**ABSTRACT** Fluorescence and electrophysiological methods were used to determine the effects of intracellular pH ( $\text{pH}_i$ ) on cellular  $\text{NH}_4^+/\text{K}^+$  transport pathways in the renal medullary thick ascending limb of Henle (MTAL) from CD1 mice. Studies were performed in suspensions of MTAL tubules (S-MTAL) and in isolated, perfused MTAL segments (IP-MTAL). Steady-state  $\text{pH}_i$  measured using 2,7-bis(carboxyethyl)-5(6)-carboxyfluorescein (BCECF) averaged  $7.42 \pm 0.02$  (mean  $\pm$  SE) in S-MTAL and  $7.26 \pm 0.04$  in IP-MTAL. The intrinsic cellular buffering power of MTAL cells was  $29.7 \pm 2.4$  mM/ $\text{pH}_i$  unit at  $\text{pH}_i$  values between 7.0 and 7.6, but below a  $\text{pH}_i$  of 7.0 the intrinsic buffering power increased linearly to  $\sim 50$  mM/ $\text{pH}_i$  unit at  $\text{pH}_i$  6.5. In IP-MTAL,  $\text{NH}_4^+$  entered cells across apical membranes via both  $\text{Ba}^{2+}$ -sensitive pathway and furosemide-sensitive  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport mechanisms. The  $K_{0.5}$  and maximal rate for combined apical entry were 0.5 mM and 83.3 mM/min, respectively. The apical  $\text{Ba}^{2+}$ -sensitive cell conductance in IP-MTAL ( $G_c$ ), which reflects the apical  $\text{K}^+$  conductance, was sensitive to  $\text{pH}_i$  over a  $\text{pH}_i$  range of 6.0–7.4 with an apparent  $K_{0.5}$  at  $\text{pH}_i$ ,  $\sim 6.7$ . The rate of cellular  $\text{NH}_4^+$  influx in IP-MTAL due to the apical  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway was sensitive to reduction in cytosolic pH whether  $\text{pH}_i$  was changed by acidifying the basolateral medium or by inhibition of the apical  $\text{Na}^+:\text{H}^+$  exchanger with amiloride at a constant  $\text{pH}_o$  of 7.4. The  $\text{pH}_i$  sensitivities of  $G_c$  and apical,  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  influx in IP-MTAL were virtually identical. The  $\text{pH}_i$  sensitivity of the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  influx in S-MTAL when exposed to (apical + basolateral)  $\text{NH}_4\text{Cl}$  was greater than that observed in IP-MTAL where  $\text{NH}_4\text{Cl}$  was added only to apical membranes, suggesting an additional effect of intracellular  $\text{NH}_4^+/\text{NH}_3$  on  $\text{NH}_4^+$  influx.  $\text{NH}_4^+$  entry via apical  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport in IP-MTAL was somewhat more sensitive to reductions in  $\text{pH}_i$  than the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  influx pathway;  $\text{NH}_4^+$  entry decreased by  $52.9 \pm 13.4\%$  on reducing  $\text{pH}_i$  from  $7.31 \pm 0.17$  to  $6.82 \pm 0.14$ . These results suggest that  $\text{pH}_i$  may provide a negative feedback signal for regulating

the rate of apical  $\text{NH}_4^+$  entry, and hence transcellular  $\text{NH}_4^+$  transport, in the MTAL. A model incorporating these results is proposed which illustrates the role of both  $\text{pH}_i$  and basolateral/intracellular  $\text{NH}_4^+/\text{NH}_3$  in regulating the rate of transcellular  $\text{NH}_4^+$  transport in the MTAL.

#### INTRODUCTION

The regulated excretion of  $\text{NH}_4^+$  by the kidney is required for maintenance of systemic acid/base balance.  $\text{NH}_4^+$  is synthesized in renal proximal tubule cells (Good and Burg, 1984) and preferentially secreted into the lumen of this nephron segment (Nagami and Kurokawa, 1985). Further downstream along the nephron, the thick ascending limb of Henle (TAL) actively reabsorbs  $\text{NH}_4^+$  (Good and Burg, 1984; Good, Knepper, and Burg, 1984; Knepper, Packer, and Good, 1989). It has been proposed that  $\text{NH}_4^+$  reabsorption by the TAL plays a major role in the maintenance of a high medullary interstitial concentration of  $\text{NH}_4^+$ , which in turn permits regulation of  $\text{NH}_4^+$  excretion independently of  $\text{H}_2\text{O}$  excretion by the terminal portion of the nephron (Knepper et al., 1989).

Good et al. (1984) have shown that  $\text{NH}_4^+$  absorption in the isolated perfused TAL occurs in the absence of a favorable transepithelial pH gradient, indicating that transepithelial pH trapping of  $\text{NH}_3$  as  $\text{NH}_4^+$  is not responsible for  $\text{NH}_4^+$  reabsorption in the TAL. We have recently described the cellular mechanisms by which the mouse medullary segment of the TAL (MTAL) mediates active, transepithelial, pH-independent, transcellular  $\text{NH}_4^+$  transport under isotonic conditions (Kikeri, Sun, Zeidel, and Hebert, 1989). These studies demonstrated that mouse MTAL cells are polarized such that apical membranes are virtually impermeable to  $\text{NH}_3$  but highly permeable to  $\text{NH}_4^+$ , while basolateral membranes are highly permeable to  $\text{NH}_3$  (Kikeri et al., 1989).  $\text{NH}_4^+$  enters mouse MTAL cells from the lumen via both an apical  $\text{Ba}^{2+}$ -sensitive pathway (possibly an apical  $\text{K}^+$  channel) and apical furosemide/bumetanide-sensitive  $\text{Na}^+:\text{K}^+:2\text{Cl}^-$  cotransport (Kikeri et al., 1989).  $\text{NH}_4^+$  appears to be carried on the  $\text{K}^+$  site of the  $\text{Na}^+:\text{K}^+:2\text{Cl}^-$  cotransporter in the TAL ( $\text{Na}^+:\text{K}^+[\text{NH}_4^+]:2\text{Cl}^-$  cotransport [Kinne, Kinne-Saffran, Schuetz, and Schloelermann, 1986]).  $\text{NH}_4^+$  exit from mouse MTAL cells occurs by  $\text{H}^+$  extrusion via apical  $\text{Na}^+:\text{H}^+$  exchange coupled to diffusion of  $\text{NH}_3$  across basolateral membranes (Kikeri et al., 1989). The lumen-positive transepithelial voltage in the mouse MTAL, which is due to  $\text{NaCl}$  absorption (Hebert and Andreoli, 1984), may provide the driving force for the transport of protons from the lumen to the basolateral (interstitial) medium via the cation-selective paracellular pathway (Kikeri et al., 1989).

Because of the unusually high  $\text{NH}_4^+$  permeability of apical membranes of MTAL cells, exposure to either apical or apical plus basolateral  $\text{NH}_4\text{Cl}$  results in a large cell acidification (Kikeri et al., 1989). Thus,  $\text{NH}_4^+$  absorption by the MTAL is associated with potentially lethal reductions in  $\text{pH}_i$ . Some of the possible factors that could limit the magnitude of the  $\text{NH}_4^+$ -induced acidification of TAL cells include (a) the cellular buffering power, (b) acid extrusion via  $\text{Na}^+:\text{H}^+$  exchange (Kikeri, Azar, Sun, Zeidel, and Hebert, 1990a) and possibly via an  $\text{H}^+$ -ATPase (Brown, Hirsch, and Gluck, 1988; Kikeri et al., 1990a), and (c) feedback inhibition of  $\text{NH}_4^+$  entry pathways by either the  $\text{NH}_4^+$ -induced cell acidification or by intracellular  $\text{NH}_4^+/\text{NH}_3$  itself (Oberleithner, Munich, Schwab, and Dietl, 1986; Paris and Pouyssegur, 1986). This latter possibility

was suggested by our earlier observation that the apical  $\text{NH}_4^+$  entry pathways in the mouse MTAL (i.e.,  $\text{K}^+$  channels and  $\text{Na}^+:\text{K}^+:2\text{Cl}^-$  cotransporters) did not appear to mediate significant exit of  $\text{NH}_4^+$  from acidified cells (Kikeri et al., 1989).

The purpose of this study was to evaluate whether some or all of the aforementioned factors contribute to modulating the effects of  $\text{NH}_4^+$  transport on  $\text{pH}_i$  in the mouse MTAL. Specifically, we used both the isolated perfused MTAL tubule and suspensions of MTAL tubules/cells from CD1 mice to determine the magnitude of the intracellular buffering power of MTAL cells and to assess the effects of  $\text{pH}_i$  on  $\text{NH}_4^+$  entry into MTAL cells via the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway and  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter. Intracellular pH transients due to  $\text{NH}_4^+$  entry into MTAL cells were measured using 2,7-biscarboxyethyl-5(6)-carboxyfluorescein (BCECF) and rates of  $\text{NH}_4^+$ -dependent  $\text{H}^+$  flux calculated using the intrinsic cellular buffer power. The results of these studies support the view that both  $\text{pH}_i$  and basolateral/intracellular  $\text{NH}_4^+/\text{NH}_3$  play an important role in regulating the rates of cellular  $\text{NH}_4^+$  entry via the  $\text{Ba}^{2+}$ -sensitive pathway and  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport in MTAL cells. In addition, we have incorporated these results into a model that illustrates the role of both  $\text{pH}_i$  and  $\text{NH}_4^+/\text{NH}_3$  in regulating  $\text{NH}_4^+$  absorption by the MTAL.

## METHODS

### *Cell Preparations*

Two MTAL cell preparations from CD1 mice were used: suspensions of MTAL tubules (S-MTAL) and the isolated perfused MTAL (IP-MTAL).

S-MTAL were prepared as described previously (Kikeri et al., 1990a). Briefly, the inner stripe of the outer medulla from the kidneys of three to six mice were isolated and subjected to collagenase digestion; thereafter, MTAL tubules were separated from other tubule fragments by sedimentation through 3 g/dl albumin. The vast majority of tubules in these suspensions (>97%) were (a) morphologically identical to MTAL tubules in vivo, and (b) labeled with anti-Tamm Horsfall antibody, indicating that these suspensions consisted almost purely of MTAL tubules (Kikeri et al., 1990a). MTAL tubules in suspensions were functionally intact since they exhibited high rates of ouabain-sensitive (transport-related) oxygen consumption that was inhibited by either furosemide or bumetanide, and responded to arginine vasopressin by accumulating cyclic AMP (Kikeri et al., 1990a). In addition, these tubules had open lumens, allowing access of drugs/ions/inhibitors to apical membranes (Kikeri et al., 1990a). The advantages of using S-MTAL preparations include ease of preparation and the ability to obtain a large number of paired measurements in a single preparation. We have shown previously that transport data obtained in S-MTAL preparations were virtually identical to those obtained in IP-MTAL tubules (Kikeri et al., 1989, 1990a).

In experiments using IP-MTAL, tubules were isolated from the inner stripe of the outer medulla and perfused in vitro using methods previously described in detail (Hebert, Culpepper, and Andreoli, 1981a; Hebert and Andreoli, 1984, 1986). The perfused MTAL segments were 0.2–0.3 mm in length. Use of the IP-MTAL permitted evaluation of the sidedness (i.e., polarity) of transport processes.

### *Measurement of $\text{pH}_i$*

Intracellular pH ( $\text{pH}_i$ ) was measured in S-MTAL or IP-MTAL with BCECF using methods described by us previously (Kikeri et al., 1989, 1990a). BCECF-loaded MTAL tubules (S-MTAL

and IP-MTAL) exhibited uniform fluorescence at both 495 and 440 nm. Background fluorescence intensities (including cellular autofluorescence) were typically <1–2% of the total fluorescence after loading with BCECF.

*S-MTAL.* Tubule suspensions were transiently exposed (15 min at 25°C) to 2.5  $\mu\text{M}$  of the tetra-acetoxymethyl ester of BCECF (BCECF-AM) and then washed free of extracellular dye. Fluorescence was monitored at 37°C in a computer-controlled SLM-Aminco SPF-500C spectrofluorometer (SLM Instruments, Inc., Urbana, IL) equipped with a water-jacketed, temperature-controlled cuvette holder and magnetic stirrer. A 50–75- $\mu\text{l}$  aliquot of BCECF-loaded S-MTAL was diluted into a plastic cuvette containing 3 ml of medium and fluorescence was monitored at 530 nm emission wavelength, while the excitation wavelength rapidly alternated between 500 and 440 nm. After each experiment, the cells were pelleted in a microcentrifuge and the fluorescence of the extracellular medium was measured at both 500 and 440 nm. By subtracting the extracellular fluorescence intensities at 500- and 440-nm excitation wavelengths from the respective total fluorescence intensities obtained during the preceding experiment (due to intracellular + extracellular dye), fluorescence intensities due to intracellular dye were obtained (Kikeri et al., 1990a). We have previously shown that leakage of BCECF from S-MTAL occurs at very low rates (Kikeri et al., 1990a). The high  $\text{K}^+$  (110 mM)/nigericin (5  $\mu\text{M}$ ) method of Thomas, Buchsbaum, Zimniak, and Racker (1979) was used to convert intracellular 500 nm/440 nm excitation ratios to units of  $\text{pH}_i$  over a  $\text{pH}_i$  range of 6.3–8 as described previously in detail by us (Kikeri et al., 1990a). Experiments were performed at 37°C in  $\text{CO}_2/\text{HCO}_3^-$ -free medium containing (mM): 140  $\text{Na}^+$ , 5  $\text{K}^+$ , 148 mM  $\text{Cl}^-$ , 1  $\text{Ca}^{2+}$ , 1  $\text{Mg}^{2+}$ , 1  $\text{PO}_4^{3-}$ , 20 mannitol, 10 glucose, 10 HEPES, and 0.2 g/dl albumin, equilibrated with 100%  $\text{O}_2$ , pH 7.4.

*IP-MTAL.* Standard  $\text{CO}_2/\text{HCO}_3^-$ -free perfusing and bathing media contained (mM): 140  $\text{Na}^+$ , 5  $\text{K}^+$ , 149.4  $\text{Cl}^-$ , 1  $\text{Ca}^{2+}$ , 1.2  $\text{Mg}^{2+}$ , 3 HEPES, 5 L-alanine, and 5.5 glucose, equilibrated with 100%  $\text{O}_2$ , pH 7.4, at 37°C. Bathing media also contained 0.2 g/dl Fraction V BSA.  $\text{NH}_4\text{Cl}$ , when added, replaced an equimolar amount of  $\text{NaCl}$  so that total osmolality and ionic strength remained constant. The perfusion flow rate was maintained between 10 and 20 nl/min, which is sufficient to minimize axial changes in perfusate ion concentrations and to chemically clamp the spontaneous transepithelial voltage along the length of the tubule. The flow rate of the bathing medium was maintained at 10–15 ml/min, which is sufficient to change completely the bath solution in <5 s (Hebert, Culpepper, and Andreoli, 1981b). Tubules were loaded with BCECF by transient exposure (10 min) to 10  $\mu\text{M}$  BCECF-AM in the bathing medium. Fluorescence was alternately measured at excitation wavelengths of 495 and 440 nm (emission wavelength = 530 nm) using a computer-controlled inverted fluorescence microscope system (Carl Zeiss, Inc., Thornwood, NY) (Boyarsky, Ganz, Sterzel, and Boron, 1988; Kikeri et al., 1989, 1990a). Background fluorescence was subtracted from fluorescence intensity at each excitation wavelength to obtain intensities of intracellular fluorescence.

Calibration runs relating 495 nm/440 nm excitation ratio and  $\text{pH}_i$  (over a  $\text{pH}_i$  range of 6.2–7.7) were performed in three perfused tubules using medium containing 110 mM  $\text{K}^+$  and 5  $\mu\text{M}$  nigericin (medium pH 6.2–7.7). Fluorescence ratios at the various  $\text{pH}_i$  levels in the calibration runs were normalized such that the 495 nm/440 nm ratio at a  $\text{pH}_i$  of 7.2 was arbitrarily set at a value of 1. Fig. 1 shows a computer-fitted pH titration curve relating the normalized 495 nm/440 nm excitation ratios and  $\text{pH}_i$  as described initially by Boyarski et al. (1988). To convert fluorescence ratios obtained during an experiment on an individual IP-MTAL, the  $\text{pH}_i$  was set at 7.2 by exposure to 110 mM  $\text{K}^+$ /5  $\mu\text{M}$  nigericin (medium pH 7.2) at the end of the given experiment, and the 495 nm/440 nm ratio was then measured (single point calibration). Fluorescence ratios obtained during the experimental period were normalized such that the 495 nm/440 nm ratio obtained with the single point calibration was equal to one, and then the fitted titration curve shown in Fig. 1 was used to convert the normalized experimental ratios to units of  $\text{pH}_i$  (Boyarsky et al., 1988).

To compare initial rates of  $\text{pH}_i$  change ( $d(\text{pH}_i)/dt$ ) in either S-MTAL or IP-MTAL, the apparent initial rate of  $\text{pH}_i$  change was obtained either by measuring the slope of a computer-fitted linear regression over the initial  $\sim 5$  s of  $\text{pH}_i$  change, or by measuring the tangent at the initial time point of an exponential curve computer-fitted to the initial time course of  $\text{pH}_i$  change. These transformations require no assumptions as to the mechanisms of  $\text{pH}_i$  change. Correlation coefficients for these fitted curves averaged  $0.96 \pm 0.02$ .

The initial rate of acid/base flux ( $J_{\text{H}}^+$ , millimolar per minute) at a given  $\text{pH}_i$  ( $(\text{pH}_i)_x$ ) was calculated using measurements of  $d(\text{pH}_i)/dt$  (in  $\text{pH}_i$  units per minute) at  $(\text{pH}_i)_x$  and total buffering power ( $\beta$ , millimolar per  $\text{pH}_i$ ) at  $(\text{pH}_i)_x$  (Fig. 3) as (Boyarsky et al., 1988):

$$J_{\text{H}}^+ = \left[ \left( \frac{d\text{pH}_i}{dt} \right)_{\text{at}(\text{pH}_i)_x} \right] \times (\beta)_{\text{at}(\text{pH}_i)_x} \quad (1)$$

These "flux" values in millimolar per minute can be converted to standard units (picomoles per second per square centimeter; see footnote 2) by using an MTAL tubule of  $20 \mu\text{m}$  i.d. and a

FIGURE 1. Calibration of BCECF fluorescence in IP-MTAL ( $n = 3$ ).  $\text{pH}_i$  was set at varying levels using the high  $\text{K}^+$ /nigericin technique (Thomas et al., 1979) and 495 nm/440 nm excitation ratios were obtained. The 495 nm/440 nm excitation ratios have been normalized so that the ratio was 1 at a  $\text{pH}_i$  of 7.20. The curve shows a computer-fitted pH titration curve ( $r = 0.98$ ; Boyarsky et al., 1988).

tubule cell volume of 0.25 nl/mm (Hebert, 1986). Comparisons among flux values reported in this paper and expressed in millimolar per minute assume that the surface-to-volume ratio for the tubule remains constant or changes negligibly.

#### Electrical Measurements in IP-MTAL

The electrical system used for the measurement of transepithelial voltage ( $V_e$ ; millivolts) and transepithelial conductance ( $G_e$ ; millisiemens per square centimeter) was identical to that used previously in this laboratory (Hebert et al. 1981a, b; Hebert and Andreoli, 1984, 1986). Briefly, the perfusion pipette was made from 2 mm o.d. theta-style electrode glass (Hilgenberg, Malsfeld, Germany) that was divided axially by a septum, permitting virtually complete electrical separation of perfusion and current passing circuits. The perfusion half of the pipette also served as an electrical bridge for measurement of  $V_e$  (lumen with respect to bath). Electrical connections were made to the free flowing perfusate and bath with 3 M KCl/Ag/AgCl bridges (MERE-2; World Precision Instruments, Sarasota, FL).  $V_e$  at the collecting end of the perfused tubule was measured with a Ag/AgCl wire placed into the collecting fluid and connected to a high impedance electrometer (VF-2; World Precision Instruments). Biphasic direct current pulses ( $I_e$ , [nanoamperes]; range =  $\pm 600$ ; duration  $\approx 1$  s) were generated by a computer-linked voltage-current clamp (VCC 600; Physiological Instruments, San Diego, CA). The magnitudes of  $I_e$ ,  $V_e$ , and voltage changes associated with current pulses were digitized (DT 2801; Data

Translation, Marlboro, MA) and stored on an IBM PC-XT computer. Transepithelial conductance ( $G_e$ ) was calculated using terminated cable equations as described previously (Hebert et al., 1981b; Hebert and Andreoli, 1986).

*Measurement of transcellular conductance ( $G_c$ ).* In the absence of  $\text{NH}_4^+$  apical membranes of the mouse MTAL are predominantly, if not exclusively, conductive to potassium via  $\text{K}^+$  channels (Hebert and Andreoli, 1984; Hebert, Friedman, and Andreoli, 1984). Recent patch clamp studies have demonstrated that this  $\text{K}^+$  channel is inhibited by  $\text{Ba}^{2+}$  (Bleich, Schlatter, and Greger, 1990; Wang, White, Geibel, and Giebisch, 1990), and we have previously shown that the apical  $\text{K}^+$  conductive pathway in mouse IP-MTAL can be completely blocked by the addition of 20 mM luminal  $\text{Ba}^{2+}$  in the absence of luminal  $\text{K}^+$  (Hebert and Andreoli, 1986). Thus, the magnitude of  $G_e$  observed in the presence of 20 mM  $\text{Ba}^{2+}/0$   $\text{K}^+$  in the luminal medium provides an estimate of the transepithelial shunt (paracellular) conductance ( $G_s$ ), and the difference between  $G_e$  observed with 0 mM  $\text{Ba}^{2+}/5$  mM  $\text{K}^+$  vs. 20 mM  $\text{Ba}^{2+}/0$  mM  $\text{K}^+$  ( $G_e^{20\text{Ba}/0\text{K}}$ ) provides a good approximation of  $G_c$ , the transcellular conductance (Hebert and Andreoli, 1986).

$$G_e = G_c + G_s \quad (2a)$$

$$G_s = G_e^{20\text{Ba}/0\text{K}} \quad (2b)$$

$$G_c = G_e - G_e^{20\text{Ba}/0\text{K}} \quad (2c)$$

The luminal  $\text{Ba}^{2+}$ -sensitive  $G_e$  (or  $G_c$ ) in the IP-MTAL was used to indirectly assess the activity of apical  $\text{K}^+$  channels. This method was used because of the difficulty in obtaining adequate long-term microelectrode impalements required for the experimental protocols used. Changes in  $G_e$  have been used previously by us to estimate changes in apical and basolateral conductive pathways (Hebert and Andreoli, 1986; Molony and Andreoli, 1988). In this study, all the electrical experiments were performed in the presence of arginine vasopressin (AVP; 10  $\mu\text{U}/\text{ml}$ ;  $\sim 5 \times 10^{-11}$  M) in the bathing medium. This concentration of AVP produces a maximal increase in  $G_e$  without affecting  $G_s$  (Hebert and Andreoli, 1984). The AVP-induced increase in apical  $G_e$  allowed us to detect small degrees of inhibition in  $G_c$ . Standard  $\text{CO}_2/\text{HCO}_3^-$ -free perfusing and bathing media used in the electrical experiments were identical to those used in the  $\text{pH}_i$  experiments.

#### *Drugs and Reagents*

BCECF-AM was obtained from Molecular Probes, Inc. (Eugene, OR). All other agents were obtained from Sigma Chemical Co. (St. Louis, MO), and were of analytical grade.

#### *Statistics*

Results on a single S-MTAL preparation or IP-MTAL constituted a single  $n$ . Unless stated, each experimental maneuver was repeated on at least three separate S-MTAL preparations or IP-MTALs. All experimental results are expressed as means  $\pm$  SE. The Student's  $t$  test was used to analyze paired data, while ANOVA was used to evaluate unpaired groups;  $P < 0.05$  was considered significant.

## RESULTS

#### *Cellular Buffering Power*

Fig. 2 shows a plot of the intrinsic buffering power ( $\beta_i$ ; millimolar per  $\text{pH}_i$  unit) of mouse MTAL cells over the  $\text{pH}_i$  range 6.5–7.6.  $\beta_i$  was measured in S-MTAL as (Roos

and Boron, 1981; Boyarsky et al., 1988):

$$\beta_i = - \frac{\Delta A}{\Delta \text{pH}} \quad (3)$$

where  $\Delta A$  is the millimolar amount of acid added and  $\Delta \text{pH}$  is the resultant drop in pH. The initial intracellular pH (segment a-b) was varied by altering extracellular pH ( $\text{pH}_o$ ) from 6.4 to 7.9. Known intracellular proton loads were then acutely delivered to MTAL cells at point b by either the abrupt removal of extracellular  $\text{NH}_4\text{Cl}$  (5 mM,  $\text{pK} = 9$ ) or the abrupt addition of extracellular sodium acetate (10 mM,  $\text{pK} = 4.75$ ), and the acute drops in  $\text{pH}_i$  (segment b-c) were monitored (Roos and Boron, 1981; Zeidel, Silva, and Seifter, 1986; Boyarsky et al., 1988). The acetate addition protocol was used to deliver acute proton loads (Zeidel et al., 1986) at  $\text{pH}_i$  levels  $> 7.1$ , since the  $\text{pH}_i$  of S-MTAL in  $\text{NH}_4^+$ -containing medium was  $< 7.1$ . To prevent  $\text{pH}_i$  regulation by  $\text{Na}^+:\text{H}^+$  exchangers and  $\text{HCO}_3^-$  transporters (Kikeri et al., 1990a), experiments were performed in  $\text{CO}_2/\text{HCO}_3^-$ -free and  $\text{Na}^+$ -free medium containing amiloride.

FIGURE 2. Intrinsic buffering power of MTAL cells. *Open circles*,  $\text{NH}_4\text{Cl}$  withdrawal; *solid circles*, sodium acetate addition; *open square*, addition of  $\text{NH}_4\text{Cl}$  in the presence of 10 mM  $\text{Ba}^{2+}$ , 1 mM furosemide, and 5 mM ouabain (see text for details). (*Insert*) Effect of  $\text{NH}_4\text{Cl}$  withdrawal. Experiments were performed in the absence of extracellular  $\text{Na}^+$  ( $\text{Na}^+$  replaced with *N*-methyl-D-glucamine $^+$ ) in the presence of 0.1–0.5 mM

amiloride. Segment a-b represents  $\text{pH}_i$  in medium containing 5 mM  $\text{NH}_4\text{Cl}$ ,  $\text{pH}_o$  7.44. At b, extracellular  $\text{NH}_4\text{Cl}$  was abruptly withdrawn.

(0.1–0.5 mM). In addition, we assumed that  $[\text{NH}_3]_i = [\text{NH}_3]_o$  and  $[\text{acetic acid}]_i = [\text{acetic acid}]_o$  in the presence of extracellular  $\text{NH}_4^+$  and acetate, respectively. The very slow rate of  $\text{pH}_i$  recovery after either extracellular  $\text{NH}_4^+$  removal or extracellular acetate addition (Fig. 2, *insert*, segment c-d) indicated that acid extrusion or acetate $^-$  entry was negligible in the absence of extracellular  $\text{Na}^+$ .

It is evident from Fig. 2 that the intrinsic buffering power remained relatively stable over a  $\text{pH}_i$  range of 7.0–7.6 ( $\beta_i = 29.7 \pm 2.4$  mM/ $\text{pH}_i$  at a  $\text{pH}_i$  of  $7.22 \pm 0.08$ ,  $n = 8$ ; slope not significantly different from zero), but gradually increased with cell acidification below a  $\text{pH}_i$  of 7.0 ( $\beta_i \approx 50$  mM/ $\text{pH}_i$  at  $\text{pH}_i$  6.5). An inverse relationship between  $\beta_i$  and  $\text{pH}_i$  has been previously described in other cell types by us (Kikeri, Zeidel, Ballermann, Brenner, and Hebert, 1990b) and others (Roos and Boron, 1981; Boyarsky et al., 1988). In addition, the observed values for  $\beta_i$  in MTAL cells are similar to those reported for proximal tubule cells (43 mM/ $\text{pH}_i$  [Krapf, Alpern, Rector, and Berry, 1987]) and white blood cells (28 mM/ $\text{pH}_i$  [Grinstein and Furuya,

1986]), but are approximately three- to sixfold greater than those reported for smooth muscle cells (9 mM/pH<sub>i</sub> in A10 cells at pH<sub>i</sub> 7.2 [Kikeri et al., 1990b]; 9 mM/pH<sub>i</sub> at pH<sub>i</sub> ~7.0 [Aickin, 1984]) or glomerular mesangial cells (5 mM/pH<sub>i</sub> at pH<sub>i</sub> 7.3 [Boyarsky et al., 1988]).

In additional experiments ( $n = 5$ ) we estimated  $\beta_i$  at pH<sub>i</sub> levels >7.1 pH units by adding 5 mM NH<sub>4</sub>Cl to S-MTAL (in standard Na<sup>+</sup>-containing, CO<sub>2</sub>/HCO<sub>3</sub><sup>-</sup>-free medium, pH<sub>o</sub> 7.4) in the presence of inhibited cellular NH<sub>4</sub><sup>+</sup> transport (i.e., in the presence of the combination of 10 mM barium, 1 mM furosemide, and 5 mM ouabain [Kikeri et al., 1989]), and measuring the acute increase in pH<sub>i</sub> (pH<sub>i</sub> 0.16 ± 0.02; see upper tracings of Figs. 4 and 9). Values of  $B_i$  obtained under these conditions (30.9 ± 3.0 mM/pH<sub>i</sub> at a mean pH<sub>i</sub> over the acute pH<sub>i</sub> of 7.48 ± 0.01,  $n = 5$ ; Fig. 2, open square) were similar to those obtained using acetate addition or N H<sub>4</sub><sup>+</sup> withdrawal at pH<sub>i</sub> levels >7.0.

#### *Cellular NH<sub>4</sub><sup>+</sup> Entry Pathways in Mouse MTAL*

Addition of NH<sub>4</sub><sup>+</sup> to the luminal perfusate in the IP-MTAL leads to a prompt cell acidification due to NH<sub>4</sub><sup>+</sup> influx across the NH<sub>3</sub>-impermeable apical membrane, and this NH<sub>4</sub><sup>+</sup>-mediated fall in pH<sub>i</sub> can be abolished by prior exposure of the apical membrane to the combination of luminal 0.1 mM furosemide and 10–20 mM luminal Ba<sup>2+</sup> (Kikeri et al., 1989). In these experiments we assessed the relative contribution of each of these two pathways to NH<sub>4</sub><sup>+</sup> entry across apical membranes of the IP-MTAL. Rates of cell acidification due to luminal addition of 0.1 mM NH<sub>4</sub><sup>+</sup> were measured before and 3–5 min after addition of either 0.1 mM furosemide or 10 mM Ba<sup>2+</sup> to luminal perfusate. Under these conditions, which mimic concentrations of NH<sub>4</sub><sup>+</sup> observed in vivo, [NH<sub>4</sub><sup>+</sup>]<sub>i</sub> would be negligible due to the high NH<sub>3</sub> permeability of the basolateral membrane and the absence of basolateral medium NH<sub>4</sub>Cl. Consequently, we assumed that  $B_i = B_o$ . Moreover, since acid extrusion (predominantly via apical Na<sup>+</sup>:H<sup>+</sup> exchange [Kikeri et al., 1990a]) and acid loading are equal at the steady-state pH<sub>i</sub>, the initial rate of H<sup>+</sup> influx (calculated according to Eq. 1) on addition of luminal NH<sub>4</sub>Cl reflects the initial rate of cellular NH<sub>4</sub><sup>+</sup> influx.<sup>1</sup> In four IP-MTAL tubules, addition of 0.1 mM NH<sub>4</sub>Cl to K<sup>+</sup>-free luminal medium at the steady-state pH<sub>i</sub> (7.38 ± 0.11,  $n = 4$ ) resulted in an initial NH<sub>4</sub><sup>+</sup> influx rate of 21.7 ± 3.3 mM/min and this NH<sub>4</sub><sup>+</sup> influx was completely blocked by addition of both 0.1 mM furosemide and 10 mM Ba<sup>2+</sup> to the luminal medium. 0.1 mM apical furosemide inhibited apical NH<sub>4</sub><sup>+</sup> entry by 55.3 ± 6.1% (11.7 ± 1.9 mM/min) and 10 mM apical Ba<sup>2+</sup> inhibited apical NH<sub>4</sub><sup>+</sup> entry by 44.8 ± 6.1% (10 ± 2.9 mM/min). Thus in the absence of inhibitors, both the apical Ba<sup>2+</sup>-sensitive pathway and Na<sup>+</sup>:K<sup>+</sup>(NH<sub>4</sub><sup>+</sup>):2Cl<sup>-</sup> cotransporter mediated significant apical entry of NH<sub>4</sub><sup>+</sup> into mouse MTAL cells at ammonium concentrations observed in vivo.

Fig. 3 shows the initial rate of apical NH<sub>4</sub><sup>+</sup> entry in IP-MTAL, via both the Ba<sup>2+</sup>- and furosemide-sensitive pathways, after addition of NH<sub>4</sub>Cl to luminal fluid at concentrations from 0.1 to 20 mM ( $n = 8$  tubules). Steady-state pH<sub>i</sub> in NH<sub>4</sub><sup>+</sup>-free medium

<sup>1</sup> This was substantiated by our previous observation that that removal of luminal NH<sub>4</sub>Cl (in the absence of basolateral NH<sub>4</sub>Cl) results only in a small cell acidification even in the absence of pH<sub>i</sub> regulation (Kikeri et al., 1989).

averaged  $7.26 \pm 0.04$  pH units. In these experiments, media contained 100 mM  $\text{Na}^+$  and 40 mM *N*-methyl-D-glucamine<sup>+</sup> (NMDG<sup>+</sup>);  $\text{NH}_4^+$  replaced NMDG<sup>+</sup> in an equimolar manner. The apparent  $K_{0.5}$  and the maximal rate of luminal  $\text{NH}_4^+$  entry were 0.5 and 83.3 mM/min, respectively.<sup>2</sup> This low  $K_{0.5}$  value may be due both to the high affinity of  $\text{NH}_4^+$  for the  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter (Kinne et al., 1986) and to inhibition of both apical  $\text{NH}_4^+$  entry mechanisms by factors such as  $\text{pH}_i$  (this possibility is evaluated in the experiments described below).

To determine if  $\text{NH}_4^+$  could enter MTAL cells via the basolateral  $\text{Na}^+:\text{K}^+$ -ATPase, ouabain-sensitive acidification was evaluated in S-MTAL in the presence of 0.5–20 mM  $\text{NH}_4\text{Cl}$  ( $n = 5$ ). Steady-state  $\text{pH}_i$  of S-MTAL in  $\text{NH}_4^+$ -free medium averaged

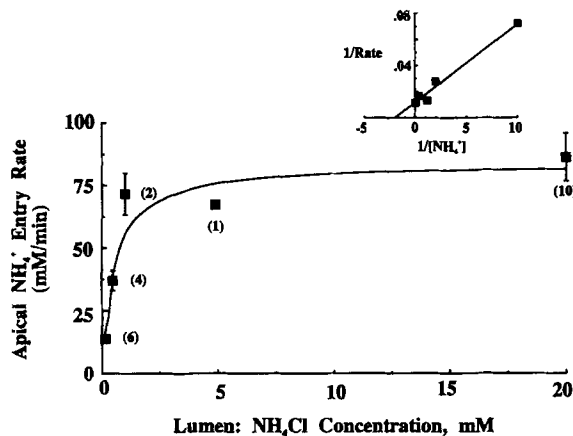

FIGURE 3. Effect of luminal medium  $\text{NH}_4\text{Cl}$  concentration on the initial rate of apical,  $\text{NH}_4\text{Cl}$ -dependent  $\text{H}^+$  influx ( $\text{NH}_4^+$  entry) in IP-MTAL.  $\text{NH}_4\text{Cl}$  was acutely added to the luminal medium in IP-MTAL and the initial rate of acidification was measured. The number in parentheses next to each symbol indicates the number of measurements. The curve represents the least-squares fit of the Michaelis-Menten relationship to the data ( $r = 0.99$ ). The

inset plot shows the double-reciprocal plot of the data ( $r = 0.99$ ;  $1/\text{rate} = 0.006(1/[\text{NH}_4^+]) + 0.012$ ;  $K_{0.5} = 0.5$  mM; maximal rate of influx = 83.3 mM/min).

$7.42 \pm 0.02$  pH units ( $n = 16$ ). In the experiments shown in Fig. 4, which were performed on a representative S-MTAL preparation, segments a-b represent steady-state  $\text{pH}_i$  of S-MTAL in  $\text{NH}_4^+$ -free medium,  $\text{pH}_i$  7.4. 5 mM  $\text{NH}_4\text{Cl}$  was then added to the extracellular medium at point b. The lower trace shows the control acidification response after addition of 5 mM  $\text{NH}_4\text{Cl}$  to the medium bathing apical and basolateral membranes of S-MTAL (b-g). However, addition of 5 mM  $\text{NH}_4\text{Cl}$  in the presence of 10 mM  $\text{Ba}^{2+}$ , 1 mM furosemide, and 5 mM ouabain resulted in rapid cell alkalinization due to entry of  $\text{NH}_3$  across  $\text{NH}_3$ -permeable basolateral membranes (Kikeri et al., 1989; compare c-d with b-g). Thus, the combination of  $\text{Ba}^{2+}$ , furosemide, and ouabain inhibited virtually all the entry of  $\text{NH}_4^+$  into MTAL cells. The  $\text{pH}_i$  on addition of  $\text{NH}_4\text{Cl}$  in the presence of inhibited  $\text{NH}_4^+$  transport was similar to the  $\text{pH}_i$  expected if cell membranes were permeable only to  $\text{NH}_3$ . In other words, inhibition of  $\text{NH}_4^+$  transport by the combination of barium plus furosemide and ouabain converted the

<sup>2</sup> The maximal rate of luminal  $\text{NH}_4^+$  entry of 83.3 mM/min can be converted to more conventional transport units, assuming a MTAL tubule inner diameter of 20  $\mu\text{m}$  and a MTAL tubule cell volume of 0.25 nl/mm tubule length (Hebert, 1986). Using these parameters,  $\text{max}J_{\text{NH}_4^+} = 20$  pmol/min·mm or 550 pmol/s·cm<sup>2</sup>. These rates are consistent with rates of net  $\text{NH}_4^+$  absorption observed in perfused thick ascending limb tubules (Knepper et al., 1989).

FIGURE 4. Role of  $\text{Na}^+:\text{K}^+$ -ATPase in mediating cellular  $\text{NH}_4^+$  entry in S-MTAL. Segments a-b, resting  $\text{pH}_i$ . At b, 5 mM  $\text{NH}_4\text{Cl}$  was added to the extracellular medium either in the presence of 10 mM  $\text{Ba}^{2+}$ , 1 mM furosemide, and 5 mM ouabain (b-c-d), in the presence of 10 mM  $\text{Ba}^{2+}$  and 1 mM furosemide (b-e-f), or in the absence of inhibitors (b-g).

highly  $\text{NH}_4^+$ -permeable, native S-MTAL cells into almost purely  $\text{NH}_3$ -permeable cells (across basolateral membranes). The selective removal of ouabain resulted in partial restoration of the acidification response to 5 mM  $\text{NH}_4\text{Cl}$  addition (e-f). The ouabain-sensitive rate of  $\text{NH}_4^+$  entry with 20 mM extracellular  $\text{NH}_4\text{Cl}$  was  $17.4 \pm 0.4$  mM/min (calculated as initial rates [e-f] - [c-d];  $n = 3$ ). In separate experiments performed in the absence of  $\text{NH}_4\text{Cl}$ , the addition of either the combination of  $\text{Ba}^{2+}$ , furosemide, and ouabain or the combination of  $\text{Ba}^{2+}$  and furosemide to S-MTAL did not alter steady-state  $\text{pH}_i$  over 200 s ( $\Delta\text{pH}_i = 0.01 \pm 0.02$ ,  $n = 2$ ). Thus, the basolateral, ouabain-sensitive  $\text{Na}^+:\text{K}^+$ -ATPase could mediate  $\text{NH}_4^+$  entry into MTAL cells.

*Effect of  $\text{pH}_i$  on Total Rate of  $\text{NH}_4^+$  Entry via  $\text{Ba}^{2+}$ -, Furosemide-, and Ouabain-sensitive Pathways in S-MTAL*

Fig. 5 illustrates the effect of  $\text{pH}_i$  on the total rate of cellular  $\text{NH}_4^+$  entry in a representative S-MTAL preparation, i.e., via the combination of the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway, the furosemide-sensitive  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter,

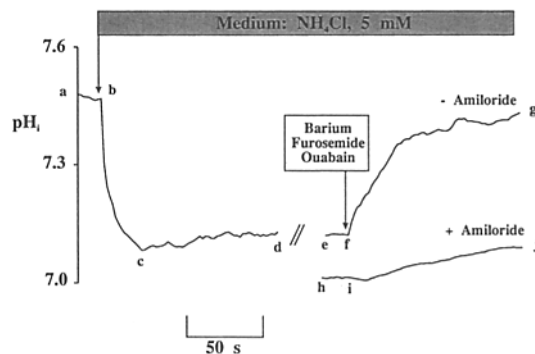

FIGURE 5. Effect of  $\text{pH}_i$  on the total rate of  $\text{NH}_4^+$  entry into S-MTAL. Segment a-b, resting  $\text{pH}_i$  of S-MTAL in  $\text{NH}_4^+$ -free medium. At b, 5 mM  $\text{NH}_4\text{Cl}$  was added to the extracellular medium and was present for the duration of the experiment. The gap in the trace represents a 3.5-min incubation period after adding either 1 mM amiloride or vehicle (DMSO) to the extracellular medium at point d. At points f and i, 10 mM  $\text{Ba}^{2+}$ , 1 mM furosemide, and 5 mM ouabain were abruptly added.

and the ouabain-sensitive  $\text{Na}^+:\text{K}^+(\text{NH}_4^+)\text{-ATPase}$ . Segment a-b represents steady-state  $\text{pH}_i$  of S-MTAL in  $\text{NH}_4^+$ -free medium ( $7.45 \pm 0.05$ ,  $n = 3$ ). Addition of 5 mM  $\text{NH}_4\text{Cl}$  at b reduced  $\text{pH}_i$  to a new steady-state level ( $7.13 \pm 0.01$ , c-d). At d, either amiloride (1 mM) or vehicle (DMSO) was added to the medium. The gap in the trace represents a 2–4-min incubation period.

Abrupt inhibition of total  $\text{NH}_4^+$  entry at point f, in the absence of amiloride, by adding the combination of 10 mM  $\text{Ba}^{2+}$ , 1 mM furosemide, and 5 mM ouabain resulted in rapid  $\text{pH}_i$  recovery (f-g). Since net rates of  $\text{NH}_4^+$  entry (via the combination of  $\text{Ba}^{2+}$ -, furosemide-, and ouabain-sensitive pathways) and  $\text{NH}_4^+$  exit (by proton extrusion via  $\text{Na}^+:\text{H}^+$  exchange coupled with  $\text{NH}_3$  diffusion across the basolateral membrane [Kikeri et al., 1989]) are probably equal during the steady state in  $\text{NH}_4^+$ -containing medium (e-f), the initial rate of acid extrusion at point f (initial  $\text{pH}_i$  recovery rate  $\times \beta_v$ , where  $\beta_i = \beta_i + \beta_{\text{NH}_3}$ ) of  $33.7 \pm 3.8$  mM/min equals the total rate of ammonium entry (via the  $\text{Ba}^{2+}$ -, furosemide-, and ouabain-sensitive pathways) during segment e-f.

Amiloride addition in the presence of 5 mM ambient  $\text{NH}_4\text{Cl}$  at point d reduced  $\text{pH}_i$  within 1 min, because of inhibition of  $\text{Na}^+:\text{H}^+$  exchange (Kikeri et al., 1990a), to a new steady-state level of  $6.96 \pm 0.02$  (h-i). As discussed above,  $\text{NH}_4^+$  entry and exit are equal during segment h-i. Inhibition of total  $\text{NH}_4^+$  entry with the combination of  $\text{Ba}^{2+}$ , furosemide, and ouabain at point i led to a markedly reduced rate of acid extrusion ( $5.9 \pm 0.07$  mM/min). Since both apical and basolateral membranes of S-MTAL are exposed to  $\text{NH}_4\text{Cl}$ , and because basolateral membrane are highly permeable to  $\text{NH}_3$ ,  $[\text{NH}_4^+]_i$  would increase as  $\text{pH}_i$  decreases. Increases in  $[\text{NH}_4^+]_i$ , in turn, would reduce the chemical gradient favoring  $\text{NH}_4^+$  uptake. Thus the combined effects of the reduction of  $\text{pH}_i$  from  $7.13 \pm 0.01$  (e-f) to  $6.96 \pm 0.02$  (h-i) and the associated rise in  $[\text{NH}_4^+]_i$  reduced the total rate of cellular  $\text{NH}_4^+$  entry across both apical and basolateral membranes by  $>80\%$ .<sup>3</sup> In addition, these data indicate that  $\text{Na}^+:\text{H}^+$  exchange plays the dominant role in  $\text{NH}_4^+$  exit ( $\text{H}^+$  extrusion coupled to  $\text{NH}_3$  diffusion [Kikeri et al., 1989]) from mouse MTAL cells in the presence of ambient  $\text{NH}_4\text{Cl}$ .

#### *Effect of $\text{pH}_o/\text{pH}_i$ on Transcellular Conductance ( $G_o$ ) in IP-MTAL*

Because of the difficulty in obtaining long-term microelectrode impalements in the small epithelial cells of the mouse MTAL and the necessity of obtaining paired data (because of large tubule-to-tubule variations in transepithelial conductance [Hebert

<sup>3</sup> Amiloride does not appear to significantly affect any of the  $\text{NH}_4^+$  entry processes. We (Kikeri et al., 1989) have shown that the combination of luminal 10 mM  $\text{Ba}^{2+}$  and luminal 0.1 mM furosemide completely abolishes the cell acidification observed with luminal 20 mM  $\text{NH}_4^+$  addition in IP-MAL and that these two agents plus 5 mM ouabain completely block  $\text{NH}_4^+$ -induced cell acidification in S-MAL. In addition, in this paper (Fig. 3) we demonstrate that inhibition of the  $\text{Na}^+:\text{H}^+$  exchanger ( $\text{Na}^+$  replaced by  $\text{NMDG}^+$ ) does not affect luminal  $\text{NH}_4^+$ -induced cell acidification in IP-MAL. Furthermore, we have previously shown (Fig. 4 in Kikeri et al., 1990a) that amiloride has no significant effect on  $\text{QO}_2$ , a sensitive index to the activity of both the apical  $\text{Na}^+:\text{K}^+/\text{NH}_4^+:\text{2Cl}^-$  entry mechanism and the basolateral  $\text{Na}^+:\text{K}^+\text{-ATPase}$  exit mechanism. Finally, if amiloride had a significant effect on the  $\text{K}^+$  channel then the cell would depolarize (for example, luminal  $\text{Ba}^{2+}$  depolarizes the mouse MTAL cell; Hebert and Andreoli, 1984) and the cell would be expected to alkalize somewhat because the driving force for  $\text{H}^+$  entry would be reduced.

and Andreoli, 1984, 1986]), we used an alternative approach to estimate the effects of  $\text{pH}_o/\text{pH}_i$  on the apical  $\text{Ba}^{2+}$ -sensitive  $\text{K}^+$  conductance using measurements of transcellular conductance ( $G_c$ ). As described in detail in Methods (see Eqs. 2a–2c), the difference between transepithelial conductance ( $G_e$ ) measurements observed in IP-MTAL with perfusate containing either 0 mM  $\text{Ba}^{2+}/5$  mM  $\text{K}^+$  (total  $G_e$ ) or 20 mM  $\text{Ba}^{2+}/0$  mM  $\text{K}^+$  (shunt conductance,  $G_s$ ) provides a good approximation of the transcellular conductance,  $G_c$ . This approach has provided valuable information on the regulation of cellular conductive pathways in the MTAL in previous studies (Hebert and Andreoli, 1984, 1986; Molony and Andreoli, 1988).

$G_c$  decreased from  $110.9 \pm 4.4$  to  $40.4 \pm 1.2$  mS/cm<sup>2</sup> ( $n = 4$ ;  $P < 0.01$ ) on changing the luminal medium from 0 mM  $\text{Ba}^{2+}/5$  mM  $\text{K}^+$  to 20 mM  $\text{Ba}^{2+}/0$  mM  $\text{K}^+$  at a constant luminal medium pH of 7.4, indicating that  $G_c$  and  $G_s$  accounted for

FIGURE 6. Effect of  $\text{pH}_{lum}$  and  $\text{pH}_i$  on relative  $\text{Ba}^{2+}$ -sensitive cell conductance ( $G_c$ ) in IP-MTAL (see Methods and Eqs. 2a–2c for procedure for assessing  $G_c$ ). The solid squares and dashed line show the relationship between  $\text{pH}_{lum}$  and relative  $G_c$ , while the solid triangles show the relationship between  $\text{pH}_i$  and relative  $G_c$ . The relation

$$\text{relative rate} = A + B \cdot \left[ \frac{10^{(\text{pH}-\text{pK})}}{1 + 10^{(\text{pH}-\text{pK})}} \right]$$

where  $A$  and  $B$  are the intercept and slope, respectively, was fit to the data.  $\text{pK} = 6.7$  ( $r = 0.95$ ) for the  $\text{pH}_i$  fit.

approximately two-thirds and one-third of  $G_e$ , respectively. Similar  $G_s:G_e$  ratios were also observed in previous studies (Hebert and Andreoli, 1984, 1986). In another set of experiments ( $n = 4$ ) the luminal medium pH ( $\text{pH}_{lum}$ ) was reduced in a stepwise manner from pH 7.4 to pH 3.0 in the presence of luminal 0 mM  $\text{Ba}^{2+}/5$  mM  $\text{K}^+$ . The solid squares in Fig. 6 show the relative changes in  $G_c$ , normalized such that  $G_c$  at  $\text{pH}_{lum}$  7.4 was arbitrarily set at 1. Changing the luminal medium from 0 mM  $\text{Ba}^{2+}/5$  mM  $\text{K}^+$  to 20 mM  $\text{Ba}^{2+}/0$  mM  $\text{K}^+$  at a constant  $\text{pH}_{lum}$  of 4 did not alter  $G_e$  ( $G_e^{0\text{Ba}} = 22.3 \pm 5.7$ ;  $G_e^{20\text{Ba}} = 31.9 \pm 11.1$ ;  $\Delta G_e = -9.6 \pm 5.4$ ,  $n = 4$ , NS). Therefore, reducing  $\text{pH}_{lum}$  from 7.4 to 4.0 abolished virtually all the cell conductance but had no significant effect on  $G_s$ . These data demonstrate indirectly that the apical  $\text{Ba}^{2+}$ -sensitive  $\text{K}^+$  conductance was sensitive to luminal medium pH.

The experiments shown in Fig. 7 were performed to determine the effect of  $\text{pH}_{\text{lum}}$  on  $\text{pH}_i$  in the IP-MTAL ( $n = 4$ ). Using experimental conditions identical to those used in the electrical experiments,  $\text{pH}_{\text{lum}}$  was reduced in a stepwise manner from pH 7.4 to pH 5.0 (luminal medium contained 0 mM  $\text{Ba}^{2+}/5$  mM  $\text{K}^+$ ) and  $\text{pH}_i$  was monitored at each luminal medium pH level. As shown in Fig. 7,  $\text{pH}_i$  was greater than luminal medium pH at acidic  $\text{pH}_i$  levels, possibly because of  $\text{pH}_i$  regulation by  $\text{Na}^+:\text{H}^+$  exchange, while  $\text{pH}_i$  was less than luminal medium pH at medium pH levels  $> 7.5$  pH units. This relationship between luminal medium pH and  $\text{pH}_i$  shown in Fig. 7 was then used to determine the relationship between  $\text{pH}_i$  and relative apical  $\text{Ba}^{2+}$ -sensitive transcellular conductance (solid triangles, Fig. 6). As shown in Fig. 6, the relative  $G_c$  was related, over a  $\text{pH}_i$  range of 6.0–7.4, to  $\text{pH}_i$  with 50% inhibition at a  $\text{pH}_i$  of  $\sim 6.7$  and/or to luminal  $\text{pH}_o$  with a 50% inhibition at  $\text{pH}_o \sim 5.5$ .

FIGURE 7. Effect of  $\text{pH}_{\text{lum}}$  on  $\text{pH}_i$  in IP-MTAL. The line is the least-squares fit of the data:  $y = 0.442x + 4.26$ ,  $r = 0.98$ .

#### Effect of $\text{pH}_i$ on $\text{NH}_4^+$ Entry due to Apical $\text{Ba}^{2+}$ -sensitive $\text{NH}_4^+$ Transport in IP-MTAL

Since  $\text{pH}_i$  in the electrical experiments shown in Fig. 6 was altered by changing luminal medium pH, either luminal medium pH ( $\text{pH}_{\text{lum}}$ ) or  $\text{pH}_i$  may have been responsible for the changes in  $G_c$ . Moreover, it is possible that the pH-dependent changes in  $G_c$  resulted from alterations in either apical or basolateral conductances, or both. We therefore assessed the effects of  $\text{pH}_i$ , independent of luminal  $\text{pH}_o$  changes, on  $\text{NH}_4^+$  entry via the apical  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway in IP-MTAL ( $n = 5$ ). The results of these experiments are shown in Fig. 8.

The rate of change in  $\text{pH}_i$  was measured after addition of 1 mM  $\text{NH}_4\text{Cl}$  to a luminal medium in which both  $\text{Na}^+$  and  $\text{K}^+$  were replaced isosmotically with  $\text{NMDG}^+$  and to which 0.1 mM furosemide was added. Under these conditions the  $\text{H}^+$  influx due to  $\text{NH}_4^+$  entry represents exclusively the apical  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway. The initial rate of  $\text{NH}_4^+$  influx,  $J_{\text{NH}_4}$  was then calculated according to Eq. 1. In addition, the removal of luminal  $\text{Na}^+$  would abolish any  $\text{H}^+$  efflux mediated by the apical  $\text{Na}^+:\text{H}^+$  exchanger. For these experiments we also assumed that  $\beta_i \approx \beta_o$  since intracellular  $\text{NH}_4^+/\text{NH}_3$  concentrations would be low due to the absence of basolateral  $\text{NH}_4\text{Cl}$  and the high basolateral membrane  $\text{NH}_3$  permeability (Kikeri et al., 1989).

To assess the effect of  $\text{pH}_i$  on the  $\text{Ba}^{2+}$ -sensitive (i.e., furosemide-insensitive) apical  $J_{\text{NH}_4}$  the  $\text{pH}_i$  (before luminal  $\text{NH}_4^+$  addition) was altered by changing the pH of the

basolateral bath solution in stepwise fashion over the range 4–8. The relationship between basolateral  $pH_o$  and  $pH_i$  was virtually identical to that observed for apical  $pH_o$  and  $pH_i$  (Fig. 7). As shown in Fig. 8, the relative rate of furosemide-insensitive, apical  $NH_4^+$  entry, normalized to the influx rate obtained at  $pH_i \sim 7.3$ , was dependent on  $pH_i$  in IP-MTAL tubules with reductions in  $pH_i$  inhibiting the apical  $NH_4^+$  flux. At  $pH_i$  values  $< 6.5$ ,  $J_{NH_4^+}$  was inhibited  $> 80\%$  compared with  $J_{NH_4^+}$  values at  $pH_i > 7.5$ . In four additional IP-MTAL tubules,  $pH_i$  was reduced with luminal amiloride (0.5 mM) in the presence of luminal  $Na^+$  and 0.1 mM furosemide (apical and basolateral  $pH_o$  7.40; Fig. 8, open squares). Inhibition of apical  $Na^+ : H^+$  exchange resulted in a decrease in  $pH_i$  of  $\sim 2.6 \pm 0.03$  pH units and a fall in relative  $J_{NH_4^+}$  of  $15.3 \pm 3.5\%$  (Fig. 8, open squares), a value that was indistinguishable from the relative reduction observed when  $pH_i$  was decreased by changing basolateral  $pH_o$ . The results in Fig. 8

FIGURE 8. Effect of  $pH_i$  on the relative rate of  $NH_4^+$  entry (millimolar per minute) via the apical  $Ba^{2+}$ -sensitive pathway in IP-MTAL. Experiments were performed in the absence of luminal  $Na^+$  and  $K^+$  and with 0.1 mM furosemide added to the luminal perfusate ( $n = 5$  tubules; solid squares).  $NH_4^+$  entry rates for each tubule were normalized to the entry rate observed at  $pH_i$  7.3, which was

set to 1.0. Open squares, experiments with and without luminal 0.5 mM amiloride (to inhibit the apical  $Na^+ : H^+$  antiporter) and in the presence of luminal  $Na^+$  ( $n = 5$ ). The solid line is a least-squares linear fit:  $y = 16.23x - 106.16$  ( $r = 0.89$ ).

demonstrate that reducing  $pH_i$  by variations in basolateral pH or by addition of luminal amiloride (at constant  $pH_o$ ) inhibited  $NH_4^+$  influx via the apical  $Ba^{2+}$ -sensitive  $NH_4^+$  transport pathway. The observations in Figs. 6–8 that reductions in  $pH_i$  to similar values by decreasing luminal or basolateral  $pH_o$  or by luminal amiloride addition at a constant  $pH_o$  led to similar fractional reductions in  $Ba^{2+}$ -sensitive  $NH_4^+$  entry (or  $K^+$  conductance) suggests that cell pH rather than  $pH_o$  was the major factor affecting the  $Ba^{2+}$ -sensitive entry mechanism.

#### Effect of $pH_i$ on $NH_4^+$ Entry due to $Ba^{2+}$ -sensitive $NH_4^+$ Transport in S-MTAL

*Determination of rate of  $NH_4^+$  entry due to  $Ba^{2+}$ -sensitive  $NH_4^+$  pathway.* Fig. 9 shows in a representative experiment on a single S-MTAL preparation (a) the control acidification response on addition of 5 mM  $NH_4Cl$  at point b to S-MTAL (b-f), (b) the effect of 1 mM furosemide plus 5 mM ouabain on the acidification response (b-e), and (c) the effect of 10 mM  $Ba^{2+}$ , furosemide, and ouabain on the  $pH_i$  response to  $NH_4Cl$  addition (b-c-d). Addition of either furosemide plus ouabain or  $Ba^{2+}$ , furosemide plus ouabain in the absence of  $NH_4Cl$  did not alter steady-state  $pH_i$  ( $n = 2$ ). As shown previously in Fig. 4 (upper curve), addition of extracellular  $NH_4Cl$  when  $NH_4^+$

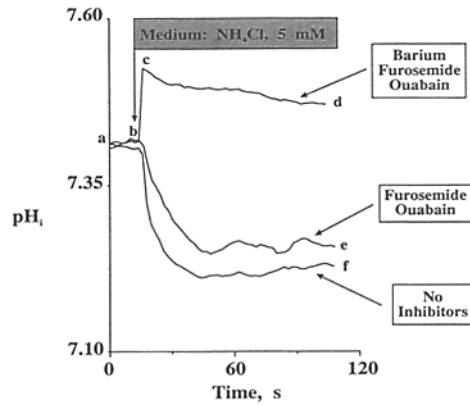

FIGURE 9.  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  entry in S-MTAL. In this representative trace, segment a-b represents resting  $\text{pH}_i$  in  $\text{NH}_4^+$ -free medium. At b, 5 mM  $\text{NH}_4\text{Cl}$  was added in the presence of either the combination of 10 mM  $\text{Ba}^{2+}$ , 1 mM furosemide, and 5 mM ouabain (b-c-d) or the combination of furosemide and ouabain (b-e), or in the absence of inhibitors (b-f).

transport was completely inhibited (i.e., in the presence of the combination of  $\text{Ba}^{2+}$ , furosemide, and ouabain) resulted in virtually instantaneous ( $< 2$  s) alkalinization (b-c;  $\Delta\text{pH}_i = 0.16 \pm 0.02$ ,  $n = 5$ ). In either the presence of furosemide plus ouabain (middle curve) or the absence of inhibitors (lower curve), sustained, rapid acidification was observed. The initial rate of decrease in  $\text{pH}_i$  in the presence of furosemide plus ouabain was taken to represent the initial rate of  $\text{NH}_4^+$  influx via  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathways.  $J_{\text{NH}_4}$  was calculated according to Eq. 1, where  $\beta_i = \beta_1 + \beta_{\text{NH}_4}$ . Since both apical and basolateral membranes in S-MTAL are exposed to ambient  $\text{NH}_4\text{Cl}$ , the observed  $J_{\text{NH}_4}$  values represent  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport across both apical and basolateral membranes. Apical membranes of MTAL cells possess an apical  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway (Kikeri et al., 1989); whether a  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway exists on basolateral membranes of MTAL cells is unknown.

*Effect of  $\text{pH}_i$  on  $\text{NH}_4^+$  entry due to  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport.* The experiments shown in Fig. 10 were used to assess  $\text{NH}_4^+$  entry via the  $\text{Ba}^{2+}$ -sensitive pathways in S-MTAL at various  $\text{pH}_i$  values using the strategy discussed above (Fig. 9). Addition of 5 mM  $\text{NH}_4\text{Cl}$  to the medium bathing S-MTAL at the resting  $\text{pH}_i$  resulted in a rapid

FIGURE 10. Effect of  $\text{pH}_i$  on  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  entry in S-MTAL. These representative experiments were performed in the presence of 1 mM furosemide and 5 mM ouabain. (A) 5 mM  $\text{NH}_4\text{Cl}$  was added at the arrow. (B) Cells were preexposed to 0.5 mM amiloride for 2–4 min before starting the experiment, and 5 mM  $\text{NH}_4\text{Cl}$  was added at the arrow.

fall in  $pH_i$  (b-c). At a  $pH_i$  of  $7.41 \pm 0.02$  ( $\sim 2$  s after addition of  $NH_4Cl$ ; point b), the initial rate of  $Ba^{2+}$ -sensitive  $NH_4^+$  entry in the presence of 5 mM  $NH_4Cl$  averaged  $32.6 \pm 3.1$  mM/min ( $n = 7$ ). Addition of amiloride to S-MTAL reduced  $pH_i$  from  $7.43 \pm 0.04$  to  $7.20 \pm 0.03$  within 1 min ( $n = 4$ ,  $P < 0.05$ ). The subsequent addition of 5 mM  $NH_4Cl$  to amiloride-treated cells (Fig. 10 B, point b) resulted in a small increase in  $pH_i$  to  $7.26 \pm 0.02$  (segment b-c) followed by a much larger fall in  $pH_i$  (segment c-d). The small rise in  $pH_i$  with exposure to  $NH_4Cl$  suggests that the initial rate of  $H^+$  entry due to  $Ba^{2+}$ -sensitive  $NH_4^+$  transport at the acidic  $pH_i$  of  $7.20 \pm 0.03$  was reduced relative to the rate of buffering of  $H^+$  due to the rapid entry of  $NH_3$  across the basolateral membrane. At a  $pH_i$  of  $7.26 \pm 0.02$ , the initial rate of  $Ba^{2+}$ -sensitive  $NH_4^+$  entry averaged  $18.8 \pm 1.2$  mM/min, a 42% reduction compared with the influx rate at  $pH_i$  7.41 ( $n = 4$ ).

Fig. 11 shows the direct relationship between  $pH_i$  and the initial rate of  $Ba^{2+}$ -sensitive  $NH_4^+$  entry in S-MTAL. Decreases in  $Ba^{2+}$ -sensitive  $J_{NH_4}$  were observed both with the spontaneous variations in resting  $pH_i$  (open circles) and with the further reductions in  $pH_i$  resulting from exposure to amiloride (solid circles). When the

FIGURE 11. Relationship between initial  $pH_i$  and initial  $Ba^{2+}$ -sensitive  $H^+$  influx ( $NH_4^+$  influx) in the presence of 5 mM  $NH_4Cl$  in S-MTAL. Closed circles, entry rates in cells acidified by amiloride addition; open circles, untreated cells.

results in Fig. 11 are taken together with those in Figs. 8 and 6, it is clear that decreasing  $pH_i$  over the physiological range of 6.0–7.8 dramatically reduces the activity of the  $Ba^{2+}$ -sensitive  $K^+/NH_4^+$  pathway in apical membranes.

#### *Effect of $pH_i$ on $NH_4^+$ Entry by Apical $Na^+:K^+/NH_4^+:2Cl^-$ Cotransport in IP-MTAL*

Experiments were performed in IP-MTAL to determine if  $NH_4^+$  entry into MTAL cells via the apical  $Na^+:K^+(NH_4^+):2Cl^-$  cotransporter (Kinne et al., 1986; Kikeri et al., 1989) was sensitive to  $pH_i$ . Fig. 12 shows representative experiments in IP-MAL illustrating the effects of initial steady-state  $pH_i$  on the rate of acidification induced by addition of 20 mM  $NH_4Cl$  to  $K^+$ -free perfusate in the presence of 20 mM  $BaCl_2$ . Since the combination of furosemide (0.1 mM) and  $Ba^{2+}$  (10–20 mM) in the luminal medium inhibits all the apical  $NH_4^+$  entry in IP-MTAL, the fall in  $pH_i$  observed on addition of luminal  $NH_4Cl$  in the presence of luminal  $Ba^{2+}$  represents  $NH_4^+$  entry via the apical  $Na^+:K^+(NH_4^+):2Cl^-$  cotransporter. Luminal  $NH_4Cl$  was added at points a, c, e, and g. Segments a-b and c-d are the acidification responses in two tubules at the different spontaneous, initial, steady-state  $pH_i$  values a and c. Addition of 0.5 mM

amiloride to the luminal fluid in the absence of  $\text{NH}_4\text{Cl}$  resulted in acidification from a to e and from c to g in these two tubules: the average amiloride-induced drop in  $\text{pH}_i$  was 0.49 pH units ( $n = 4$ ).<sup>4</sup> The data in Fig. 12 clearly demonstrate that as the initial steady-state  $\text{pH}_i$  is reduced, the rate of cellular acidification mediated by luminal  $\text{NH}_4^+$  influx via the cotransporter is considerably slowed.

Fig. 13 shows the direct relationship between the initial steady-state  $\text{pH}_i$  and the initial rate of  $\text{NH}_4^+$  entry via apical  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter. Note that the open squares show the usual spontaneous variability of resting  $\text{pH}_i$ ; in the absence of

FIGURE 12. Effect of  $\text{pH}_i$  on  $\text{NH}_4^+$  entry rate via apical  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  in IP-MTAL. Reducing  $\text{pH}_i$  by luminal addition of 0.5 mM amiloride (from  $7.31 \pm 0.17$  to  $6.82 \pm 0.14$ ; not shown in figure) decreased the initial rate of apical, furosemide-sensitive  $\text{H}^+$  entry rate on addition of 0.1 mM  $\text{NH}_4\text{Cl}$  to the luminal medium by  $52.9 \pm 13.4\%$ .

amiloride these spontaneous variations in  $\text{pH}_i$  correlated closely with the observed rate of ammonium entry. The amiloride-mediated reduction in  $\text{pH}_i$  from  $7.31 \pm 0.17$  to  $6.8 \pm 0.14$  pH units was associated with a  $52.9 \pm 13.4\%$  decrease in the rate of  $\text{NH}_4^+$  influx via the  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter. Thus, apical  $\text{NH}_4^+$  entry via the furosemide-sensitive cotransporter, like that through the  $\text{Ba}^{2+}$ -sensitive apical pathway, was markedly sensitive to  $\text{pH}_i$ .

<sup>4</sup> It should be noted that the decrease in  $\text{pH}_i$  in IP-MTAL with luminal amiloride addition in the presence of luminal  $\text{Ba}^{2+}$  (0.49 pH units) was larger than that observed in the presence of furosemide (0.26 pH units in IP-MTAL; 0.23 pH units in S-MTAL). Although the reason for this difference was not evaluated further in this study, it is possible that reduction of metabolic acid production because of inhibition of salt transport-related energy consumption by furosemide (in the MTAL, furosemide-sensitive oxygen consumption accounts for  $> 50\%$  of the total rate of oxygen consumption [Kikeri et al., 1990a]) may partially explain this difference.

## DISCUSSION

The results of this study demonstrate that (a)  $\text{NH}_4^+$  is transported at high affinity and at high rates across apical membranes of MTAL cells via a  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway and  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport; (b)  $\text{NH}_4^+$  entry via both the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway and  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport was sensitive to  $\text{pH}_i$  over a  $\text{pH}_i$  range of 6.8–7.2 pH units; (c) the effect of  $\text{pH}_i$  on  $\text{NH}_4^+$  entry via the  $\text{Ba}^{2+}$ -sensitive pathway was greater in S-MTAL (42% reduction on decreasing  $\text{pH}_i$  from 7.41 to 7.26) than in IP-MTAL (15% reduction on decreasing  $\text{pH}_i$  from 7.27 to 7.01), suggesting a modulatory effect of  $\text{NH}_3/\text{NH}_4^+$ ; and (d)  $\text{NH}_4^+$  could enter MTAL cells via the basolateral  $\text{Na}^+:\text{K}^+$ -ATPase, i.e.  $\text{Na}^+:\text{K}^+(\text{NH}_4^+)$ -ATPase.

FIGURE 13. Relationship between  $\text{pH}_i$  and the rate of  $\text{NH}_4^+$  entry via the apical  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter in IP-MTAL.  $\text{pH}_o$  7.40 in all experiments. Closed circles, entry rates in tubule cells acidified by addition of 0.5 mM amiloride; open circles, untreated tubules. The curve is the least-squares linear fit ( $y = 16.2x - 106.2$ ;  $r = 0.86$ ).

#### $\text{NH}_4^+$ Transport by the $\text{Ba}^{2+}$ -sensitive Pathway and $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$ Cotransport

In mouse MTAL cells ~45% of the initial rate of apical  $\text{NH}_4^+$  entry occurred via the  $\text{Ba}^{2+}$ -sensitive pathway while 55% was mediated by  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport. Apical membranes of mouse MTAL cells also possess a  $\text{Na}^+:\text{H}^+$  exchanger (Kikeri et al., 1990a); epithelial  $\text{Na}^+:\text{H}^+$  exchangers can transport  $\text{NH}_4^+$  (Kinsella and Aronson, 1981). However, the  $\text{NH}_4^+$ -induced acidification rate in S-MTAL was reduced by  $98.5 \pm 0.6\%$  ( $n = 7$ ) by the combination of  $\text{Ba}^{2+}$ , furosemide, and ouabain (compare segments c-d and b-g in Fig. 4, and segments c-d and b-f in Fig. 9). Moreover, the combination of luminal  $\text{Ba}^{2+}$  and furosemide in the IP-MTAL completely abolished the acidification observed on adding luminal  $\text{NH}_4^+$  (Kikeri et al., 1989). Thus, the apical  $\text{Na}^+:\text{H}^+$  exchanger in the mouse MTAL does not appear to mediate significant entry of  $\text{NH}_4^+$  ions when compared with the entry attributable to the combination of the  $\text{Ba}^{2+}$ -sensitive pathway and the furosemide-sensitive cotransporter.

In the isolated perfused rat TAL, Good et al. (1984) found that luminal furosemide virtually abolished transepithelial  $\text{NH}_4^+$  absorption. By contrast, in the rabbit TAL, furosemide inhibited only ~75% of active transcellular  $\text{NH}_4^+$  flux (Garvin, Burg, and Knepper, 1985), indicating a role for a furosemide-independent apical  $\text{NH}_4^+$  transport pathway. The apparent absence of furosemide-insensitive transepithelial  $\text{NH}_4^+$

transport in the rat TAL may be due to species differences. Alternatively, the effects of paracellular and transcellular ammonium fluxes, as well as backfluxes from basolateral to apical solutions, may have obscured furosemide-insensitive  $\text{NH}_4^+$  transport in studies of net transepithelial  $\text{NH}_4^+$  transport. Thus, all species tested to date absorb  $\text{NH}_4^+$  via the apical  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter, yet there may be considerable species differences in the role of the apical, barium-sensitive  $\text{K}^+(\text{NH}_4^+)$  pathway in  $\text{NH}_4^+$  absorption (mouse > rabbit > rat).

The  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport in MTAL: pH sensitivity and permeation via the apical  $\text{K}^+$  channel. Fig. 14 A summarizes the effects of  $\text{pH}_i$  on the apical  $\text{Ba}^{2+}$ -sensitive

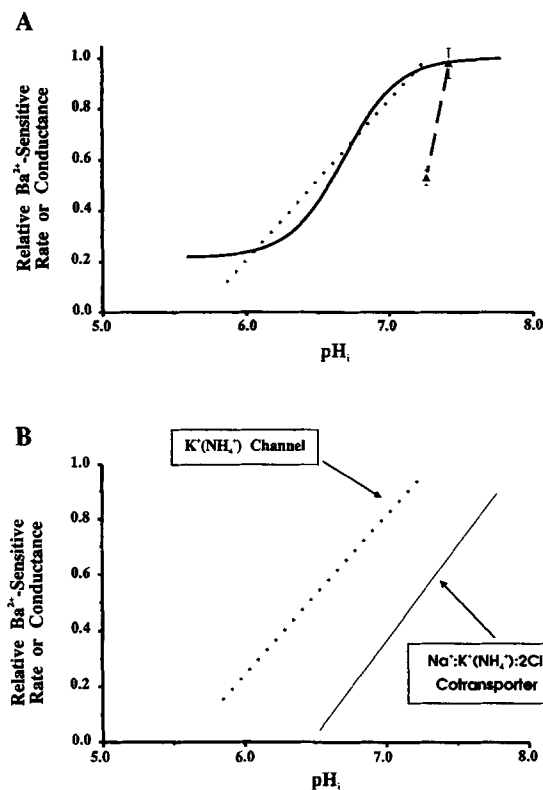

FIGURE 14. (A) Relationship between  $\text{pH}_i$  and relative, apical,  $\text{Ba}^{2+}$ -sensitive  $G_c$  (solid line), relative, apical,  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  entry in IP-MTAL (dotted line), or relative,  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  entry in S-MTAL (dashed line). (B) Relationship between  $\text{pH}_i$  and relative apical  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  entry in IP-MTAL (dotted line), or relative apical  $\text{NH}_4^+$  entry via  $\text{Na}^+:\text{K}^+/\text{NH}_4^+:2\text{Cl}^-$  (solid line) in IP-MTAL.

transcellular conductance ( $G_c$ ; solid line) in IP-MTAL, the apical,  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway in IP-MTAL (dotted line), and the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway in S-MTAL (dashed line; see below). In both S-MTAL and IP-MTAL preparations,  $J_{\text{NH}_4}$  was quite sensitive to  $\text{pH}_i$  changes over the physiological pH range 6–8. The finding that the  $\text{pH}_i$ - $J_{\text{NH}_4}$  relationships obtained in IP-MTAL were similar (Fig. 8; dotted line in Fig. 14 A) whether  $\text{pH}_i$  was altered by basolateral  $\text{pH}_o$  or by luminal amiloride at constant apical and basolateral  $\text{pH}_o$ , indicated that the pH sensitivity of this  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway in IP-MTAL is cytosolic rather than extracellular.

The similarities of the effects of  $\text{pH}_i$  on  $G_c$  and the apical,  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  influx suggests that both  $\text{K}^+$  and  $\text{NH}_4^+$  are being transported via the same or strikingly similar conductive pathways in apical membranes of MTAL cells. This possibility is supported by several recent observations. A  $\text{Ba}^{2+}$ -inhibitible  $\text{K}^+$  channel with similar cytosolic  $\text{pH}$  sensitivity was observed by Bleich et al. (1990) in recent patch clamp studies of the apical membrane from in vitro perfused rat TAL segments. This was the only type of  $\text{K}^+$  channel identified in apical membranes of rat TAL by these investigators, and the other observed properties of this channel indicated that it belonged to the class of ATP-regulated, inwardly rectifying  $\text{K}^+$  channels ( $\text{K}_{\text{ATP}}$ ). In fact,  $\text{K}_{\text{ATP}}$  channels with similar  $\text{pH}$  sensitivities have also been identified in patch clamp studies of principal cells from the rat renal cortical collecting duct (Wang et al., 1990), of early distal tubule cells from the kidney of *Rana pipens* (Hunter, Oberleithner, Henderson, and Giebisch, 1988; Wang, Henderson, Geibel, White, and Giebisch, 1989), and of B cells from the pancreatic islet (Rosario and Rojas, 1986a; Mislser, Gillis, and Tabcharani, 1989). While Bleich et al. (1990) found that the  $\text{K}_{\text{ATP}}$  channel in apical membranes of rat TAL had similar permeabilities for  $\text{K}^+$  and  $\text{NH}_4^+$ , they were unable to demonstrate any significant  $\text{NH}_4^+$  current in cell excised patches (although this issue was not extensively evaluated in this study). Interestingly, the  $\text{K}_{\text{ATP}}$  channel found in pancreatic B cells does appear to exhibit a significant  $\text{NH}_4^+$  permeability, the permeability ratio  $P_{\text{K}}:P_{\text{NH}_4^+}$ , estimated from fitting the  $I$ - $V$  relations to the Goldman-Hodgkin-Katz equation, was 1:3 (Rosario and Rojas, 1986b). Finally, recent studies using site-directed mutagenesis of the *Drosophila* Shaker  $\text{K}^+$  channel (although not a  $\text{K}_{\text{ATP}}$ -type channel) has demonstrated that certain mutations involving the H5 region, thought to line the channel pore (Guy and Conti, 1990; Yellen, Jurman, Abramson, and MacKinnon, 1991), significantly increased single channel  $\text{NH}_4^+$  conductance (Yool and Schwarz, 1991). Thus it is possible that  $\text{K}^+$  and  $\text{NH}_4^+$  are being transported across apical membranes of the mouse MTAL via the same  $\text{K}_{\text{ATP}}$  channels.

From the curves shown in Fig. 14 A, it is also evident that the relative reduction in  $J_{\text{NH}_4}$  observed with decreasing  $\text{pH}_i$  in S-MTAL (Fig. 14 A, dashed line) was much steeper than that observed in the IP-MTAL (Fig. 14 A, solid and dotted lines). One or more of at least three factors may have accounted for the rightward shift of the  $J_{\text{NH}_4}$ - $\text{pH}_i$  curve in S-MTAL. First, because basolateral membranes of MTAL cells are highly permeable to  $\text{NH}_3$ ,  $[\text{NH}_3]_i = [\text{NH}_3]_o$  in the presence of basolateral  $\text{NH}_4^+/\text{NH}_3$ , and consequently,  $[\text{NH}_4^+]_i$  will increase with decreasing  $\text{pH}_i$ .  $\text{pH}_i$ -dependent increases in  $[\text{NH}_4^+]_i$  would in turn reduce the electrochemical gradient for  $\text{NH}_4^+$  entry, and thus, contribute to the  $\text{pH}_i$ -associated reduction of  $J_{\text{NH}_4}$  in S-MTAL. In contrast,  $[\text{NH}_4^+]_i$  would not increase appreciably in IP-MTAL since basolateral medium did not contain  $\text{NH}_4^+$ . A second possible explanation for the rightward shift of the  $J_{\text{NH}_4}$ - $\text{pH}_i$  curve in S-MTAL is that intracellular  $\text{NH}_4^+/\text{NH}_3$  may have affected the activity of the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway, independent of its effects on the  $\text{NH}_4^+$  chemical gradient. While we know of no specific data addressing this issue for the  $\text{K}_{\text{ATP}}$  channel, a regulatory role for ammonium on another  $\text{K}^+(\text{NH}_4^+)$  transporter has been suggested by other investigators (Kurtz and Balaban, 1986; Hamm, Gillespie, and Klahr, 1985). A third possible reason for the different  $\text{pH}_i$  sensitivities of the  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway in S-MTAL and IP-MTAL may be

related to differences in cytosolic ATP (or other as yet unknown cytosolic factors regulating  $\text{K}_{\text{ATP}}$  channels). In support of this possibility, Misler et al. (1989) found that the  $\text{pH}_i$  sensitivity of the  $\text{K}_{\text{ATP}}$  channel observed in cell-attached membrane patches of pancreatic B cells was essentially abolished in cell-detached, inside-out patches. Furthermore, exposure of the inside-out patches to small concentrations of ATP restored much of the pH sensitivity of these channels.

*pH<sub>i</sub> regulation of  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport.* The apical  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter mediated high rates of  $\text{NH}_4^+$  entry into MTAL cells, in agreement with previous observations in TAL cells (Kinne et al., 1986; Garvin, Burg, and Knepper, 1988).  $\text{NH}_4^+$  influx via  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport was sensitive to  $\text{pH}_i$  (Fig. 13). Paris and Pouyssegur (1986) have shown previously that the activity of growth factor-activated  $\text{Na}^+:\text{K}^+:2\text{Cl}^-$  cotransport in fibroblasts was also reduced by cell acidification from  $\sim 7.5$  to 6.5 pH units. Our observations are qualitatively similar. The mechanisms by which changes in  $\text{pH}_i$  alter  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport and  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport are unknown.

TABLE I

Effect of Cell pH on Electrical Parameters of NaCl Transport in the Mouse MTAL

Buffer	$\text{pH}_i$	$V_e$	$G_e$	$J_e$

$J_e$  = rate of net NaCl absorption calculated as  $(V_e \cdot G_e)/F$ .

\*Data from Kikeri et al., 1990a.

<sup>‡</sup>Data from Hebert, 1987.

Fig. 14 B compares the  $\text{pH}_i$  sensitivity curves of the apical,  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway and the apical, furosemide-sensitive  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter observed in the present IP-MAL studies. In the absence of basolateral/intracellular  $\text{NH}_4^+/\text{NH}_3$ , the  $\text{pH}_i$  sensitivity curve of  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransport is located  $\sim 0.5$  pH units to the right of the  $\text{pH}_i$  sensitivity curve of the apical  $\text{Ba}^{2+}$ -sensitive  $\text{NH}_4^+$  transport pathway.

The differences in the  $\text{pH}_i$  sensitivities of the  $\text{Na}^+:\text{K}^+(\text{NH}_4^+):2\text{Cl}^-$  cotransporter and  $\text{K}^+(\text{NH}_4^+)$  channel observed in this study can explain our prior observation that switching from HEPES- to  $(\text{CO}_2/\text{HCO}_3^-)$ -buffered media diminished salt absorption in the mouse IP-MTAL (Hebert, 1987; Kikeri et al., 1990a). The pertinent results from these studies are summarized in Table I. Addition of  $\text{CO}_2/\text{HCO}_3^-$  to the external solutions bathing the IP-MAL resulted in a reduction in  $\text{pH}_i$  from 7.41 to 7.23. This cell acidification was associated with 17% decreases in  $V_e$  and the rate of NaCl absorption ( $J_e$ ), but no significant change in  $G_e$ . These results are entirely consistent with the differences in the  $\text{pH}_i$  sensitivities of the two apical  $\text{NH}_4^+$  transporters shown in Fig. 14 B. The arguments are as follows. If the  $(\text{CO}_2/\text{HCO}_3^-)$ -mediated fall in  $\text{pH}_i$  altered the apical cotransporter and not the apical  $\text{K}^+(\text{NH}_4^+)$  channel, then the fall in

NaCl absorption should be quantitatively predicted by the  $\text{pH}_i$  sensitivity of the cotransporter. Using the  $\text{pH}_i$  titration equation fitted to the data in Figs. 13 and 14 B, the predicted rates of cotransporter activity would be 14.3 mM/min at  $\text{pH}_i$  7.41 and 11.0 mM/min at  $\text{pH}_i$  7.23, or a fall in cotransporter activity of  $\sim 13\%$ , a value quite similar to the observed 17% fall in  $J_e$ . On the other hand, the lack of a significant change in  $G_e$  (Table I) is consistent with the lower  $\text{pH}_i$  sensitivity of the  $\text{K}^+(\text{NH}_4^+)$  channel (Fig. 14 B).

*Model of Effects of  $\text{pH}_i$  on Transcellular  $\text{NH}_4^+$  Transport in MTAL*

A model for the regulation of  $\text{NH}_4^+$  transport, based on these and previous observations (Kikeri et al., 1989, 1990a), is presented in Fig. 15. Fig. 15 A shows the steady-state concentrations of extracellular and intracellular  $\text{NH}_4^+/\text{NH}_3$  in MTAL cells in the presence of 5 mM ambient  $\text{NH}_4\text{Cl}$  (luminal/basolateral medium pH 7.4). Although apical membranes of mouse MTAL cells are virtually impermeable to  $\text{NH}_3$ , the concentrations of intracellular and basolateral (interstitial)  $\text{NH}_3$  would be virtually equal since basolateral membranes of MTAL cells are highly permeable to  $\text{NH}_3$  (Kikeri et al., 1989). Thus, the concentration of intracellular  $\text{NH}_4^+$  will depend on the  $\text{pH}_i$  and the  $\text{NH}_3$  concentration of the basolateral medium. For this example the steady-state  $\text{pH}_i$  in the presence of 5 mM ambient  $\text{NH}_4\text{Cl}$  would be 7.13. Fig. 15 B depicts the effects of both  $\text{NH}_4^+$ -induced  $\text{pH}_i$  changes and intracellular  $\text{NH}_4^+/\text{NH}_3$  on transcellular  $\text{NH}_4^+$  transport in the mouse MTAL in the presence of ambient 5 mM  $\text{NH}_4\text{Cl}$ .  $\text{NH}_4^+$  entry from the lumen would result in the net generation of  $\text{H}^+$  with  $\text{NH}_3$  diffusing down its gradient into the medullary interstitium. Because of the negligible apical membrane  $\text{NH}_3$  permeability,  $\text{NH}_3$  backleak from the cytoplasm to the lumen would be minimal (Kikeri et al., 1989). Because of the large cellular buffering power,  $B_i$ , most of the  $\text{H}^+$  load due to  $\text{NH}_4^+$  entry would be buffered, thus attenuating the drop in  $\text{pH}_i$ . The increasing  $B_i$  with acidification below a pH of 7.0 (Fig. 2) would also help to attenuate  $\text{pH}_i$  changes resulting from apical  $\text{NH}_4^+$  entry. Nevertheless, cell acidification due to  $\text{NH}_4^+$  entry would (a) inhibit  $\text{NH}_4^+$  entry via the apical entry pathways, and (b) increase the rate of apical (Kikeri et al., 1990a) and basolateral (Sun and Hebert, 1990)  $\text{Na}^+:\text{H}^+$  exchange. The combined effect of reduced  $\text{NH}_4^+$  entry and increased  $\text{Na}^+:\text{H}^+$  exchange would result in an increase in  $\text{pH}_i$ , which would tend to restore  $\text{NH}_4^+$  entry via the apical entry pathways and decrease the rate of  $\text{Na}^+:\text{H}^+$  exchange. At the steady-state  $\text{pH}_i$  in the presence of 5 mM ambient  $\text{NH}_4\text{Cl}$  (7.13 pH units),  $\text{H}^+$  influx due to  $\text{NH}_4^+$  entry would be balanced by  $\text{H}^+$  efflux (predominantly via  $\text{Na}^+:\text{H}^+$  exchange) due to  $\text{NH}_4^+$  exit (Fig. 5).

*Some Physiological Implications of This Model for  $\text{NH}_4^+$  and NaCl Transport*

Changes in  $\text{pH}_i$  in the presence of basolateral/intracellular  $\text{NH}_4^+/\text{NH}_3$  may affect the rate of apical  $\text{NH}_4^+$  transport by altering the  $\text{NH}_4^+$  chemical gradient. Thus, the concentration of  $\text{NH}_3$  in the medullary interstitium surrounding the MTAL may play an important role in regulating transcellular  $\text{NH}_4^+$  absorption by the in vivo MTAL; the rate of transcellular  $\text{NH}_4^+$  flux would be high in the presence of low interstitial  $\text{NH}_3$  concentrations and vice versa. In other words, as the medullary interstitial concentration of  $\text{NH}_4^+/\text{NH}_3$  rises, transcellular  $\text{NH}_4^+$  transport would be inhibited because of an increase in intracellular  $\text{NH}_4^+/\text{NH}_3$  concentrations. The inhibitory effect

of intracellular  $\text{NH}_4^+/\text{NH}_3$  on transcellular  $\text{NH}_4^+$  transport could be due to either a reduction in the  $\text{NH}_4^+$  chemical gradient or an effect (either directly or indirectly) of intracellular  $\text{NH}_4^+/\text{NH}_3$  on the apical  $\text{NH}_4^+$  transport pathways. This "negative feedback loop" would limit the maximum interstitial concentrations of  $\text{NH}_4^+/\text{NH}_3$ , which in turn is believed to play an important role in regulating renal  $\text{NH}_4^+$  excretion (Knepper et al., 1989).

NaCl reabsorption by the MTAL both dilutes the urine and provides the single effect of the countercurrent multiplication process which is required for vasopressin-dependent concentration of urine in the medullary collecting duct. Net NaCl absorption by the mouse MTAL is dependent on the activities of both the apical  $\text{Na}^+:\text{K}^+:2\text{Cl}^-$  cotransporter and the apical  $\text{K}^+$  channel (Hebert and Andreoli, 1986). Given the results of this study, it seems reasonable to speculate that the  $\text{pH}_i$  and/or the presence of basolateral/intracellular  $\text{NH}_4^+/\text{NH}_3$  may affect the rate of transepithelial NaCl absorption in the mouse MTAL by altering the activities of both of these ion transporters. Several lines of evidence support this possibility. First, as discussed above, the results in Table I are consistent with this notion. Second, Wingo (1986) has demonstrated that both respiratory and metabolic acidosis result in a reduction of transepithelial  $\text{Cl}^-$  transport in the TAL. Since both an increase in ambient  $\text{CO}_2$  concentration (Kikeri et al., 1990a) and metabolic acidosis would be expected to lead to cell acidification, inhibition of apical ion transport pathways in the TAL by cell acidification may explain the acidosis-induced reduction of transepithelial  $\text{Cl}^-$  absorption observed by Wingo (1986). Third, the MTAL in the isolated perfused rat kidney is exquisitely vulnerable to hypoxic injury (Brezis, Rosen, Silva, and Epstein, 1984a) because of the high rates of transport-related energy consumption by the MTAL (measured as ouabain-sensitive oxygen consumption [Brezis, Rosen, Silva, and Epstein, 1984b]). Reduction of the perfusate pH (acidosis) markedly attenuates hypoxic injury to MTAL in the isolated perfused rat kidney (Shanley, Shapiro, Chan, Burke, and Johnson, 1988). An attractive explanation for the acidosis-induced protection against hypoxic MTAL cell injury is that inhibition of ion transport-dependent oxygen consumption in the MTAL (>50% of total oxygen consumption [Kikeri et al., 1990a]) by cell acidification may protect against cell damage in hypoxic conditions. Fourth, it has long been recognized that the oral administration of an  $\text{NH}_4\text{Cl}$  load leads to diuresis, natriuresis, and kaliuresis without a consistent change in glomerular filtration rate (Pitts, 1959; Sartorius, Roemmelt, and Pitts, 1949). Inhibition of apical ion transporters in the TAL and possibly in other nephron segments by  $\text{NH}_4^+$ -induced cell acidification or by intracellular  $\text{NH}_4^+/\text{NH}_3$  itself may at least partially explain the effects of acute  $\text{NH}_4\text{Cl}$  loading on salt and  $\text{H}_2\text{O}$  excretion by the kidney. Finally, alterations in  $\text{pH}_i$  have been suggested to alter transport processes in diluting segments. Weigt, Dietl, Silbernagl, and Oberleithner (1987) and Wang et al. (1989) have suggested that the effect of aldosterone on the apical  $\text{K}^+$  channel in the frog diluting segment is mediated by cell alkalization due to activation of  $\text{Na}^+:\text{H}^+$  exchange.
