Novel adaptations often cause pleiotropic reductions in fitness. Under optimal conditions individual organisms may be able to compensate for, or reduce, these fitness costs. Declining environmental quality may therefore lead to larger costs. We investigated whether reduced plant quality would increase the fitness costs associated with resistance to *Bacillus thuringiensis* in two populations of the diamondback moth *Plutella xylostella*. We also measured the rate of decline in resistance on two host-plant (*Brassica*) species for one insect population (Karak). Population × plant species interactions determined the fitness costs in this study. Poor plant quality increased the fitness costs in terms of development time for both populations. However, fitness costs seen in larval survival did not always increase as plant quality declined. Both the fitness and the stability experiment indicated that fitness costs were higher on the most suitable plant for one population. Theoretically, if the fitness cost of a mutation interacts additively with environmental factors, the relative fitness of resistant insects will decrease with environmental quality. However, multiplicative costs do not necessarily increase with declining quality and may be harder to detect when fitness parameters are more subject to variation in poorer environments.

Keywords: *Bacillus thuringiensis*; fitness cost; gene × environment interaction; tritrophic interaction; *Plutella*; *Brassica*

1. INTRODUCTION

Adaptation to novel evolutionary challenges such as pesticides or new habitats often imposes a fitness cost (Crow 1957), which is a reduction in fitness relative to susceptibles in the absence of the selective agent. Fitness costs are commonly enhanced or more easily detected in stressful environments: e.g. under high competition (Kraaijeveld & Godfray 1997; Raymond *et al.* 2005); in low nutrient conditions (Bergelson 1994); or during overwintering (Foster *et al.* 1997; Carrière *et al.* 2001). Thus, costs may be reduced when environmental conditions are benign or when resource quality is high, perhaps because

physiologically less stressed organisms may be able to rely on compensatory mechanisms to mask physiological deficiencies. Host-plant defences can represent a significant source of stress and mortality for herbivores. Moreover, the magnitude and genetics of fitness costs of resistance to the bacterium *Bacillus thuringiensis* (*Bt*) can be altered by plant defence compounds (Carrière *et al.* 2004) and may be greater on crop plants that are better defended against herbivore attack (Janmaat & Myers 2005). If the fitness costs of resistance to pesticides can vary predictably with food-plant defences, these characteristics may be important tools in resistance management. Conversely, high resource quality (e.g. escape from competition) may be generally important for the spread of novel adaptations through a population.

We hypothesized that fitness costs to a lepidopteran host associated with resistance to *Bt* should increase on better-defended food plants. Our study species, the diamondback moth, *Plutella xylostella* L., has repeatedly evolved resistance to *Bt* (Ferré & Van Rie 2002). This bacterium is widely used as a bio-pesticide (e.g. DiPel) and *Bt* genes expressing insect-specific toxins are commonly incorporated into genetically modified crops.

2. MATERIAL AND METHODS

(a) Insects, plants and selection protocols

Two resistant populations of *P. xylostella* (Karak and Keluang) were collected from Malaysia in 2001 and 2002, respectively, from Chinese cabbage, *Brassica pekinensis*, farms 200 km apart that are regularly sprayed with DiPel. The strains differ in their mode of inheritance of resistance: incompletely recessive in Karak (Sayyed *et al.* 2004); semi-dominant in Keluang (A. Sayyed 2003, unpublished data), although the mechanism of resistance has only been described for Karak (Sayyed *et al.* 2004). Revertant strains, i.e. previously selected strains that had lost resistance to *Bt*, were produced by long-term culture on Chinese cabbage *B. pekinensis*; resistant strains were selected periodically with Cry1Ac (the predominant crystal toxin in DiPel) as described previously (Raymond *et al.* 2005). Prior to experiments, resistance levels to Cry1Ac were checked using leaf-dip bioassays (Sayyed *et al.* 2000).

The common cabbage, *Brassica oleracea* L., var. 'Wheelers Imperial', and the Chinese cabbage, *B. pekinensis*, var. 'One Kilo, S.B', were used in this study at eight and five weeks old, respectively. *B. oleracea* has defences against lepidopteran attack (waxiness, toughness and glucosinolate levels) that are much reduced in *B. pekinensis*. Plants were grown in a climate-controlled glasshouse maintained at $20 \pm 1^\circ\text{C}$ with supplementary lighting (400 W sodium and halide lamps: min. incident radiation 300 W m^{-2}).

(b) Performance of revertant and resistant populations on two plant species

Cry1Ac resistant and susceptible revertant strains from the Karak and Keluang populations were used in a full-factorial experiment with plants of both *Brassica* species. Individual plants ($n=9-10$) were randomly allocated to treatments. We added 45 and 35 freshly emerged neonates to each *B. oleracea* and *B. pekinensis* plant, respectively. Mean mass and number of larvae on each plant were recorded after 5 days. After 7 days, plants were checked daily and pupae removed and weighed. Female fecundity was measured by rearing up to three individual pairs from each plant in 50 mm diameter Petri dishes (one dish per pair) with access to 20% honey solution for 5 days. The means of data from each plant were used in analyses to avoid pseudo-replication.

(c) Stability of resistance on *B. oleracea* and *B. pekinensis*

This experiment tested whether variation in plant-associated fitness costs in the Karak population would lead to different rates of decline of resistance in culture. Each replicate was initiated with 200 neonates from the resistant Karak population with four plants per replicate cage and four cages per treatment. Thereafter, each generation was propagated with 40–50 pupae. Replicates were reared in individual culture cages (at $25 \pm 1^\circ\text{C}$, 50–60% RH, 16 h photophase) for three generations. Thereafter, all populations were reared for a single generation on *B. pekinensis* in order to control for

plant-based maternal effects and bioassayed in the following generation ($N=35\text{--}40$ larvae per dose and six doses).

(d) Data analysis

Statistical analysis was carried out in R (<http://www.r-project.org>) using analysis of variance and generalized linear modelling. Proportional data were logit-transformed and models were scaled to correct for overdispersion, where appropriate. The stability experiment was analysed with a mixed model analysis of covariance, with replicate as a random effect and bioassay dose nested within replicate. In the mixed model, mortality data were arcsine transformed and doses log-transformed.

3. RESULTS

(a) Performance of revertant and resistant populations on two plant species

Susceptibility to Cry1Ac differed between resistant and revertant lines of the Keluang ($F_{1,17}=15.0$, $p<0.01$) and Karak populations ($F_{1,6}=44.2$, $p<0.001$) immediately prior to this experiment. The LC_{50} s for the Keluang lines were 30.1 and $1.50\ \mu\text{g ml}^{-1}$, respectively and for the Karak lines were 96.7 and $3.3\ \mu\text{g ml}^{-1}$, respectively. *Brassica oleracea* was demonstrably a poorer quality host for *P. xylostella*: growth rates were slower and survival was reduced on this species (figure 1a–c; table 1).

Fitness costs did not consistently increase on the poorer quality plant species. Karak insects showed reduced larval growth rates relative to revertant susceptibles on both species (table 1; figure 1a). Only development time showed increasing fitness costs with declining plant quality across both populations (table 1; figure 1b). Resistance affected survival to pupation differently for the two populations, there being a significant three-way interaction between resistance, cabbage species and population (table 1; figure 1c). Karak larvae showed fitness costs in terms of survival on the high-quality plant (*B. pekinensis*), whereas Keluang larvae showed the opposite pattern, i.e. improved survival of resistant larvae on *B. pekinensis* (figure 1c).

For the other fitness components, there was no detectable difference between resistant and susceptible sub-populations (table 1). There were insufficient data to analyse the fecundity of Karak insects feeding on *B. oleracea*, owing to poor survival to pupation (figure 1c). However, resistance did not influence the fecundity of Keluang insects ($F_{1,25}=0.2$, $p>0.05$) nor the fecundity of Karak insects reared on *B. pekinensis* ($F_{1,17}=0.29$, $p>0.05$).

(b) Stability of resistance on *B. oleracea* and *B. pekinensis* in the Karak strain

We expected that resistance would decline more rapidly on the plant species (*B. pekinensis*) on which Karak showed higher relative fitness costs in terms of survival (figure 1c). One *B. pekinensis* replicate went extinct in this experiment, leaving four replicates on *B. oleracea* and three on *B. pekinensis*. As predicted, Cry1Ac mortality was highest in the populations cultured on *B. pekinensis* (plant species treatment, mixed model ANCOVA, d.f. = 1,6, likelihood ratio 5.65, $p=0.017$). Inspection of the 95% confidence limits of the LC_{50} s confirms that resistance fell faster in two out of the three *B. pekinensis* replicates relative to the *B. oleracea* replicates (figure 2).

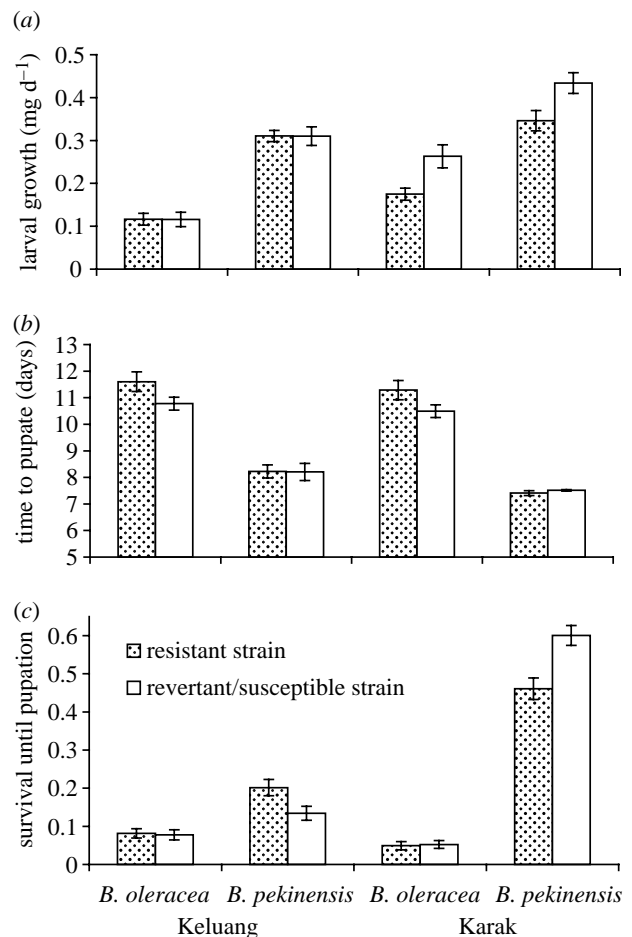

Figure 1. Performance of Cry1Ac resistant and revertant/susceptible *P. xylostella* from two populations (Karak and Keluang) on the plant species *B. oleracea* and *B. pekinensis*. Data are mean \pm s.e. Standard errors for survival are based on the normal approximation to the binomial.

4. DISCUSSION

Contrary to our expectation, the lower quality of plants did not consistently increase the fitness costs of resistance to *Bt* in *P. xylostella*. Larval development time was extended for both resistant Karak and Keluang populations on the better-defended host. However, fitness costs acting on survival depended on interactions between population and environment, as found previously (Carrière et al. 2004; Raymond et al. 2005), and for one population (Karak) increased on the higher-quality plants. While population-level effects were tested with very low statistical power ($n=2$) in the performance experiment, these results reflect our experience of the stability of resistance in these two populations in culture and formal experiments (figure 2). Independent mutations conferring resistance in different strains could be responsible for the variation in fitness costs. Alternatively, differences in genetic background can also alter pleiotropic fitness costs (Bohannan et al. 1999).

A mechanistic explanation of different patterns shown by different performance parameters (survival and development time) with respect to resource quality is beyond the scope of this paper. However, some simple theory can illustrate how different models of fitness costs can make very different

Table 1. Summary of ANOVAs exploring the factors affecting five fitness components of Cry1Ac resistant and revertant susceptible populations of *P. xylostella*. (Two insect populations (Karak and Keluang) and two host-plant species (*B. oleracea* and *B. pekinensis*) were used in this experiment, $n=9-10$ plants per treatment. Key to significance levels: * $p<0.05$; ** $p<0.01$; *** $p<0.001$.)

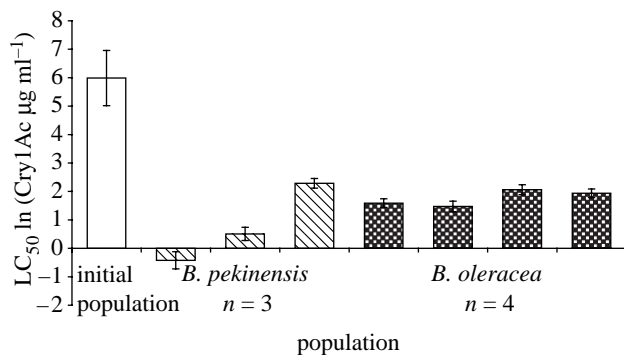

Figure 2. The susceptibility to the Bt toxin Cry1Ac after three generations of culture on two different plants species. Data are LC_{50} s for individual replicates in each treatment ($N=3$ or 4), with 95% confidence limits and the LC_{50} of the population used to start the experiment. Data are calculated from ln-transformed doses.

Table 2. The impact of resource quality (q) and additive or multiplicative fitness costs on the relative fitness of resistant and susceptible strains. (Fitness calculated as per discussion, see §4.)

<i>c</i> -fitness cost	additive costs $q=0.4$	additive costs $q=0.6$	additive costs $q=0.9$	multiplicative costs (all $q>0$)
0.05	0.92	0.83	0.5	0.95
0.1	0.83	0.67	0	0.90
0.15	0.75	0.50	0	0.85
0.2	0.67	0.33	0	0.80
0.25	0.58	0.17	0	0.75
0.3	0.50	0	0	0.7

predictions for the impact of resource quality on fitness costs. If fitness costs act additively, the proportional reduction in fitness is independent of resource quality. Thus, the fitness of homozygous susceptibles is $W_{SS}=1-q$, where q is the impact of resource quality on fitness, and the fitness of homozygous resistant individuals is $W_{RR}=1-q-c$, where c is the cost of resistance. If $c+q>1$, W_{RR} is

assumed to be zero. Under a multiplicative model, the effects of resistance are a fixed proportion of the effects of resource quality, thus $W_{RR}=(1-q)(1-c)$. The relative fitness of resistant individuals is W_{RR}/W_{SS} in all cases. Using data from these experiments, it can be seen that the two different models make very different predictions (table 2).

There are no *a priori* reasons for expecting either the multiplicative or the additive model to be true for the fitness costs associated with novel adaptations. With a multiplicative model, only additional costs (i.e. an increase in c with declining quality) will alter relative fitness. Differences in fitness at lower resource quality may also be harder to resolve if poor resource quality leads to lower sample size and reduced statistical power. With *P. xylostella*, fitness costs for survival of Cry1Ac resistant individuals have only been identified on *B. oleracea* plants significantly older than those used in this study (four months and above; Raymond *et al.* 2005; Raymond *et al.* 2006, unpublished data). Older plants are increasingly better defended against insect attack (Verkerk & Wright 1994), suggesting that values of c may vary within species with only subtle variations in resource quality. If there is an additive component to fitness costs, a decline in resource quality will automatically increase the difference in relative fitness between genotypes. Greater reductions in resource quality will also lead to larger differences in relative fitness, as found for Bt-resistant *Trichoplusia ni* feeding on a range of species (Janmaat & Myers 2005).
