7d/7a as compared to the IFI and EMB isoforms indicate that the interactions with the nucleotide made by the exon 7d domain are different from those for the exon 7a domain. Previously, a 4-fold difference between the rate constants of eda-deac ADP release from IFI and EMB in the absence of actin was observed [11]. Presently, a three-fold change for the EMB-7d and EMB-7d/7a isoforms resulted from altering only exon 7. EMB-7d is more like IFI than EMB in this parameter and EMB-7d/7a is even more similar to IFI. These results suggest that the other variable domains do not play a major role in defining this parameter and that the surface domain of exon 7 has the most influence on ADP release in the absence of actin. The exon 7 domain might influence the interaction of nucleotide with the motor domain directly or indirectly. Homology modeling indicated that N^{324} (present in the lip of exon 7d in the IFI isoform) can make a shorter hydrogen bond to the oxygen of the ADP than can S^{324} in exon 7a of the EMB isoform. A simple argument therefore predicts a more tightly bound ADP, and a lower release rate constant (k_{-D}) in IFI than in EMB. However, the result was opposite to what was predicted; the IFI ADP release rate is faster than the EMB isoform. Thus, the role of the exon 7 domain in ADP binding is more indirect than via a single hydrogen bond between the exon 7 domain and the nucleotide.

The effect of the exon 7 domain on eda-deac ADP affinity suggested that this domain could also affect ATP and ADP binding in the presence of actin. In the present work, we observed that the apparent second order rate constant of ATP binding (K_1k_{+2}) decreased by 30% when all or part of exon 7a was replaced by 7d in the EMB isoform and when 7a replaced 7d in the IFI isoform. In addition, the affinity of acto-S1 for ADP (K_{AD}) was reduced more than 2-fold for either the lip or surface domain exchanges and the IFI-7a isoform, but was unchanged for EMB-7d. Together these results confirm the ability of the exon 7 domain to modulate nucleotide binding parameters in the presence of actin and may help to explain the differences in nucleotide affinity recently observed between the IFI and EMB-containing fibers [14].

Additional observations support the conclusion that the interactions between the exon 7 domain and the nucleotide differ depending on the presence of exon 7a or 7d. The plot of k_{rel} vs. ADP concentration for the EMB-7a/7d S1 isoform exhibited an unusual sigmoidal shape (Fig. 5C), rather than the characteristic hyperbolic shape observed with all other S1 isoforms. For IFI-7a and EMB-7d/7a S1 (Fig. 3B and D), we also observed a difference in the direction of the coumarin fluorescence signal relative to all other S1 isoforms; these results probably reflect local structural differences in the probe environment.

Myosin is capable of binding both actin and ADP simultaneously; the ratio K_{AD}/K_D (Table 3) or K_{DA}/K_A describes the effect of actin on ADP affinity or the effect of ADP on actin affinity, respectively, and is termed the thermodynamic coupling constant [28]. Fast skeletal myosins exhibit a high coupling constant (~50) indicating that the presence of actin significantly weakens ADP affinity and vice versa. The coupling for IFI-7a (51), EMB-7d (139), EMB-7a/7d (73) and EMB-7d/7a (36) S1 suggests that the exon 7 domain interactions with the nucleotide in these isoforms are more similar to IFI (55) than to EMB (326). For EMB-7d S1 the alteration in K_D but not K_{AD} reveals the exon 7d domain has more influence on interactions in the nucleotide-binding pocket in the absence of actin than in the presence of actin. On the other hand, the changes in both K_{AD} and K_D for the IFI-7a, EMB-7a/7d and EMB-7d/7a S1 indicate that these exon 7 regions interact differently with the nucleotide, thus modulating the response of myosin to the presence or absence of actin.

Molecular mechanism by which the exon 7 region modulates *Drosophila* myosin isoform function

The location of the exon 7 domain places certain residues in favorable positions for potential direct interactions with the nucleotide (Fig. 8). Several studies have established that the upper 50 kD domain, which includes the exon 7 area, moves as myosin transits through the biochemical cycle [29-32]. At a minimum, these results show that the domain is shifting position in response to actin and/or the nucleotide state. Yet, only a single study of pre-powerstroke and near rigor scallop myosin crystal structures implicates direct interaction of an exon 7 domain residue with the nucleotide [33]. This study observed an interaction between N^{321} (S^{324} in *Drosophila* exon 7a and N^{324} in exon 7d regions: Fig. 8) and the diphosphate moiety of ADP that strengthened as myosin transitioned from the pre-powerstroke to near rigor state. None of the other surrounding residues appeared to form any direct interactions. In *Drosophila* myosin isoforms, the variation at this position in exon 7a (a serine) versus exon 7d (an asparagine) suggests a possible direct mechanism for modulation of the kinetics observed here and in previous studies [10-13, 16-19]. Examination of the remaining nonconserved residues (Fig. 1B) between exon 7a and exon 7d uncovers no obvious changes in charge (unless the histidine at 313 is protonated), a few changes in polarity (for instance, I/N^{314} and T/A^{334}), a change in flexibility (A/P^{323}) and a change in size (A/G^{328}). If the direct interaction between the nucleotide and residue 324 exists in *Drosophila* myosin isoforms, variation in the other nonconserved residues may modulate the strength of this interaction and affect kinetic transitions.

The idea discussed above is supported by the homology models, which indicate that the exon 7 domain could act as part of the signal relay pathway between the nucleotide binding site and the actin binding site through the following mechanism. Residue 324 (‘lip domain’), which varies between IFI and EMB, makes direct contact with the nucleotide and is able to ‘sense’ the state of switch I via a highly conserved salt-bridge between D^{327} and R^{283} (and contacts around R^{283}, the ‘relay’ area) toward switch I. Although one should interpret the measured distances with care, all the homology models which contain N^{324} show that the side-chain of this residue is consistently closer to the nucleotide than the models which have a serine at that position. Additional variable residues at the N-terminus of the exon 7 domain (304, 313 and 314) are subsequently involved in relaying the signal toward helix L. The exon 7d domain makes more contacts toward both the nucleotide and helix L than exon 7a, which might result in a more efficient signal relay and faster ADP release in the absence of actin. We observed that introduction of 7a into IFI reduces ADP release rates significantly (Table 3), whereas introducing 7d into EMB enhances ADP release rates. Comparing EMB-7d/7a, which has an increased ADP release rate, to EMB-7a/7d, which has a k_{-D} close to EMB, suggests the N-terminus of the exon 7 domain may have more effect on the efficiency of signal relay than the C-terminus. This result is confirmed by the homology models, which indicate that the variable residues at the N-terminus of exon 7 are involved in relaying the signal towards helix L. In the presence of actin, the picture is more complex because other variable domains are involved, in particular those encoded by exons 3 and 9. One should also keep in mind that these homology models are based on myosin crystal structures without actin present, since actomyosin structures are not yet available. Apart from EMB-7d, all the other chimeric S1 isoforms show much higher ADP affinity in the presence of actin as compared to EMB (Table 2), indicating that the communication pathway between the actin-binding site and the nucleotide-binding site is altered in these isoforms.

The observation that myosin VI has two extra inserts [34], compared to other myosins, is also of interest because insert 1 is in the middle of the exon 7 area (Fig. 7). Kinetic measurements suggested that this insert has a crucial function in slowing ADP release and ATP-induced actomyosin dissociation [34]. The myosin VI structure reveals that the presence of insert 1 does

not alter the conformation of switch I relative to the upper 50 kDa domain. However, the presence of insert 1 does allow for a repositioning of helix K, which is now able to interact directly with switch 1 and also protrudes within the nucleotide-binding pocket, resulting in a decrease in nucleotide accessibility. Additional support for the hypothesis that the exon 7 domain is part of the signal relay pathway between the nucleotide and actin-binding sites comes from the observation that both the exon 7 domain and helix L in β-myosin heavy chain contain several sites that, when mutated, cause hypertrophic cardiomyopathy. Mutations have been reported for F^{312}/C (Van Driest et al. [35]), V^{320}/M (Havndrup et al. [36]), A^{326}/P (Van Driest et al. [35]), and E^{328}/G (Yu et al. [37]). The equivalent residues in *Drosophila* are I/N^{314}, V^{322}, A/G^{328} and E^{330} respectively (see Figure 7). We propose that these mutations alter myosin function by disrupting the relay pathway between the nucleotide and actin-binding sites.

Conclusions

This study was designed to investigate in detail the modulatory effects of the exon 7 domain on *Drosophila* myosin isoform kinetics. Our results indicate that the sequence differences created in the IFI-7a, EMB-7d, EMB-7a/7d and EMB-7d/7a isoforms induced biochemical and structural changes in the exon 7 domain, thereby influencing attached and detached myosin kinetic transitions. Homology models suggest a mechanism by which the exon 7 domain transmits these changes between the nucleotide and actin-binding sites. Interestingly, all *Drosophila* myosin isoform kinetic parameters that have been measured *in vitro* (Table 3 and Miller et al. [11]) show small differences (4-fold or less) between isoforms. Thus, small kinetic modifications, controlled by sequence differences in the variable domains, are sufficient to tune *Drosophila* myosin isoforms for their physiological function.

Materials and Methods

Preparation of exon 7 chimeric subdomain transgenes

To create P element based constructs *EMB-7a/7d* and *EMB-7d/7a*, we exchanged small parts of exon 7d into the EMB-encoding transgene (*P [$w^+$$Mhc^{emb}$] w^3* or Mhc^{emb}) [27] to replace portions of the endogenous exon 7a. The following primers to exon 4 (containing a *Stu* I site), to exon 8 (containing a *Bgl* II site), and to exon 7a and exon 7d were generated in order to amplify the replacement DNA by PCR: Primer W (exon 4): 5' GAAGGCCTTCGGTAACGCCA 3', Primer X (exon 7a reverse): 5' GGTGTAACAGAGGGTCCCATTTCATTGAC 3', Primer Y (exon 7d forward): 5' CCACATTGTCTCCCAGGGTAAAGTAACTG 3', Primer M (exon 7a forward): 5' ACAGTGACCTTGCCCTGGGATACGTTATAGT 3', Primer N (exon 7d reverse): 5' TACTATAACGTATCCCAGGGCAAGGTCACTGTA, Primer Z (exon 8): 5' GAAGATCTCAAACCAGCAATA 3'.

To produce the exon 4 to exon 8 fragment with either exon 7a/7d or 7d/7a, the final DNA segment was generated using three rounds of PCR followed by ligation of the final PCR fragment into a vector. To create *EMB-7a/7d*, the *Emb* DNA (Mhc^{emb}) [27] was used as a template in the first PCR reaction with Primers W and X, yielding an ~270 bp band. A second PCR reaction with *EMB-7d* DNA [16] as a template for Primers Y and Z generated a band of ~460 bp. An overlapping region between the products of these two PCR reactions allowed them to be mixed together and serve as a template for the final PCR reaction. Prior to amplification of the full-length product (730 bp) using Primers W and Z, the 3' ends were extended during an incubation period to create the full length template. The final PCR product was gel purified and digested with *Stu* I (exon 4 – Primer W) and *Bgl* II (exon 8 – Primer Z) and ligated into the Litmus 29 vector (New England BioLabs, Beverly, MA). To generate the final *EMB-7a/7d* construct, Mhc^{emb} DNA was digested with *Stu* I (exon 4) and *Sph* I (exon 17) to isolate a 12 kb fragment containing a portion of *Emb* DNA and the vector. A second digest

of the *Mhc*^{emb} DNA with *Bgl* II (exon 8) and *Sph* I (exon 13) isolated a fragment of ~1.2 kb including exons 8 - 13. A triple ligation between these two fragments (12 kb and 1.2 kb) and the *Stu* I (exon 4) to *Bgl* II (exon 8) fragment digested from the Litmus 29 construct produced a plasmid containing exon 7a/7d but missing exons 13-17. To create the final *EMB-7a/7d* DNA, this plasmid was digested with *Sph* I, dephosphorylated and then ligated together with a fragment containing exons 13-17 that was isolated from a *Sph* I digest of *Mhc*^{emb} DNA. All enzyme sites and the exon 7 region were sequenced to verify proper ligation and orientation of all fragments prior to large scale DNA purification.

To create *EMB-7d/7a*, a similar procedure was used. The differences include: the first PCR reaction contained *EMB-7d* DNA [16] as a template for Primers W and N while the second PCR utilized *Mhc*^{Emb} [27] as a template for Primers M and Z. Details for the final round of PCR and ligation of exon 4 to exon 8 into the Litmus 29 vector were the same as described above for *EMB-7a/7d*. In addition, the steps to produce the final *EMB-7d/7a* construct were analogous to that described for *EMB-7a/7d*. Again, all ligation sites and the exon 7 region were sequenced to verify that no errors were introduced during creation of the P element constructs. An *Eco* RI site present at the end of exon 7d was used to distinguish between the *EMB-7a/7d* and *EMB-7d/7a* DNA. When digested with *Eco* RI, the former construct produced 4 bands and the latter yielded 3 bands.

Transformation of *Drosophila* with chimeric exon 7 transgenes

To create the transgenic organisms, 600 - 800 *yw* embryos were injected with *EMB-7a/7d* or *EMB-7d/7a* DNA (0.4 mg ml^{-1}) along with Δ 2-3 helper plasmid DNA (0.06 mg ml^{-1}), serving as the source of transposase necessary for insertion of the *P* element vector into the germline DNA [20, 21]. Viable flies were crossed to the *yw* fly line; progeny resulting from these matings were screened for pigmented eyes indicating germline transformation by insertion of the *P* element vector. Standard genetic crosses with the balancer line *w*^{1118}*; CyO/Bl; TM2/TM6b* were used to map each chromosome insertion event. Individual fly lines with inserts mapping to chromosome 1 (X), 3 or 4 were crossed into a *Mhc*^{10} background, which is null for MHC production in the indirect flight and jump muscles [22], in order to eliminate endogenous MHC expression in these muscle types.

Transgene and protein expression

To determine proper transgenic expression of the altered *Mhc* gene, mRNA was extracted (RNeasy, Qiagen, Valencia, CA) from 60 – 80 transgenic fly dorsolongitudinal IFM's expressing either *EMB-7a/7d* or *EMB-7d/7a* transcripts in a *Mhc*^{10} background [22]. In separate PCR reactions, the isolated mRNA from each transgenic fly line was used as a template for primers flanking the exon 7 domain. The sequence of the primers are as follows: exon 5 (+) 5' GGCTGGTGCTGATATTGAGA 3' and exon 10 (−) 5' TGTTGGTCAGCTTCTCCGAGA 3'. Each PCR reaction amplified a 900 bp band from exon 5 to exon 10 that was subsequently ligated into the pGEM – T easy vector (Promega, Madison, WI) and sequenced to confirm the change (exon 7a/7d or 7d/7a in place of exon 7a).

Protein expression studies determined the level of myosin isoform accumulation in the IFM's of transformed flies in the *Mhc*^{10} null background [22]. The results are presented as mean ± S.E. This method was previously described [16]. For each myosin isoform, a single fly line expressing the highest level of MHC was selected for characterization. To produce EMB-7a/7d line #2 was used, which expressed at 97 ± 3% of wild-type MHC. For EMB-7d/7a line #200A was used, which expressed 105 ± 3% of wild-type MHC.

Drosophila myosin isolation and S1 preparation

Myosin was purified, according to previously described methods [12], from the IFM tissue (dorsolongitudinal fibers) of 150-180 transgenic flies expressing the MHC isoform of interest in a *Mhc*^{10} background. For myosin steady-state Mg^{2+}ATPase assays the resulting myosin pellets (300-400 μg) were resuspended in 30-50 μl of myosin storage buffer (pH 7.0: 0.5 M KCl, 20 mM MOPS, 2 mM $MgCl_2$ and 10 mM DTT). The final myosin concentration was determined at 280 nm absorbance with an extinction coefficient of $E^{1\%} = 0.53\ cm^{-1}$ [38] and a molecular mass of 200 kDa. To produce S1 by α-chymotrypsin (Worthington Biochemical Corp., Lakewood, NJ) digestion, the final myosin pellets were resuspended in 60-100 μl of digestion buffer (120 mM NaCl, 20 mM Na_2PO_4, 1 mM EDTA, pH 7.0, 4 mM DTT) and prepared as described [11]. S1 concentration was quantified at 280 nm absorbance using an extinction coefficient of $E^{1\%} = 0.75\ cm^{-1}$ and a molecular mass of 115 kDa. A typical S1 preparation yielded 100-200 μg; all purified S1 isoforms were stored on ice at 4°C and used within two weeks.

Actin isolation

F-actin was extracted from chicken skeletal muscle acetone powder and quantified using previously described methods [39]. Final actin pellets were resuspended in actin storage buffer (pH 7.0: 0.1 M KCl, 4 mM imidazole, 2 mM $MgCl_2$, 0.5 mM ATP, 1 mM sodium azide and 1 mM DTT), stored on ice at 4°C, and used within one month of preparation for actin-activated Mg^{2+}ATPase assays.

Rabbit skeletal muscle actin was used for transient kinetic experiments and prepared according to the method of Spudich and Watt [40]. Quantification of the purified actin was based on a molecular mass of 42 kDa and an extinction coefficient of $E^{1\%} = 1.104\ cm^{-1}$ at 280 nm absorbance [41]. Prior to use, rabbit F-actin was mixed with an equimolar concentration of phalloidin and incubated at 4°C for at least four hours in order to stabilize the filaments.

Steady-state Mg^{2+}ATPase assays

Myosin steady-state basal and actin-activated Mg^{2+}ATPase assays were performed immediately following purification using malachite green / ammonium molybdate to detect phosphate production according to methods described [10]. Data collected from multiple myosin preparations ($n \geq 5$) activated with 0-7.5 μM actin in a low salt buffer (20 mM KCl, 20 mM imidazole, 0.1 mM $CaCl_2$, 5 mM $MgCl_2$, pH 6.0, and 10 mM DTT) were averaged, fit with a two - parameter regression to determine the V_{max} and K_M and reported as mean ± S.E (SigmaPlot, v7.101, SPSS Inc).

Chemicals

Caged ATP (cATP) was purchased from Molecular Probes and coumarin labelled ATP (3'-O-{N-[2-(7-diethylaminocoumarin-3-carboxamido)ethyl]carbamoyl}ATP abbreviated to eda-deac ATP or ADP) was a gift from Martin Webb (National Institute for Medical Research, Mill Hill, London, UK). The cmATP (eda-deac ATP analog) was prepared for use in the transient kinetic studies according to methods previously described [42].

Flash photolysis system

Due to the small amount of protein available and the relatively poor fluorescence signal changes observed with pyrene labeled actin, flash photolysis was the method of choice to investigate the kinetic properties of the *Drosophila* myosin S1 isoforms. In particular, the ATP-induced dissociation of the acto-S1 complex and the ADP affinity, either in the presence (K_{AD}) or absence of actin (K_D), were investigated. The flash photolysis experimental system, described previously [11, 24], was used to monitor the ATP-induced dissociation of the acto-S1 complex

by following changes in the light scattering signal and to monitor the dissociation of nucleotide from S1 by fluorescence changes. In brief, the 20 μl sample was held in a quartz cuvette and ATP was liberated by a single 5 ns flash at 353 nm from a neodymium-yttrium-aluminum-garnet laser (Surelite I-10, 70 mJ maximum power) along the vertical axis of the cell at a rate of 90 s^{-1} to start the reaction. Both absorbance (to determine the ATP concentration) and light scattering (to monitor the acto-S1 complex) or fluorescence (to determine eda-deac ADP release) were measured from the cuvette simultaneously following the laser flash. White light > 389 nm was introduced to the sample from a 100 watt halogen lamp and the change in the amount of light scattered at 90° was monitored after each flash. The absorbance at 405 nm was measured with a monochromator to determine the amount of ATP liberated from caged ATP during each laser flash. Coumarin fluorescence changes were detected by monitoring the emission through a 455 nm cut-off filter after excitation at 434 nm (75-watt xenon/mercury lamp).

All light scattering experiments were conducted in a low salt buffer (pH 7.0: 30 mM KCl, 5 mM $MgCl_2$, 20 mM MOPS and 4 mM DTT) with 1 μM actin, 1-3 μM S1, 500 μM cATP, 10 mM DTT and either apyrase (2 units/ml: ATP-induced dissociation of acto-S1) or ADP (various concentrations) and a glucose-hexokinase system (0.03 units/ml hexokinase, 1 mM glucose and 100 μM Ap_5A: K_{AD} determination). Each sample was subjected to multiple laser flashes. During K_{AD} determination ADP and cATP were added after each flash. eda-deac ADP dissociation experiments were also performed in this low salt buffer and contained 4 μM S1, 10 μM eda-deac ATP (source of eda-deac ADP) and 100 μM cATP.

Analysis of the transient kinetic data

The following equation was derived from the interaction of actin and S1 with ATP and ADP shown in Scheme 1 and was used to determine K_{AD}.

$$k_{obs} = K_1 k_{+2}\left([\mathrm{ATP}] / \left(1 + [\mathrm{ADP}] / K_{AD}\right)\right) \qquad \text{(equation 1)}$$

where k_{obs} is the observed rate constant for the ATP-induced dissociation of acto-S1; K_1k_{+2} is the second-order rate constant for ATP binding to acto-S1; K_{AD} is the equilibrium dissociation constant for the binding of ADP to acto-S1. The equation $k_{rel} = k_{obs}/k_o$ was used to determine the relative rate constant (k_{rel}) shown in Figure 6, where k_o is the value when the [ADP] = 0.

Homology Modeling:

Three-dimensional homology models were generated for the *Drosophila* IFI and EMB myosin motor domain and the exon 7 mutants using the SWISS-MODEL automatic comparative protein modeling server, as described previously [43]. Briefly, SWISS-MODEL uses four steps: template superposition, target-template alignment, model building and energy minimization. The templates are weighted by their sequence similarity to the target and significantly deviating atom positions are excluded. Since the template coordinates cannot be used to model regions with insertions or deletions in the target-template alignment, an ensemble of fragments compatible with the neighboring stems is generated using constraint space programming (CSP). The best loop is selected using a scoring scheme which includes force field energy, steric hindrance and hydrogen bond formation. If no suitable loop can be identified, the flanking residues are included in the rebuilt fragment to allow for more flexibility. Reconstruction of the model side-chains is based on weighted positions of corresponding residues in the template structures. Starting with conserved residues, the model side-chains are built by iso-sterically replacing template structure side-chains. Possible side-chain formations are selected from a backbone dependent rotamer library and the most likely conformation is selected using a scoring function that assesses favorable interactions (e.g. hydrogen-bonds, disulphide bridges) and unfavorable close contacts. Finally, the generated model is subjected to steepest descent

energy minimization using the GROMOS96 force field. The primary sequences of the *Drosophila* IFI and EMB isoform were pairwise aligned with the sequence of four scallop myosin structures as templates (ExPDB 1kk8, 1qvi, 1s5g and 1sr6) using the CLUSTALW alignment protocol. The alignments were then submitted to the alignment interface of SWISS-MODEL and the generated models were validated using WHAT CHECK [44].

Acknowledgements

This work was supported by NIH research grant GM32443 (to SIB), Wellcome Trust Grant 070021 (to MAG and MJB), Hungarian National Research Foundation grants K60186 and K60968 (to MN), and a predoctoral fellowship (to BMM) from the Western States Affiliate of the American Heart Association. M.N. holds a Wellcome Trust International Senior Research Fellowship in Biomedical Sciences. We thank Martin Webb for the coumarin ATP/ADP used in this work and Corey Dambacher for excellent technical assistance. In addition, we thank Dr. Douglas Swank for helpful comments on the manuscript.

The following abbreviations were used in the manuscript

ATP, adenosine triphosphate; MHC, myosin heavy chain; EMB, embryonic body wall muscle; IFI, indirect flight muscle isoform; IFM, indirect flight muscle; eda-deac ADP, coumarin ADP; cATP, caged ATP; ADP, adenosine diphosphate.

Scheme 1.

The interaction of S1 with actin, ATP and ADP. M, A, T and D symbolize S1, actin, ATP and ADP, respectively.

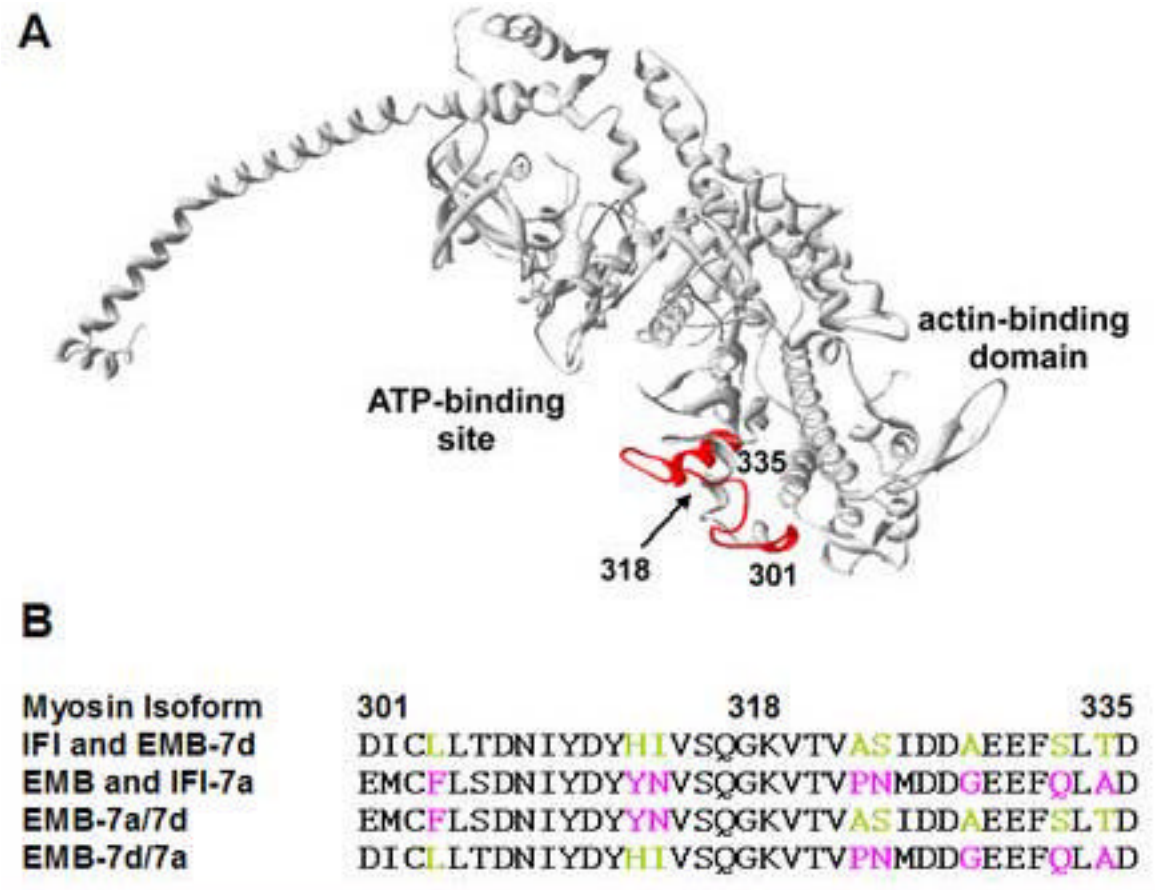

Figure 1.

Location and amino acid sequence of the *Drosophila* exon 7 domain

A) The chicken skeletal S1 crystal structure minus the light chains (2MYS.pdb) is shown with residues 301-335, which correspond to the *Drosophila* exon 7 domain, colored red; the location of residues 301, 318 and 335 are indicated. To create EMB-7a/7d and EMB-7d/7a myosin isoforms, the exon 7 sequence was split in half: 1) 301-318 (surface domain) and 2) 319-335 (lip domain). In EMB-7d/7a, the 7a surface domain was replaced by 7d and in EMB-7a/7d the 7a lip domain was replaced by 7d. B) The sequences of exon 7 in the IFI, EMB and four chimeric isoforms are aligned; nonconserved residues are colored according to their origin (IFI/exon 7d are green and EMB/exon 7a are magenta).

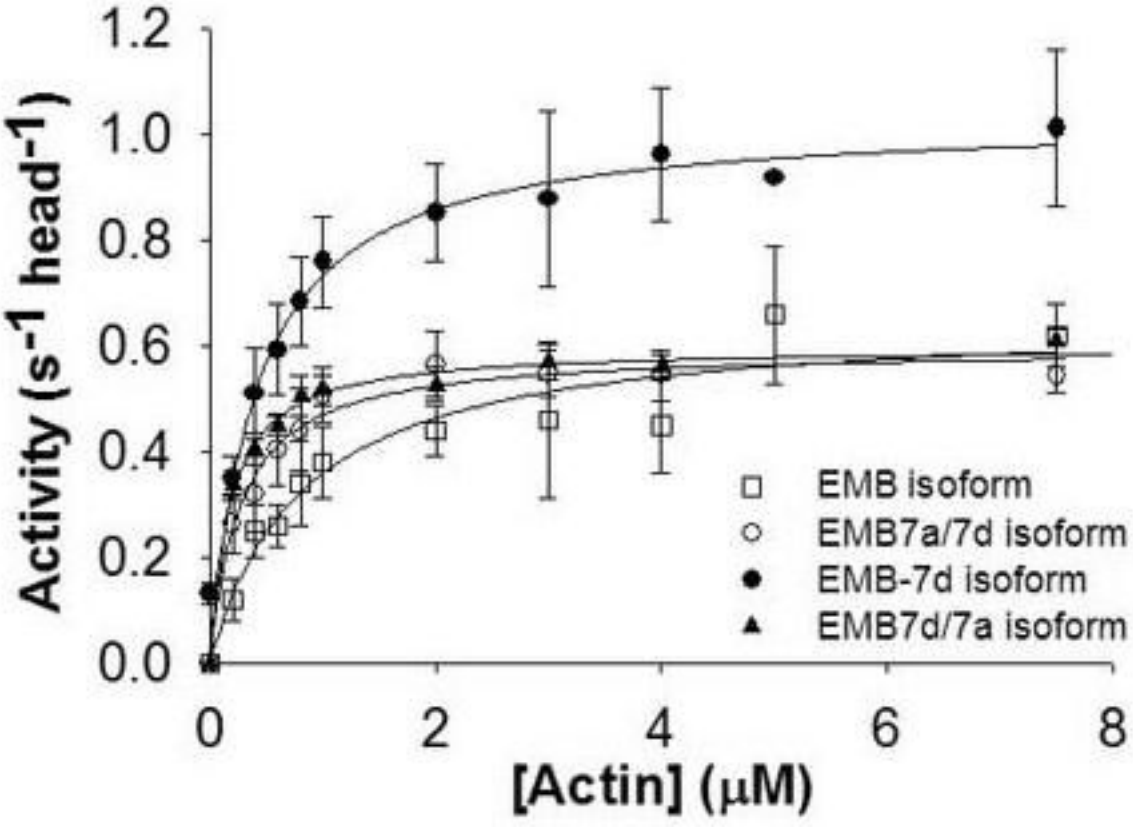

Figure 2.

Actin-activated Mg^{2+}ATPase activity of EMB-7a/7d and EMB-7d/7a isoforms

The maximal actin-activated ATPase activities for the exon 7 domain chimeric myosin isoforms (closed triangles: EMB-7d/7a, open circles: EMB-7a/7d) show no difference compared to the EMB isoform (open squares) but are decreased relative to the EMB-7d isoform (closed circles). Data were collected and fit with $V = V_{max}$ [actin] / (K_M + [actin]) to determine V_{max} and K_M (Table 1). EMB data are from Littlefield et al. [10] and EMB-7d data are from Miller et al [16].

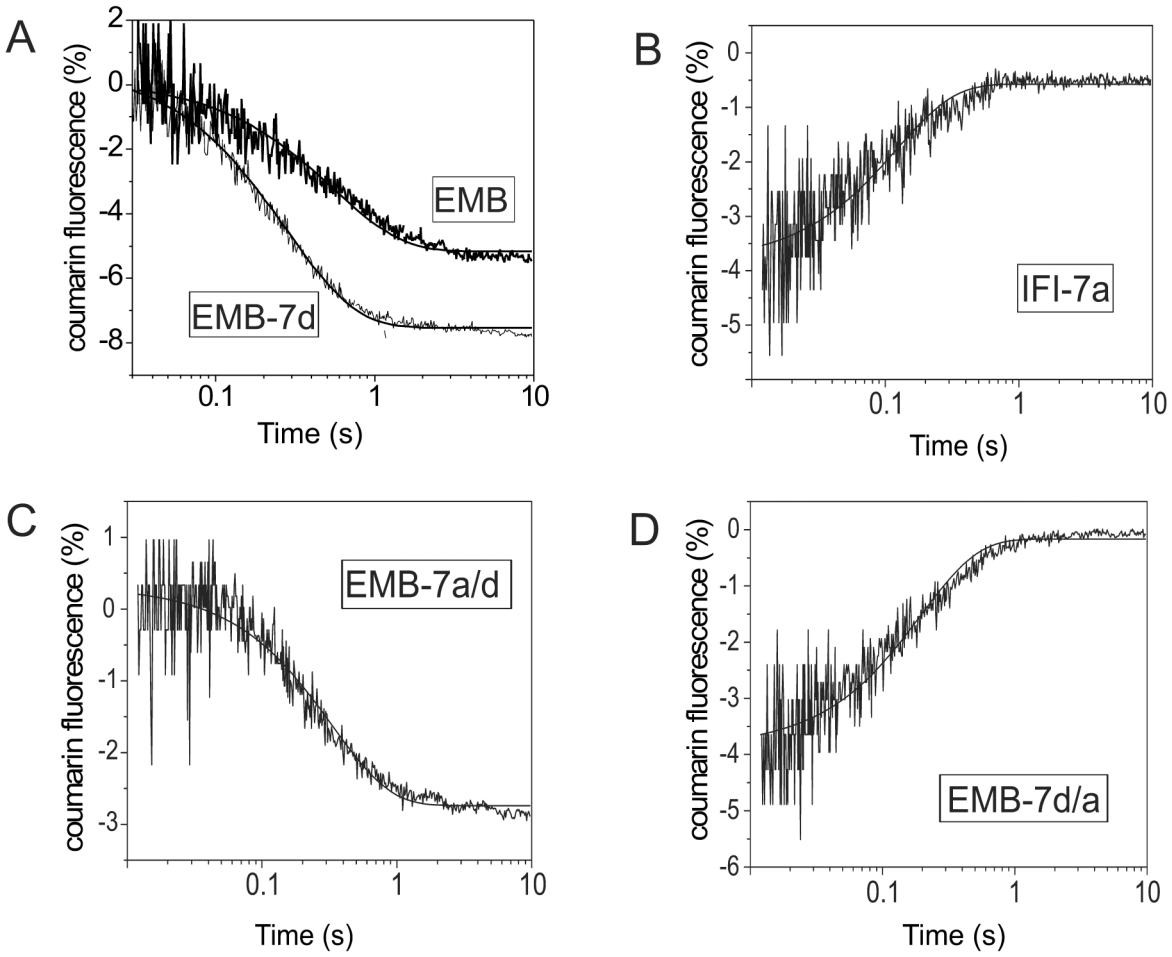

Figure 3.

Rate of eda-deac ADP dissociation (k_{-D}) from *Drosophila* S1 isoforms

The rate constant for ADP dissociation (k_{-D}) from S1 in the absence of actin was determined. Addition of ATP (15 μM) from cagedATP (100 μM) by a single laser flash displaced the eda-deac ADP bound to S1. The change in eda-deac ADP fluorescence upon release from S1 was measured and fit with a single exponential to determine k_{-D}. Exchange of either the exon 7a or 7d domain resulted in a modulation of the eda-deac ADP release rate. The dissociation rate for EMB-7d (A: 4.3 s^{-1}) is faster than EMB (A: 1.8 s^{-1}) while that of IFI-7a (B: 4.7 s^{-1}) is slower than IFI (7.5 s^{-1}). The observed rate constant of eda-deac ADP dissociation (k_{-D}) from EMB-7a/7d (C) and EMB-7d/7a (D) S1 gave mean values of 6.1 s^{-1} and 2.6 s^{-1}, respectively. The conditions were: 20 mM MOPS, 30 mM KCl, 5 mM $MgCl_2$, 10 mM DTT, pH 7.

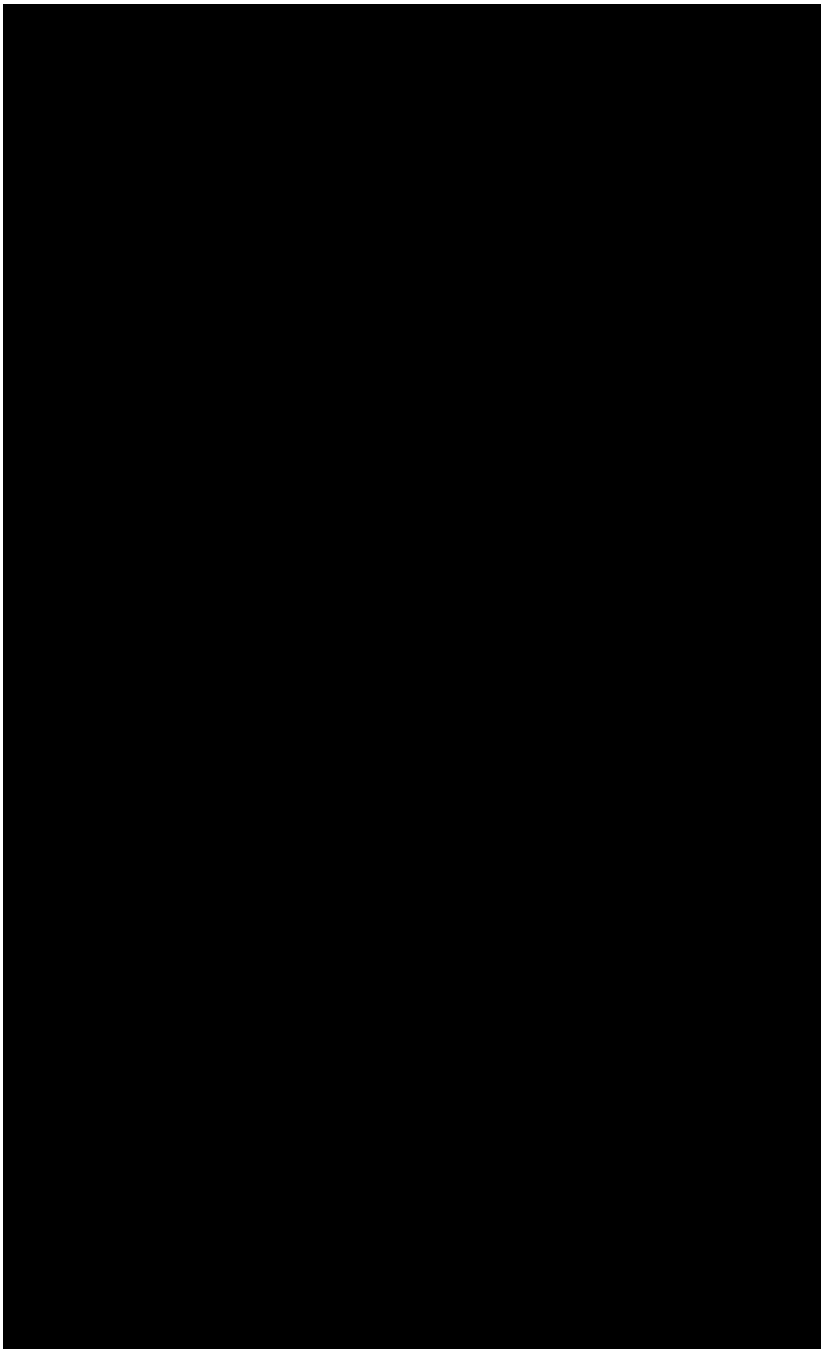

Figure 4.

Kinetic determination of the ATP-induced dissociation rate (K_1k_{+2}) of the S1 isoforms from actin

The second order rate constant for the dissociation of S1 from actin is determined from a linear fit to the plot of the k_{obs} vs. [ATP]. Light scattering transients monitoring dissociation of the acto-S1 complex (data not shown) were fitted with a single exponential at each ATP concentration in order to determine the k_{obs}. A) The linear fits yielded values of 0.33 ± 0.07 10^6 M^{-1} s^{-1} for IFI-7a (filled triangles) as compared to as compared to 0.75 ± 0.08 10^6 M^{-1} s^{-1} for IFI (open triangles). B) The linear fits yielded mean values of 0.67 ± 0.18 10^6 M^{-1} s^{-1} for EMB-7a/7d S1 (filled triangles) and 0.66 ± 0.14 10^6 M^{-1} s^{-1} for EMB-7d/7a S1 (open

triangles) as compared to 0.91 ± 0.13 10^6 M^{-1} s^{-1} for EMB S1 (empty squares) and 0.64 ± 0.05 10^6 M^{-1} s^{-1} for EMB-7d S1 (closed squares).

Figure 5.

The affinity of ADP (K_{AD}) for acto-S1

The dissociation of acto-S1 was induced by ATP in the presence of ADP ranging from 0-1500 μM. The light scattering traces were fitted with single exponentials to determine the k_{obs}. Hyperbolic plots of the k_{obs} vs. ADP concentration were fitted with an equation derived from Scheme 1 ($k_{obs} = K_1k_{+2}([ATP]/(1 + [ADP]/K_{AD}))$ to determine K_{AD}. Shown are the relative k_{obs} (k_{rel}) vs. ADP concentration plots for easier comparison. A) The fits yielded a value of 607 ± 44 μM for EMB-7d (empty squares) as compared to 587 ± 38 μM for EMB (filled squares). B) The fits yielded values of 409 ± 26 μM (open circles) for IFI and 239 ± 32 μM for IFI-7a (closed circles). The K_{AD} for EMB-7a/7d (C) and EMB-7d/7a (D) S1 isoforms were measured with the following alterations. The dissociation of acto-S1 was calculated in the presence of 0 – 400 μM ADP and the K_{AD} for EMB-7a/7d S1 was determined to be the ADP concentration at 50% inhibition. All preparations for EMB-7a/7d produced the sigmoidal-shaped curve observed here. The fits yielded values of 191 ± 59 μM for EMB-7a/7d and 220 ± 33 μM for EMB-7d/7a.

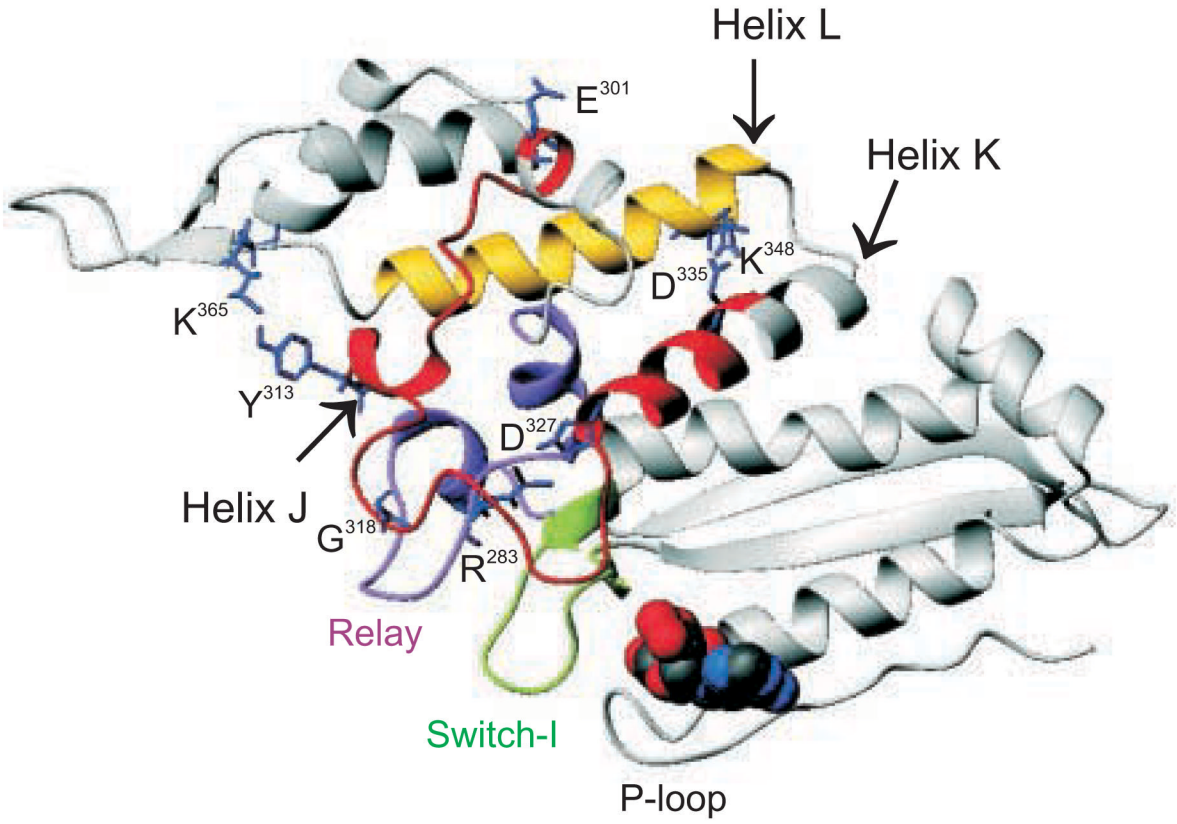

Figure 6.

Interactions of the exon 7 domain with nearby structural elements

Homology model of IFI in the pre-power-stroke state (ExPDB 1qvi: bound nucleotide is ADP-VO4), showing the exon 7 area (residues 301-335 in red), the relay area (magenta), switch I (green) and helix L (yellow). The highly conserved salt-bridge between exon 7 residue D^{327} and relay area residue R^{283} is indicated. Note the proximity of switch I toward the relay area. Interactions from the non-conserved exon 7 residues Y^{313} and D^{327} toward helix L (yellow) are also shown.

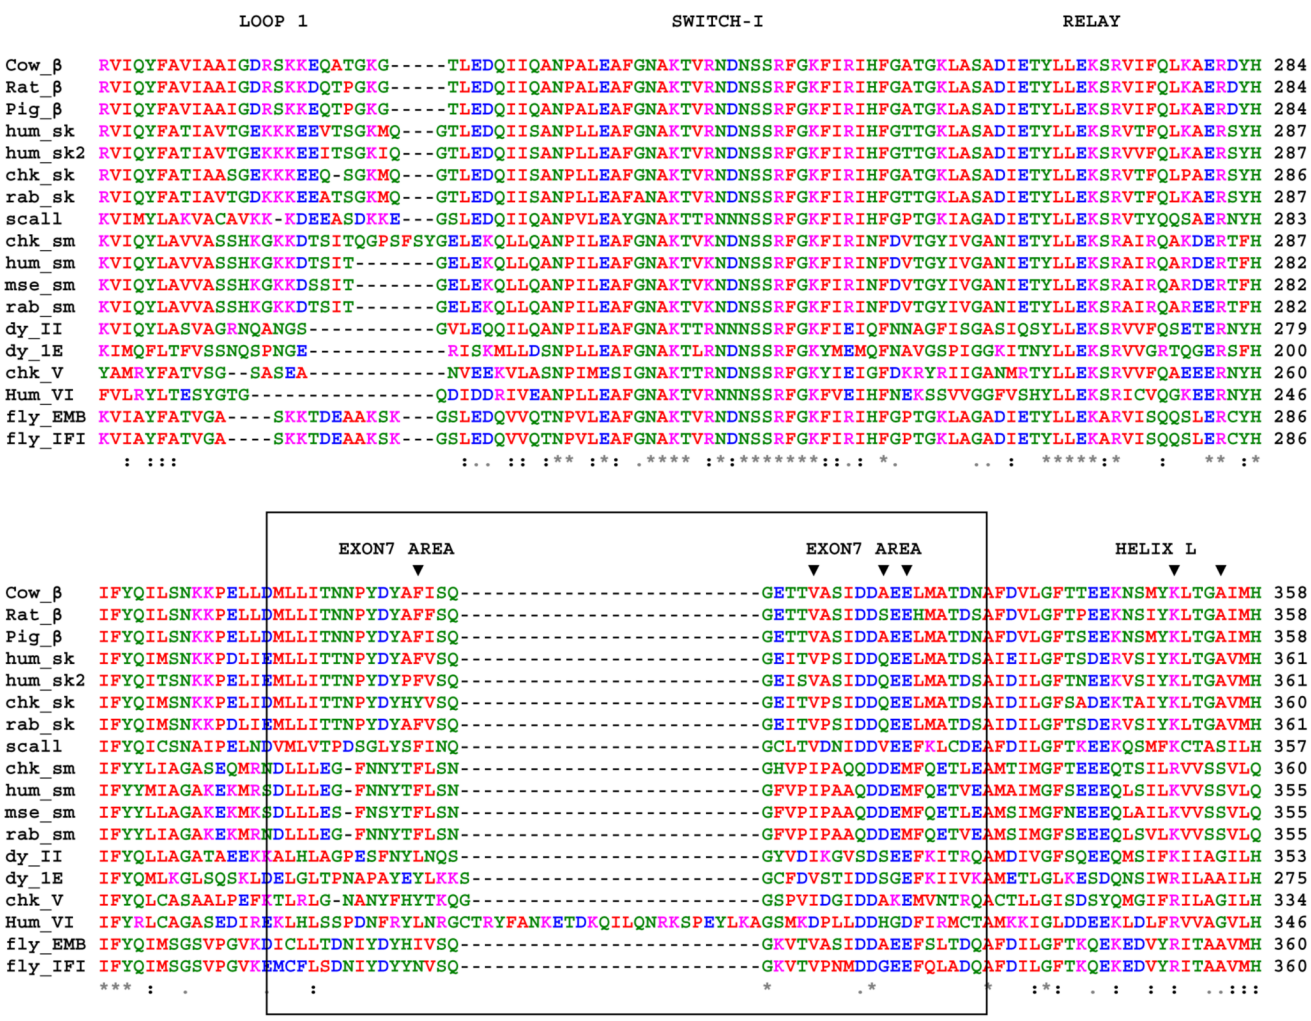

Figure 7.

Myosin sequence alignments

Sequence alignment of various myosins showing exon 7 (in the boxed area), together with loop 1, switch I and the relay area. "*" means that the residues are identical in all sequences in the alignment."**:**" represents conserved substitutions, whereas "**.**" indicates semi-conserved substitutions. Only two residues in exon 7 are 100 % conserved (G^{318} and D^{327}) of which D^{327} forms a salt-bridge towards the highly conserved R^{283} (scallop numbering). Note that myosin VI has an insert in the middle of the exon 7 domain. The corresponding cardiomyopathy sites in the exon 7 domain and helix L are indicated with a ▼.

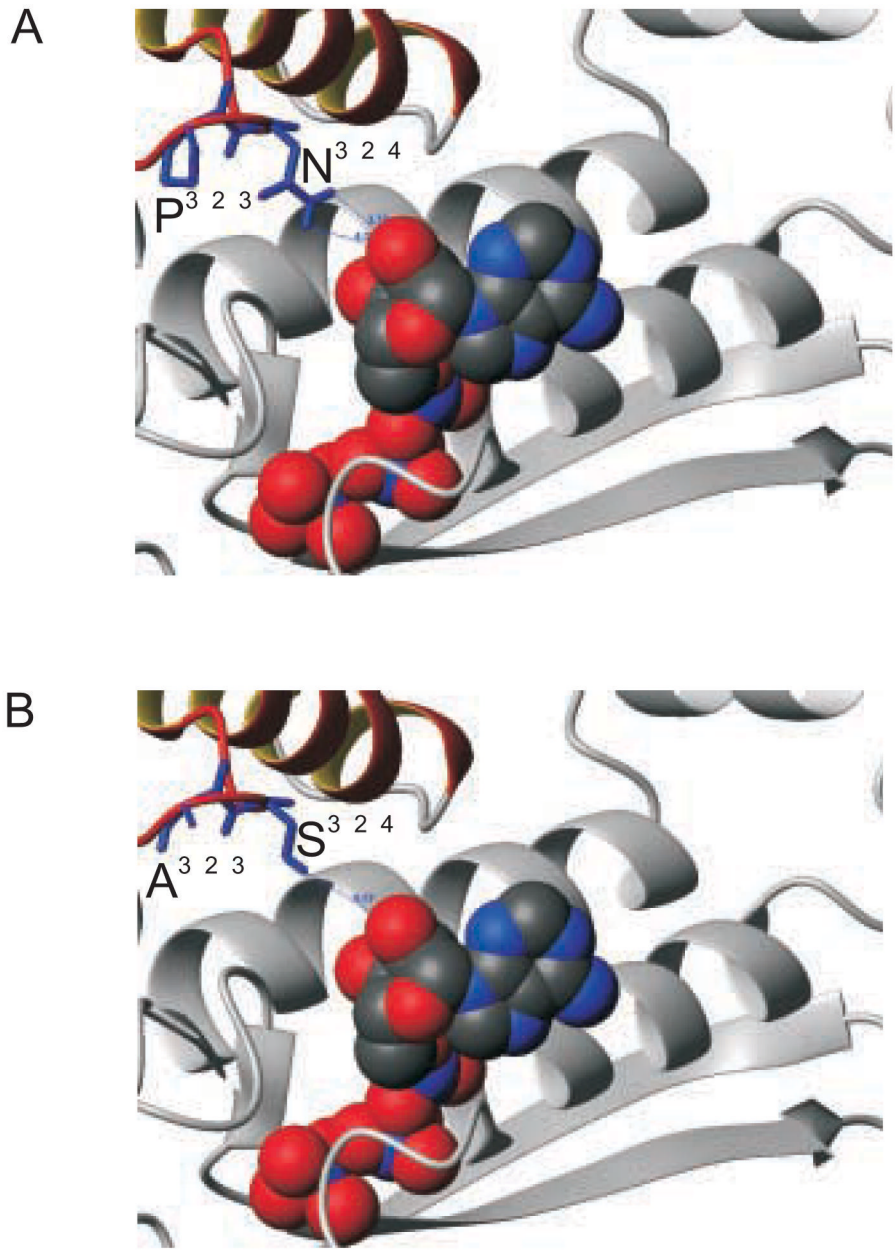

Figure 8.

Interactions of residue 324 with the nucleotide

Close-up of the interactions between exon 7 residue 324 and the bound nucleotide in the prepowerstroke state. Inspection of the homology models indicates that the H-donor of the asparagine side-chain found in the exon 7d region (A) is almost 1 Å closer to the nucleotide oxygen than the H-donor of the serine side-chain found in 7a (B).

Table 1

Steady-state kinetic parameters for the exon 7 domain chimeric myosin isoforms

Myosin Isoform	EMB[a]	EMB-7d[a]	EMB-7a/7d	EMB-7d/7a
Basal ATPase rate (s^{-1} $head^{-1}$)	0.07 ± 0.01	0.13 ± 0.02	0.06 ± 0.01[b]	0.08 ± 0.02[b]
V_{max} (s^{-1} $head^{-1}$)	0.7 ± 0.05 (5)	0.91 ± 0.04 (6)	0.6 ± 0.02 (5)	0.6 ± 0.01 (5)
K_M actin (μM)	0.8 ± 0.2	0.5 ± 0.09	0.3 ± 0.04[c]	0.2 ± 0.02[c]

Values are the mean ± S.E. with parentheses indicating the number of preparations.

[a] EMB data are from Littlefield et al. [10] and EMB-7d data are from Miller et al. [16]

[b] $p < 0.05$ determined by Student's t-test as compared to EMB-7d

[c] $p < 0.05$ determined by Z-test on the parameter fits of V_{max} and K_M (EMB-7a/7d and EMB-7d/7a vs. EMB-7d or EMB)

Table 2

Transient kinetic parameters measured for the exon 7 chimeric S1 isoforms Values are mean ± S.D. based on a minimum of 3 preparations. K_1k_{+2} is the second order rate constant for ATP-induced dissociation of acto-S1. K_D and K_{AD} are dissociation equilibrium constants determined by division of the dissociation rate constant by the association rate constant (e.g. $K_3 = k_{-3} / k_{+3}$). k_{-D} and k_{-AD} are the ADP dissociation rate constants in the absence and presence of actin, respectively. K_{AD} / K_D is the thermodynamic coupling constant describing the relationship between actin and ADP affinities [28].

S1 Isoform	IFI†	IFI-7a	EMB†	EMB-7d	EMB-7a/7d	EMB-7d/7a
K_1k_{+2} (10^6 M^{-1} s^{-1})	0.75 ± 0.08	0.33 ± 0.07	0.91 ± 0.13	0.64 ± 0.05	0.67 ± 0.18	0.66 ± 0.14
k_{-D} (s^{-1})	7.5 ± 1.3[d]	4.7 ± 0.8,[cd]	1.8 ± 0.4[c]	4.3 ± 0.7,[cd]	2.6± 0.04,[cd]	6.1 ± 0.08[d]
K_D (μM)[a]	7.5	4.7	1.8	4.3	2.6	6.1
K_{AD} (μM)	409 ± 26[d]	239 ± 52,[cd]	587 ± 48[c]	596 ± 39[c]	191 ± 59,[cd]	220 ± 33,[cd]
k_{-AD} (s^{-1})[b]	4090	2390	5870	5960	1910	2200
K_{AD} / K_D	55	51	326	139	73	36

[a] Data are estimated from k_{-D} assuming an association rate constant of 10^6 M^{-1} s^{-1}.

[b] Data are estimated from K_{AD} assuming an association rate constant of 10^7 M^{-1} s^{-1}.

† Data are from Miller et al. [11]

[c] $p < 0.05$ determined by Student's t-test as compared to IFI

[d] $p < 0.05$ determined by Student's t-test as compared to EMB
