### Summary

*Pygopus* has recently been identified in *Drosophila* as an essential component of the nuclear complex required for canonical Wnt signaling. Here, we have investigated the role of the mammalian *pygopus* ortholog, *mPygo2*, in pancreas development. We show that a null mutation of *mPygo2* in mice causes pancreas hypoplasia due to decreased progenitor cell proliferation after embryonic day (e) 12.5. During the same time window, *mPygo2*-deficient embryos begin to display a reduction in endocrine progenitors and consequently a decrease in islet endocrine cell mass. Consistent with its function after e12.5, late-developing endocrine cell types, such as beta, delta and PP cells, are specifically reduced, while the earlier-forming alpha cells develop normally. We find canonical Wnt signaling to be predominantly active in the mesenchyme at the time when *mPygo2* is required and demonstrate the dependence of Wnt signal transduction on *mPygo2*. Furthermore, conditional deletion of *mPygo2*<sup>fllox</sup> allele in the pancreatic epithelium does not phenocopy the defects in *mPygo2*-null mutants. Since *mPygo2* is expressed in the pancreatic mesenchyme and the role of the mesenchyme in epithelial progenitor cell expansion is well documented, our findings suggest an indirect role for *mPygo2* in epithelial growth and differentiation through regulation of mesenchymal signals. Together, our data suggest a previously unappreciated role for mesenchymal Wnt signaling in regulating pancreatic organ growth and cell differentiation.

## Introduction

In mammals, the pancreas develops as separate ventral and dorsal evaginations from the gut endoderm (Slack, 1995). As the dorsal and ventral pancreatic buds appear at embryonic day (e) 9.5 and e10.5, respectively, they each become surrounded by a cap of dense mesenchyme. Subsequent proliferation of the epithelial progenitors rapidly leads to formation of a branched epithelium that gives rise to an endocrine and an exocrine tissue compartment. The pancreatic endocrine compartment is comprised of glucagon-producing alpha-, the insulin-producing beta-, the somatostatin-producing delta- and pancreatic polypeptide (PP)-producing cells that form sequentially during development and cluster in so-called islets of Langerhans shortly before birth. The exocrine acinar cells and ducts become visible as distinct structures by about e14.5.

All pancreatic cells arise from a common pool of pancreatic epithelial progenitor cells that are marked by the transcription factor Pdx1 (Gu et al., 2002). Expression of the transcription factors Ngn3 and after e13.5, Ptf1a, subsequently restrict the developmental potential of these pluripotent progenitors to an endocrine and exocrine fate, respectively (Gu et al., 2002; Zhou et al., 2007). Since the pancreas has limited capacity for adaptive growth, the final size of the endocrine and exocrine cell compartments at birth is largely determined by the size of the highly proliferative pluripotent progenitor cell pool at the pancreatic bud stage (Stanger et al., 2007). Mutations that affect progenitor cell expansion early in development therefore commonly result in peri- and postnatal pancreatic hypoplasia. Proliferation and branching of the epithelial buds is controlled by both autonomous cues in the epithelium as well as non-autonomous signals from the surrounding mesenchyme (Murtaugh, 2007). When cultured in the absence of mesenchyme, epithelial buds show minimal growth and branching, which is restored upon recombination with mesenchyme (Golosow and Grobstein, 1962; Wessells and Cohen, 1967). The mesenchyme not only controls progenitor cell expansion, but also promotes both endocrine and exocrine cell differentiation (Attali et al., 2007; Li et al., 2004b; Scharfmann, 2000).

Previous studies have provided evidence that the Wnt signaling pathway controls several aspects of pancreatic development. Early in development, the level of endodermal Wnt activity appears to control the specification of intestinal, liver and pancreatic fates in foregut endoderm (Heller et al., 2002; McLin et al., 2007; Ober et al., 2006). Gain- and loss-of-function studies in mice further indicate that during pancreas morphogenesis, Wnt signaling is required for growth and differentiation of the epithelium (Dessimoz et al., 2005; Heiser et al., 2006; Murtaugh et al., 2005; Papadopoulou and Edlund, 2005; Wells et al., 2007). Additional roles for Wnt signaling have been further suggested during the perinatal and postnatal periods in islet formation, islet cell proliferation and beta cell function (Fujino et al., 2003; Kim et al., 2005; Rulifson et al., 2007).

While these studies have established that Wnt signaling is important in the pancreas, the spatial and temporal pattern of Wnt signal transduction and the specific requirements for Wnt activity in the epithelium and mesenchyme have remained elusive. Notably, Wnt signals can be intracellularly transduced through a so-called canonical (Wnt/ $\beta$ -catenin) pathway or non-canonical (Wnt/ $\text{Ca}^{2+}$  and Wnt/planar cell polarity) pathways (Miller, 2002). The existence of parallel pathways leaves ambiguity as to which intracellular signals control the phenotype when Wnt signaling is perturbed at the Wnt ligand or frizzled receptor level. As conditional deletion of the Wnt-effector  $\beta$ -catenin in pancreatic epithelial progenitor cells causes defects in progenitor cell expansion and exocrine cell differentiation, it has been recently suggested that normal pancreas morphogenesis requires canonical Wnt signaling autonomously in the epithelium (Murtaugh et al., 2005; Wells et al., 2007). However, interpretation of the mechanisms that underlie these phenotypic changes is complicated by the fact that  $\beta$ -catenin

also has Wnt-independent functions in cell adhesion (Nelson and Nusse, 2004). To better understand the role of canonical Wnt signaling in pancreas development, it is therefore necessary to compare the effects of perturbing signal transduction at several levels of the pathway.

In response to Wnt signaling, cytoplasmic  $\beta$ -catenin becomes stabilized and enters the nucleus, where it functions in a complex with Tcf/Lef transcription factors to activate Wnt target genes (Nelson and Nusse, 2004). Recently, *pygopus* has been identified as an additional core component of this complex in *Drosophila* and appears to act as a nuclear anchor as well as coactivator for the  $\beta$ -catenin/Tcf/Lef complex (Kramps et al., 2002; Kriehoff et al., 2006; Stadeli and Basler, 2005; Thompson, 2004; Townsley et al., 2004a; Townsley et al., 2004b). Analysis of loss-of-function phenotypes in *Drosophila* and *Xenopus* have shown that *pygopus* is an essential regulator of canonical Wnt pathway responses (Belenkaya et al., 2002; Lake and Kao, 2003; Parker et al., 2002; Thompson et al., 2002). The murine genome contains two *pygopus* orthologs, *pygopus 1* (*mPygo1*) and *pygopus 2* (*mPygo2*). Consistent with the broader expression of *mPygo2* than *mPygo1* during development and in adult tissues (Li et al., 2004a), loss of *mPygo2* function causes severe developmental defects in various Wnt-dependent tissues, while *mPygo1*-deficient mice exhibit no apparent abnormalities (Li et al., 2007; Schwab et al., 2007; Song et al., 2007). Therefore, *mPygo2* appears to be the functionally important ortholog in mice.

We show here that germline mutation of *mPygo2* in mice causes pancreatic hypoplasia and a specific defect in endocrine cell differentiation. We find that these defects result from decreased proliferation of undifferentiated pancreatic progenitors and reduced formation of endocrine progenitors after e13. Since the pancreas develops normally in mice with a pancreatic epithelial-specific deletion of *mPygo2*, our data suggest that *mPygo2* controls mesenchymal signals required for pancreatic growth and differentiation. Accordingly, we find that canonical Wnt signaling is active in the pancreatic mesenchyme at the time *mPygo2* mutant mice first show a phenotype and demonstrate dependence of this signal on *mPygo2* function. Therefore, our results suggest that expansion and differentiation of pancreatic epithelial progenitors requires canonical Wnt signaling in the mesenchyme.

## Material and Methods

### Mice

Mice carrying the null allele for *mPygo2* were generated by Cre-mediated recombination in ES cells (Li et al., 2007). For pancreas-specific deletion of *mPygo2*, mice with a floxed *mPygo2* allele (*mPygo2<sup>fllox</sup>*) (Li et al., 2007) were crossed with *Pdx1-Cre* mice (Gu et al., 2002). In these experiments, *mPygo2<sup>fllox/+</sup>;Pdx1-Cre* or *mPygo2<sup>+/-</sup>;Pdx1-Cre* littermates served as controls. PCR detection of the *mPygo2<sup>fllox</sup>* allele was performed using primers forward 5'-AGC GTG TCT AAG GTC AGC CAG AGG TTT G-3' and reverse 5'-GTA AAG CGT TGG GGG AGA GGA GGA GGA C-3'. *Axin2<sup>+lacZ</sup>* and *BatGAL* mice have been previously described (Lustig et al., 2002; Maretto et al., 2003). All strains were maintained on a C57BL/6J background. Experiments were performed with the approval of the UC Irvine Institutional Animal Care and Use Committee protocol 2002–2420. Noon of the vaginal plug day was considered as e0.5. To label S-phase nuclei, some mice were injected with 50 $\mu$ g/g body weight of BrdU i.p. 45 min prior to sacrifice.

### Tissue processing, immunohistochemistry and microscopy

Pancreata were fixed in 4% paraformaldehyde in PBS for 4 hours and immunofluorescence was performed on 10  $\mu$ m cryopreserved or 7  $\mu$ m paraffin sections. Staining with hematoxylin/eosin (Fisher) was performed according to the manufacturer's instructions. For

immunostaining we followed a previously described protocol (Sander et al., 1997). The following antibodies were used: rabbit anti-mPygo2 (1:500; (Li et al., 2007), guinea pig anti-insulin (1:5000; Linco), mouse anti-glucagon (1:50; Sigma), mouse anti-somatostatin (1:3000; gift from Palle Serup, Hagedorn Institute), rabbit anti-pancreatic polypeptide (1:2000; Dako), rabbit anti-amylase (1:500; Sigma), armenian hamster anti-MUC1 (1:200; Lab Vision Corporation), mouse anti- $\beta$ -catenin (1:100; Sigma), guinea pig anti-Pdx1 (1:5000; gift from Chris Wright, Vanderbilt University), guinea pig anti-Ngn3 (1:1000; (Henseleit et al., 2005)), rabbit anti-Ptf1a (1:2000; gift from Helena Edlund, Umea University), mouse anti-BrdU (1:100; Chemicon), rat anti-E-cadherin (1:2000; Sigma), rabbit anti-mPygo1 (1:3000; Schwab et al., 2007), guinea pig anti-Pbx1 (1:400; Kim et al., 2002), guinea pig anti-Is11 (1:5000; gift from Johan Ericson, Karolinska, Stockholm), rabbit anti-Sox9 (1:2000; Chemicon). For immunohistochemistry, biotinylated anti-mouse or anti-guinea pig IgG antibodies were used (1:200; Vector Laboratories). For immunofluorescence, antigen-antibody complexes were detected with Cy3- (1:2000; Jackson Laboratory) or Alexa488- conjugated (1:2000; Molecular Probes) goat-raised secondary antibodies. For detection of Pdx1, Ptf1a, Ngn3 and BrdU, antigen retrieval was performed by incubation in pH 6.0 citrate buffer at 37°C for 1h. Glucagon and BrdU were detected using the M.O.M. Immunodetection Kit (Vector Laboratories). TUNEL assays were performed using the ApopTag® Plus Peroxidase In Situ Apoptosis Detection Kit (Chemicon). Using 5-bromo-4-chloro-3-indolyl-beta-D-galactopyranoside (X-gal) as a substrate, whole-mount X-gal staining was performed on either whole embryos or isolated abdominal organs as described (Mombaerts et al., 1996). Images were collected on a Zeiss Axioplan2 microscope with a Zeiss AxioCam driven by Zeiss AxioVision v. 4.0 software.

### Morphometric quantification of cell numbers and area

For morphometric analysis, all pancreata were embedded in the same orientation and serial sections were collected from the entire organ. Following immunostaining, images from an entire pancreas section were acquired and if necessary assembled in Adobe Photoshop. Cell counting and morphometric analysis were performed on every fifth section. E-cadherin was used to visualize the entire pancreatic epithelial area and DAPI staining for detection of individual nuclei. Mesenchymal cell area was measured by subtracting the epithelial cell area from the total pancreatic area, including the mesenchyme. Morphometry was conducted using Image-Pro Plus v. 5.0.1 (Media Cybernetics). The data are displayed as averages  $\pm$  standard error of the mean. Statistical significance was determined using Student's *t*-test (Minitab v. 14.20).

### RNA preparation and RT-PCR and real-time quantitative PCR

Total RNA from dissected pancreatic anlagen was extracted with the RNeasy kit (Qiagen) and treated with DNase. cDNA was prepared by *in vitro* transcription using the iScript cDNA synthesis kit (Biorad). The following primers were used for PCR: for detection of *mPygo2* forward 5'-GGA GCG AAG AAA GTC CAA TAC-3' and reverse 5'-GTT AGA AGC GAC CAG ATG ATC-3' (75 bp product); for detection of *mPygo1* forward 5'-GTG GTG ACA GTG GAC TGG ATG-3' and reverse 5'-CTG AGT GAG TAA GGA CCA CAG-3' (323 bp product); for detection of  $\beta$ -actin as an internal control forward 5'-TGT TAC CAA CTG GGA CGA CA-3' and reverse 5'-GGG GTG TTG AAG GTC TCA AA-3'. Amplification was performed for 35 PCR cycles.

For quantitative RT-PCR analysis, all transcripts were amplified with 1x SYBR Green PCR master mix (Applied Biosystems), as described previously (Kioussi et al., 2006). Listed 5' to 3', primer sequences were as follows: *mPygo1* forward: CCATCGCGCTGAAGAGAGTTA; *mPygo1* reverse: GTGTGTTGGCCTTGCGTTTT; *mPygo2* forward: AAGCCCGGTCTGCAAATGAA; *mPygo2* reverse: GTTAGAAGCGACCAGATGATCC;

Axin2 forward: TGA<sub>CTCTCCTTCCAGATCCCA</sub>; Axin2 reverse: TGCCCACTAGGCTGACA.

## Results

### Expression pattern of mPygo2 in the developing pancreas

To determine the domains of mPygo2 expression, we performed co-immunofluorescence analyses with an anti-mPygo2 specific antiserum in conjunction with antibodies against various pancreatic markers on embryonic pancreas sections. Specificity of the anti-mPygo2 antibody was demonstrated by absence of immunostaining in pancreas from *mPygo2*-null mutant embryos (Supplementary Fig. 1D–F). Similar to previously analyzed tissues (Li et al., 2007; Schwab et al., 2007), pancreatic mPygo2 expression was exclusively nuclear at all stages (Fig. 1). Between e10.5 and e12.5, when the pancreatic epithelium is still largely undifferentiated, mPygo2 broadly co-localized with the pancreatic epithelial progenitor cell marker Pdx1 throughout the ventral and dorsal pancreatic anlage (Fig. 1A–F, data not shown). The level of mPygo2 expression varied between cells in the epithelium, with some cells expressing high and others low levels of mPygo2. Strong mPygo2 immunoreactivity was also found in mesenchymal cells surrounding the ventral and the dorsal pancreatic anlage at e10.5 and e12.5 (Fig. 1A–F, data not shown). Similar to mPygo2, the Wnt effector  $\beta$ -catenin was also expressed in both the pancreatic epithelium and surrounding mesenchyme (Fig. 1G–I). Consistent with previous reports (Heiser et al., 2006), nuclear localization of  $\beta$ -catenin was not observed. At e15.5, mPygo2 expression in E-cadherin<sup>+</sup> cells suggested persistence of the epithelial mPygo2 expression (Fig. 1J–L). In addition to its epithelial expression, the presence of scattered E-cadherin-negative/mPygo2<sup>+</sup> interstitial cells indicated persistent expression of mPygo2 also in the mesenchyme (Fig. 1L, arrowheads). The staining intensity of mPygo2 in the epithelium varied between different cell types. While newly differentiated beta cells, characterized by high levels of Pdx1 expression, showed weak mPygo2 immunoreactivity (Fig. 1O), strong expression was seen in the forming acinar compartment (Fig. 1M–O). Scattered mPygo2<sup>+</sup> mesenchymal cells were also detected in late gestation (Fig. 1P–R). At e18.5, mPygo2 was no longer found in the acinar and endocrine compartments (Fig. 1Q,R), but persisted in a subset of ductal cells (Fig. 1P,R). In contrast to mPygo2, mPygo1 was predominantly localized to the pancreatic mesenchyme, but scattered Pdx1<sup>+</sup> epithelial cells expressing mPygo1 were also found (Supplementary Fig. 1J–H). In the absence of mPygo2 activity, the overall expression pattern (Supplementary Fig. 1K–M) and mRNA levels (Supplementary Fig. 1O) of mPygo1 were unchanged. However, the number of epithelial cells expressing mPygo1 appeared to be reduced in mPygo2-deficient mice (Supplementary Fig. 1M). Different from mPygo2, *mPygo1* expression was only transiently detected in the pancreas and no longer found after e15.5 (Supplementary Fig. 1G,N).

### Reduced pancreas size in *mPygo2*<sup>-/-</sup> embryos

To determine whether pancreas development is dependent on the function of mPygo2, we analyzed pancreata from *mPygo2*<sup>-/-</sup> embryos at e18.5. The perinatal lethality associated with *mPygo2*-null mutations precluded studies in postnatal mice (Li et al., 2007; Schwab et al., 2007). Inspection of pancreas morphology revealed a marked reduction in organ size in mPygo2-deficient embryos (Fig. 2A,B). The reduction was evident in both the duodenal portion of the pancreas, which is derived from the ventral pancreatic anlage, as well as the splenic portion, which originates from the dorsal anlage. To exclude the possibility that the reduced pancreatic size is a mere consequence of the 15–20% reduction in body weight of neonatal *mPygo2*<sup>-/-</sup> embryos (Li et al., 2007), we normalized pancreatic weight to the total body weight of the embryo. The ratio of pancreatic weight to body weight showed a statistically significant ~20% reduction in *mPygo2*<sup>-/-</sup> embryos compared to their wild type littermates (Fig. 2C). Histological analysis of pancreas sections revealed grossly normal exocrine and endocrine

cell compartments (Fig. 2D,E). To determine the origin of pancreas hypoplasia in *mPygo2*-deficient embryos, we examined whether a reduction in pancreatic size is already present at earlier developmental time points. At e15.5, when the overall size and weight of *mPygo2*<sup>-/-</sup> embryos is indistinguishable from wild type littermates (data not shown), the ventral and dorsal pancreas showed a similar size reduction as observed at e18.5 (Fig. 2F–H). Prior to e15.5, we assessed pancreatic size by separate quantitative morphometric measurements of the ventral and dorsal pancreatic epithelial area. At e13.5, the pancreatic epithelium in *mPygo2*<sup>-/-</sup> embryos showed less branching and a significant reduction in size (Fig. 2I–K). At e12.5, however, no difference was found between *mPygo2*<sup>-/-</sup> and wild type embryos (Fig. 2L–N). Thus, *mPygo2* is first required for growth and branching of the pancreatic epithelium after e12.5.

To reveal the mechanism that underlies impaired pancreatic growth in *mPygo2*<sup>-/-</sup> embryos, we studied whether *mPygo2* controls the timing of cell differentiation, cell proliferation or cell survival. During pancreas development, major cell differentiation of both the exocrine and endocrine compartments does not occur until after e13.5. With the exception of occasional insulin-producing cells, glucagon-expressing cells are the only cell type that differentiates between e10.5 and e13.5. To assess whether the diminished size of the pancreas in *mPygo2*-deficient embryos results from depletion of the pancreatic progenitor cell pool due to premature cell cycle exit and differentiation, we quantified the number of glucagon<sup>+</sup> cells in relation to the number of Pdx1<sup>+</sup> pancreatic progenitors between e10.5 and e13.5. The relative number of glucagon<sup>+</sup> cells was similar in *mPygo2*<sup>-/-</sup> embryos and wild type littermates (Fig. 3A–C, data not shown), suggesting that absence of *mPygo2* is not associated with premature cell differentiation. This conclusion was further supported by the finding that insulin<sup>+</sup> or exocrine cells also do not differentiate prematurely (data not shown). To determine whether absence of *mPygo2* affects pancreatic cell proliferation, we next compared the number of BrdU-incorporating cells in *mPygo2*<sup>-/-</sup> and control embryos at e13.5, which is the time point when the epithelial size reduction is first evident in *mPygo2*<sup>-/-</sup> embryos. *mPygo2*-null mutants showed a consistent 20–25% reduction in the proliferative rate of Sox9<sup>+</sup> progenitor cells in both the ventral and the dorsal pancreatic anlage (Fig. 3D–F). Significantly, no difference was observed at e12.5, when the epithelium is still normal in size (data not shown). Since apoptotic cells were rarely seen in the pancreatic epithelium or mesenchyme and no difference was found between *mPygo2*<sup>-/-</sup> and control embryos (Supplementary Fig. 2A,B), our findings suggest that *mPygo2* controls pancreatic growth by ensuring proliferation of undifferentiated pancreatic progenitor cells after e13. As the size of the pancreatic progenitor cell pool has recently been shown to dictate final organ size (Stanger et al., 2007), this early function of *mPygo2* in progenitor cell proliferation most likely also accounts for the reduced pancreas size in neonatal *mPygo2*<sup>-/-</sup> mice.

### ***mPygo2* controls endocrine but not exocrine cell formation**

To assess a potential role for *mPygo2* in pancreatic cell differentiation, we compared the size of the endocrine and exocrine cell compartments in *mPygo2*-null mutant embryos to their littermate controls. Morphometric analysis of the insulin- and glucagon-expressing cell areas in relation to total pancreatic size revealed a reduction in beta cells, but not in alpha cells in *mPygo2*<sup>-/-</sup> mutants at e15.5 and at birth (Fig. 4A–F, data not shown). A similar reduction as was observed for beta cells was also seen for somatostatin- and PP-producing cells (Fig. 4G–L). Unlike the endocrine cell compartment, the amylase<sup>+</sup> acinar cell compartment was not affected by *mPygo2*-deficiency at both ages (Fig. 4M–O, data not shown). As assessed by histology and immunofluorescence for DBA and mucin, the ductal cell compartment developed normally in *mPygo2*<sup>-/-</sup> mice (data not shown).

The numbers of Ptf1a<sup>+</sup> progenitors, which become restricted to an exocrine fate around e13.5 (Zhou et al., 2007), appeared slightly increased in *mPygo2*<sup>-/-</sup> embryos (Fig. 5A–C). However,

this difference did not reach statistical significance (Fig. 5C). To determine whether the reduction in endocrine cells can be attributed to a lower rate of cell differentiation, we analyzed the number of Ngn3<sup>+</sup> endocrine progenitors. The 50% reduction in beta cells in *mPygo2*<sup>-/-</sup> embryos (Fig. 4C) was indeed preceded by a 40–50% reduction in endocrine progenitors in the ventral and dorsal pancreatic anlage at e13.5 (Fig. 5D–F). Notably, Ngn3<sup>+</sup> cell numbers were normal in *mPygo2*<sup>-/-</sup> mutants at e12.5 (data not shown). As a recent study has demonstrated that beta, delta and PP cells are the major endocrine cell types to arise from Ngn3<sup>+</sup> progenitors after e13 (Johansson et al., 2007), the selective reduction in these cell types in *Pygo2*<sup>-/-</sup> mutants may be explained by a specific requirement for mPygo2 in the generation of endocrine progenitors during this time window. Combined, our data show that mPygo2 has a critical role for progenitor cell proliferation and endocrine cell genesis after e12.5.

### Wnt signaling is mainly active in the pancreatic mesenchyme when mPygo2 is required

In *Drosophila*, *pygopus* has been shown to be an obligatory regulator of Wnt signal transduction (Belenkaya et al., 2002; Kramps et al., 2002; Parker et al., 2002; Stadeli and Basler, 2005; Thompson et al., 2002; Thompson, 2004; Townsley et al., 2004a). To determine whether a similar genetic interaction exists between *mPygo2* and Wnt signaling in the mammalian pancreas, we analyzed the spatial and temporal profile of Wnt signal transduction during pancreas development. A similar analysis has been previously performed in pancreas from e14.5 embryos and older, but not at earlier embryonic stages (Dessimoz et al., 2005). To identify sites of active Wnt signaling in mouse tissue, a number of different *lacZ*-based reporter strains have been developed. One of these strains is based on the expression of *Axin2*, which is exclusively expressed at sites of Wnt signal transduction (Jho et al., 2002; Lustig et al., 2002). In embryos that express *lacZ* under control of the *Axin2* locus,  $\beta$ -galactosidase ( $\beta$ -gal) activity was mainly confined to the undifferentiated pancreatic epithelium and early differentiated glucagon<sup>+</sup> cells, but was also detected in scattered cells in the surrounding mesenchyme at e10.5 (Fig. 6A). At e13.5, the pattern was reversed, evidenced by abundant *lacZ* expression in the mesenchyme and only occasional *lacZ*<sup>+</sup> cells in the epithelium (Fig. 6B). The predominant localization of  $\beta$ -gal activity to the mesenchyme persisted at e15.5 (Fig. 6C). Consistent with the previous study (Dessimoz et al., 2005), few glucagon<sup>+</sup> cells also showed detectable *lacZ* expression (Fig. 6B and C, inset). At e18.5, *lacZ*<sup>+</sup> cells were found in the pancreatic ducts, but were largely absent from the endocrine and exocrine compartments (Fig. 6D,E). Since reporter mouse lines for Wnt activity have been shown to not necessarily monitor all sites of Wnt signal transduction, we confirmed our results in *BatGAL* mice, in which expression of a *lacZ* transgene is controlled by tandem repeats of Wnt-dependent Tcf/Lef transcription factor binding sites (Maretto et al., 2003). The sites of  $\beta$ -gal activity in the developing pancreas of *BatGAL* embryos largely mirrored those identified in *Axin2*<sup>+/lacZ</sup> mice (Fig. 6F–J). The overall number of *lacZ*<sup>+</sup> pancreatic cells, however, was smaller in *BatGAL* mice at all stages. In the adult pancreas,  $\beta$ -gal activity was not detected in either Wnt reporter strain (data not shown).

To address whether loss of mPygo2 affects Wnt signaling, we crossed the *BatGAL* transgene into the *mPygo2*-null mutant background and assayed for  $\beta$ -gal activity in the pancreas. Previous studies have shown that in many tissues deletion of *mPygo2* results in a reduction but not complete absence of *BatGAL* transgene expression (Li et al., 2007; Schwab et al., 2007). After a four-hour incubation in X-Gal staining solution, we consistently observed *lacZ*<sup>+</sup> cells in wild type pancreas, but no signal was detected in pancreas of *mPygo2*<sup>-/-</sup> embryos (Fig. 7A,B). However, after more than 12 hours in X-Gal staining solution, we occasionally observed *lacZ*<sup>+</sup> cells also in *mPygo2*-null mutants (data not shown). These findings indicate that loss of pancreatic mPygo2 activity results in a drastic reduction, but not complete block of Wnt signal transduction. This was further supported by the observation that the mRNA of *Axin2* was reduced, but not absent in mPygo2-deficient pancreata (Supplementary Fig. 10). Consistent

with observations in other tissues, mPygo2 therefore appears to function as a modulator of Wnt signaling in the developing pancreas.

### Pancreatic growth and cell differentiation depends on mPygo2 activity in the mesenchyme

Since the mesenchyme is known to stimulate proliferation of pancreatic progenitor cells, we considered the possibility that the effects of germline *mPygo2* deletion on epithelial growth and differentiation are non-autonomous and mediated by mesenchymal mPygo2 function. To distinguish between autonomous functions for mPygo2 in the epithelium and non-autonomous functions in the mesenchyme, we selectively ablated *mPygo2* in pancreatic epithelial precursors. Previous studies have shown that *Pdx1-Cre* transgenic mice efficiently target ventral and dorsal pancreas precursors at the time of pancreatic bud formation (Gu et al., 2002; Heiser et al., 2006; Seymour et al., 2007). Consistent with these reports, we observed complete recombination in progenitors of both pancreatic anlagen by e9.5, when *Pdx1-Cre* mice were crossed to the *R26R* (Soriano, 1999) reporter mouse strain (data not shown). To ablate *mPygo2* in pancreatic epithelial precursors, we used the *Pdx1-Cre* transgene to delete a floxed *mPygo2* (*mPygo2<sup>fllox</sup>*) allele (Fig. 8A). Analysis of pancreata from *mPygo2<sup>fllox</sup><sup>-/-</sup>;Pdx1-Cre* (*mPygo2<sup>Δpan</sup><sup>-/-</sup>*) embryos revealed efficient pancreatic recombination of the *mPygo2<sup>fllox</sup>* allele (Fig. 8B). mPygo2 immunoreactivity was almost completely absent from the pancreatic epithelium, but maintained in the surrounding mesenchyme (Fig. 8C–H). A few mPygo2<sup>+</sup> cells, however, were occasionally observed in the epithelium (Fig. 8H). Unlike *mPygo2<sup>-/-</sup>* mice, *mPygo2<sup>Δpan</sup><sup>-/-</sup>* embryos showed a pancreas of normal size and weight at both e15.5 and e18.5 (Fig. 9A–C; data not shown). Similarly, at e13.5 the overall size and branching pattern of the ventral and dorsal pancreatic epithelium was indistinguishable between *mPygo2<sup>Δpan</sup><sup>-/-</sup>* embryos and control littermates (Fig. 9D–F). Thus, epithelial-specific deletion of *mPygo2* does not phenocopy the pancreatic hypoplasia observed in *mPygo2*-null mutant mice. Likewise, in contrast to *mPygo2*-null mutants (Fig. 4A–C), beta cell mass in *mPygo2<sup>Δpan</sup><sup>-/-</sup>* embryos was equivalent to control littermates (Fig. 9G–I). We considered the possibility that mPygo2 is required for expansion and maintenance of the pancreatic mesenchyme, which would explain the lack of epithelial growth. However, the mesenchymal compartment was of normal size in *mPygo2<sup>-/-</sup>* embryos (Supplementary Fig. 2C–F), suggesting that mPygo2 is not required for formation of the pancreatic mesenchyme. Consistent with this notion, the expression of *Isl1* and *Pbx1* was not affected by *mPygo2* deletion (Supplementary Fig. 3). Together, these findings suggest that mPygo2 controls expansion of pancreatic progenitors and endocrine cell formation by a non-autonomous mechanism, possibly by regulating signals from the mesenchyme.

## Discussion

In this study, we have defined the role of pygopus, a nuclear component of the canonical Wnt signaling pathway, in pancreas development. We show that *mPygo2* is required for pancreatic progenitor cell proliferation and endocrine cell neogenesis. While mPygo2 is expressed in both the pancreatic epithelium and mesenchyme, we identify the mesenchyme as a predominant site of canonical Wnt signaling around e13 and show that absence of mPygo2 impairs transduction of this signal. Our finding that conditional deletion of *mPygo2* in just the epithelium fails to phenocopy the null mutant defects suggests a role for mesenchymal Wnt signaling in pancreas organogenesis.

### Does mPygo2 function in the Wnt signaling pathway?

Genetic studies in *Drosophila* have identified *pygopus* as an obligatory component of the wingless signaling pathway (Belenkaya et al., 2002; Kramps et al., 2002; Parker et al., 2002; Stadeli and Basler, 2005; Thompson et al., 2002; Thompson, 2004; Townsley et al., 2004a). Recent studies of pygopus function in mammals, however, suggest that complete loss of

pygopus activity reduces, but does not completely abrogate Wnt signaling (Li et al., 2007; Schwab et al., 2007). Though deletion of *mPygo1* and *mPygo2* affects the development of many Wnt-dependent tissues, the developmental defects caused by absence of pygopus activity in mice are notably milder than those observed when Wnt signal transduction is completely blocked (Li et al., 2007; Schwab et al., 2007; Song et al., 2007). Some Wnt-dependent phenotypes, such as the defect in early embryonic axis formation as a result of  $\beta$ -catenin deficiency or the defect in intestinal stem cell proliferation caused by loss of Tcf4 activity (Haegel et al., 1995; Huelsken et al., 2000; Korinek et al., 1998), are not phenocopied by the combined deletion of both murine *pygopus* orthologs (Li et al., 2007; Schwab et al., 2007; Song et al., 2007). These findings have led to the suggestion that *Pygo1* and *Pygo2* are not obligatory for canonical Wnt signaling in mammals, but rather function as modulators of Wnt signaling intensity. Our observation that even though significantly reduced, *BatGAL* reporter activity and *Axin2* mRNA were still detectable in mPygo2-deficient pancreas supports the idea that mPygo2 also functions as a Wnt modulator during pancreas development. Remaining Wnt activity in the absence of mPygo2 may also explain why *mPygo2<sup>Δpan/-</sup>* mice do not display pancreatic hypoplasia and defects in acinar cell development, as observed in mice after *Pdx1-Cre*-mediated  $\beta$ -catenin ablation (Dessimoz et al., 2005; Murtaugh et al., 2005; Wells et al., 2007). Alternatively, compensation of mPygo1 for mPygo2 function could account for the difference in phenotype caused by pancreatic  $\beta$ -catenin and *mPygo2* ablation. We consider this possibility highly unlikely, as we detected mPygo2 protein predominantly in the mesenchyme and only in scattered epithelial cells. Moreover, mPygo1-deficient mice are indistinguishable from wild type mice and no apparent genetic cooperativity has been observed between *Pygo1* and *Pygo2* in mice (Schwab et al., 2007; Song et al., 2007). Notably, since  $\beta$ -catenin is known to have Wnt-independent functions in cell adhesion (Nelson and Nusse, 2004), it is also possible that the reported defects in  $\beta$ -catenin-deficient pancreata are not dependent on Wnt signaling. To obtain a more complete understanding of Wnt function in the pancreas, it will be necessary to study the effects of inactivation of additional Wnt signaling components on pancreas development.

### mPygo2 function in pancreas development

Starting at e13.5, we found that mPygo2-deficient pancreata are significantly smaller than wild type controls. Our data show that a reduced proliferation rate of pancreatic progenitors and not increased apoptosis or premature differentiation accounts for the observed hypoplasia of mPygo2-deficient pancreata. Surprisingly, these defects were not detected after a specific deletion of *mPygo2* in the epithelium. Since mPygo2 protein was almost completely absent from the epithelium of *mPygo2<sup>Δpan/-</sup>* embryos at e13.5, we consider it unlikely that competition by residual wild type cells accounts for the difference in phenotype. Because the phenotype of *mPygo2<sup>-/-</sup>* mutants is strikingly similar to the defects associated with perturbations in mesenchymal signaling, we favor the explanation that mPygo2 controls pancreatic growth indirectly through functions in the pancreatic mesenchyme. Similar to mPygo2-deficiency, lack of mesenchymal signals results in reduced proliferation of undifferentiated Pdx1<sup>+</sup> pancreatic progenitors (Attali et al., 2007; Bhushan et al., 2001; Pictet and Rutter, 1972). A mesenchymal function for mPygo2 is also consistent with the observed reduction in endocrine cells in *mPygo2<sup>-/-</sup>* mutants, as signals from the mesenchyme have been shown to positively influence the numbers of Ngn3<sup>+</sup> precursors and final beta cell numbers (Attali et al., 2007). The specific effect of *mPygo2* deletion on the beta, delta and PP cell lineages, but not on alpha cells can be explained by the fact that the specification of glucagon<sup>+</sup> cells precedes the time window, during which mPygo2 is functionally important in the mesenchyme. Consistent with this notion, it has been shown that Pdx1<sup>+</sup> pancreatic progenitors acquire competence to differentiate into alpha cells as early as e9.5, while competence to differentiate into the other endocrine cell types is not acquired until e11.5 (Johansson et al., 2007). Notably, our study does not entirely exclude the possibility that mPygo2 affects pancreatic development through

functions in endothelial cells. However, we consider this explanation unlikely, as *mPygo2*<sup>-/-</sup> mutants are viable until birth and vascular defects are associated with early embryonic lethality (Li et al., 2007) (Edsbagge et al., 2005; Esni et al., 2001). Direct demonstration of a mesenchymal role for mPygo2 will require a Cre-expressing mouse that specifically targets the pancreatic mesenchyme, which is currently not available.

Previous studies have shown that the development of the pancreatic mesenchyme critically depends on the transcription factors Isl1 or Pbx1. In the absence of either Isl1 or Pbx1 the pancreatic mesenchyme is severely hypoplastic, which in turn results in impaired epithelial growth and differentiation (Ahlgren et al., 1997; Kim et al., 2002). This phenotype is strikingly different from mPygo2-deficient embryos, which do not show mesenchymal hypoplasia. Accordingly, we found that mPygo2 does not control the expression of either Isl1 or Pbx1. More likely, mesenchymal mPygo2 is required to regulate key mesenchymal signals that mediate cross talk between mesenchyme and epithelium. Fibroblast growth factors (FGFs) and epidermal growth factor (EGF) are two signaling molecules that have been shown to positively affect progenitor cell proliferation in pancreas explants *in vitro* (Cras-Meneur et al., 2001; Elghazi et al., 2002; Miralles et al., 1999). While analysis of receptor mutants have confirmed the importance of these signaling pathways for pancreatic growth *in vivo* (Miettinen et al., 2000; Pulkkinen et al., 2003), little is known about which specific mesenchymal ligand(s) mediate(s) the response at different developmental stages. One more recently identified mesenchymal signal is FGF10, which is specifically expressed in the pancreatic mesenchyme between e9.5 and e12.5 (Bhushan et al., 2001). *Fgf10* mutant embryos display a severe reduction in the Pdx1<sup>+</sup> progenitor cell pool and hypoplastic dorsal and ventral pancreata (Bhushan et al., 2001). We therefore considered the possibility that deletion of *mPygo2* affects mesenchymal *Fgf10* expression, but did not detect a difference in pancreatic *Fgf10* mRNA expression between wild type and *mPygo2*<sup>-/-</sup> embryos (data not shown). It is important to note that the peak of mesenchymal *Fgf10* expression precedes the occurrence of pancreatic hypoplasia in *mPygo2*-null mutant embryos (Bhushan et al., 2001). Future work will address which FGFs regulate pancreatic growth at later time points and whether mPygo2 is involved in regulating their expression.

An important question to consider is whether the pancreatic defects in mPygo2-deficient embryos are a consequence of perturbed Wnt signaling or whether mPygo2 possibly has Wnt-independent functions. Together with previous reports that several Wnt genes, frizzled receptors and Tcf/Lef transcription factors are expressed in the pancreatic mesenchyme (Heller et al., 2002; Kim et al., 2005; Lin et al., 2001), our current findings in Wnt-reporter mice underscore the notion that Wnt signaling is active in the mesenchyme. The idea that mPygo2 may exert its effects by regulating mesenchymal Wnt activity is consistent with our observation that Wnt-reporter gene activity is dependent on mPygo2 and that the occurrence of the pancreatic phenotype in *mPygo2*<sup>-/-</sup> mutants coincides with the time point at which Wnt signaling is most active in the mesenchyme. However, as the role of mesenchymal Wnt signaling in pancreatic development is still entirely unknown, understanding of the relationship between mPygo2 and Wnt signaling will require a better knowledge of mesenchymal Wnt function. Notably, Wnt-independent functions for mPygo2 have recently been described in lens development and have also been noted for pygopus in *Drosophila* (Belenkaya et al., 2002; de la Roche and Bienz, 2007; Parker et al., 2002; Song et al., 2007). The broader expression of mPygo2 compared to the locations of Wnt signaling activity may be an indication that mPygo2 also has Wnt-independent functions in the pancreas.

In summary, our study demonstrates that Wnt signaling is active in the pancreatic mesenchyme during the phase of major pancreatic growth and differentiation. The combined evidence that this Wnt activity depends on mPygo2 function and that global, but not pancreatic epithelial-specific deletion of *mPygo2* impairs pancreatic development, points to a possible role of

mesenchymal Wnt signaling in pancreas organogenesis. Since our study is the first to identify a potential function for Wnt in the mesenchyme, additional studies will be required to fully understand how Wnt signaling mediates the cross talk between the pancreatic mesenchyme and epithelium.

**Figure 1. mPygo2 is expressed in the pancreatic epithelium and mesenchyme**  
 Immunofluorescence detection of mPygo2 protein (red) at e10.5 (A–C), e12.5 (D–I), e15.5 (J–O) and e18.5 (P–R). (A–C) At e10.5, mPygo2 (B and C) colocalizes with the progenitor cell marker Pdx1 (green in A and C) in both dorsal and ventral pancreatic anlage. (D–F) At e12.5, colocalization of mPygo2 (E,H) with Pdx1 (green in D,G) persists in pancreatic epithelial cells. mPygo2 is also abundantly detected in the mesenchyme surrounding both pancreatic anlagen at e10.5 (B) and e12.5 (E). (G–I)  $\beta$ -catenin (green in G and I) is coexpressed with mPygo2 (H and I) in the epithelium and the mesenchyme. (J–L) At e15.5, most E-cadherin<sup>+</sup> epithelial cells (green in J and L) still express mPygo2 (K and L). The interstitial mPygo2<sup>+</sup>, but E-cadherin<sup>-</sup> cells (arrowheads in L) suggest persistent mesenchymal expression of mPygo2 at

e15.5. **(M,N)** Immunostaining for amylase (green in M) and mPygo2 (red in N) on adjacent sections demonstrates localization of mPygo2 to the same cluster of cells that expresses amylase (arrowheads in M and N). **(O)** mPygo2 (red) and Pdx1 (green) are co-expressed in epithelial cell clusters that resemble forming exocrine acini (inset in O). **(P-R)** At e18.5, mPygo2 expression is restricted to mucin 1 (MUC1)<sup>+</sup> ductal cells (inset in P) and interstitial cells, but absent from insulin<sup>+</sup> (ins, inset in Q) or glucagon<sup>+</sup> (glc, inset in R) cells. VP, ventral pancreas; DP, dorsal pancreas; scale bars = 50  $\mu$ m.

n=6). (I–N) The pancreatic epithelium was visualized by Pdx1 immunofluorescence staining (red in I,J and L,M) and the immunopositive area morphometrically quantified (K,N). The dorsal and ventral pancreatic epithelial area in *mPygo2*-null mutants is reduced at e13.5 (K;  $p < 0.02$  for ventral pancreas; not statistically significant for dorsal pancreas; n=5), but normal at e12.5 (N; n=3). Scale bar = 50  $\mu\text{m}$ .

**Figure 3. Pancreatic hypoplasia in *mPygo2*<sup>-/-</sup> mice correlates with decreased epithelial cell proliferation**

(A–C) Immunofluorescence staining for glucagon (glc, red in A and B) and Pdx1 (green in A and B). Morphometric quantification of the number of glucagon<sup>+</sup> cells in relation to the total area occupied by Pdx1<sup>+</sup> pancreatic progenitor cells reveals no premature differentiation of glucagon<sup>+</sup> cells in *mPygo2*<sup>-/-</sup> pancreas at e13.5 (C; n=3). (D–F) By contrast, quantification of the number of cells co-immunopositive for BrdU (red in D and E) and the progenitor cell marker Sox9 (green in D and E) reveals a ~20% decrease in the proliferative rate of ventral and dorsal pancreatic progenitor cells in *mPygo2*<sup>-/-</sup> mutants at e13.5 (F; p<0.01; n=5). Scale bar = 50  $\mu$ m.

**Figure 4. Loss of mPygo2 activity affects formation of late-born endocrine cells**

(A–C) Insulin immunofluorescence staining (green in A and B) and morphometric quantification of the insulin<sup>+</sup> area over total pancreatic epithelial area at e15.5 reveals a 50% reduction of beta cells in mPygo2-deficient pancreas compared to control littermates (C;  $p < 0.05$ ;  $n = 3$ ). (D–F) Similar analysis for the glucagon<sup>+</sup> (red in D and E) cell area at e15.5 shows no reduction in alpha cells (F;  $n = 3$ ). (G–L) The somatostatin<sup>+</sup> (green in G and H) and pancreatic polypeptide<sup>+</sup> areas (red in J and K) at e18.5 are similarly reduced as the insulin<sup>+</sup> area (I, L;  $p < 0.01$ ;  $n = 3$ ). (M–O) The relative area occupied by amylase<sup>+</sup> cells (red in M and N) is similar in e15.5 control and mPygo2-null mutant embryos (O;  $n = 3$ ). Scale bar = 50  $\mu\text{m}$ .

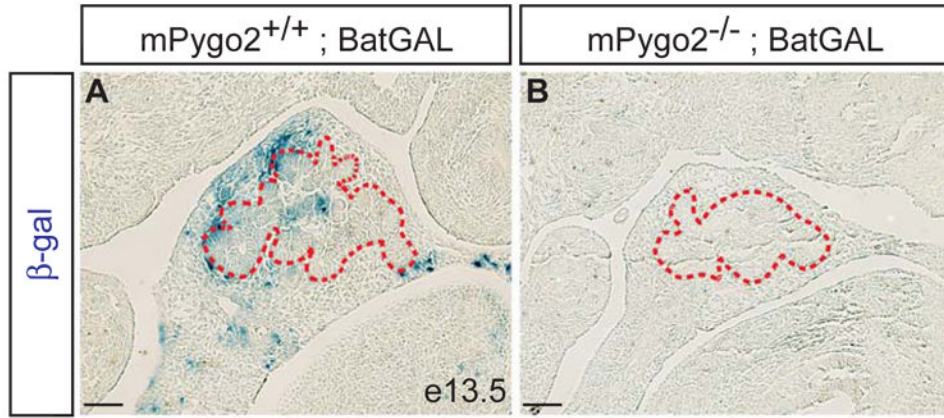

**Figure 5. Loss of mPygo2 activity affects formation of endocrine progenitors after e13**  
 (A–C) Consistent with normal development of the exocrine compartment, *mPygo2*-null mutant embryos show no reduction in Ptf1a<sup>+</sup> progenitor cells (red in A and B) at e13.5 (C; n=4). (D–F) By contrast, the relative number of Ngn3<sup>+</sup> endocrine progenitor cells (red in D and E) is 50% reduced in *mPygo2*<sup>-/-</sup> embryos at e13.5 (F; p<0.01; n=5). Scale bar = 50 μm.

**Figure 6. The canonical Wnt signaling pathway is predominantly active in the pancreatic mesenchyme at the time mPygo2 activity is required in pancreas development**  
 X-gal staining of pancreata from *Axin2<sup>+/-lacZ</sup>* (A–E) or *BatGAL* embryos (F–J) and subsequent immunoperoxidase detection of glucagon (glc, A–D and F–I) or insulin (ins, E and J) on paraffin sections. The dashed red line in A,B,F,G demarcates the outer margin of the pancreatic epithelium. At e10.5,  $\beta$ -galactosidase ( $\beta$ -gal) activity is predominantly found in the pancreatic epithelium, but occasional  $\beta$ -gal<sup>+</sup> cells are also detected in the surrounding mesenchyme of both *Axin2<sup>+/-lacZ</sup>* (A) and *BatGAL* embryos (F). Some overlap between  $\beta$ -gal and glucagon expression is observed (inset in A,B). At e13.5, mesenchymal cells are uniformly  $\beta$ -gal<sup>+</sup> in *Axin2<sup>+/-lacZ</sup>* mice (B), while scattered  $\beta$ -gal activity is detected throughout the mesenchyme of

*BatGAL* mice (**G**). In both *Axin2<sup>+lacZ</sup>* and *BatGAL* embryos, pancreatic epithelial cells are rarely  $\beta$ -gal<sup>+</sup> at e13.5, and those that are occasionally express glucagons (inset in B,G). With the exception of occasional epithelial cells, some of which are glucagon/ $\beta$ -gal co-positive in *Axin2<sup>+lacZ</sup>* mice (inset in C,H), the predominantly mesenchymal location of  $\beta$ -gal activity persists at e15.5 in both reporter strains (**C,H**). At e18.5,  $\beta$ -gal activity is largely absent from glucagon<sup>+</sup> (**D,I**) and insulin<sup>+</sup> cells (**E,J**) and predominantly localized to the pancreatic ducts in both *Axin2<sup>+lacZ</sup>* and *BatGAL* embryos (arrowheads in **D,I**). DP, dorsal pancreatic epithelium; i, islet. Scale bar = 50  $\mu$ m.

**Figure 7. *mPygo2* deletion reduces transduction of canonical Wnt signals in the pancreas**  
 Pancreatic sections from X-gal stained *mPygo2*<sup>+/+</sup>;*BatGAL* (A) or *mPygo2*<sup>-/-</sup>;*BatGAL* (B) embryos at e12.5. *mPygo2*-deficiency results in absence of  $\beta$ -galactosidase ( $\beta$ -gal)<sup>+</sup> cells in both the pancreatic epithelium and mesenchyme. The dashed red lines demarcate the outer margin of the pancreatic epithelium. Scale bar = 50  $\mu$ m.

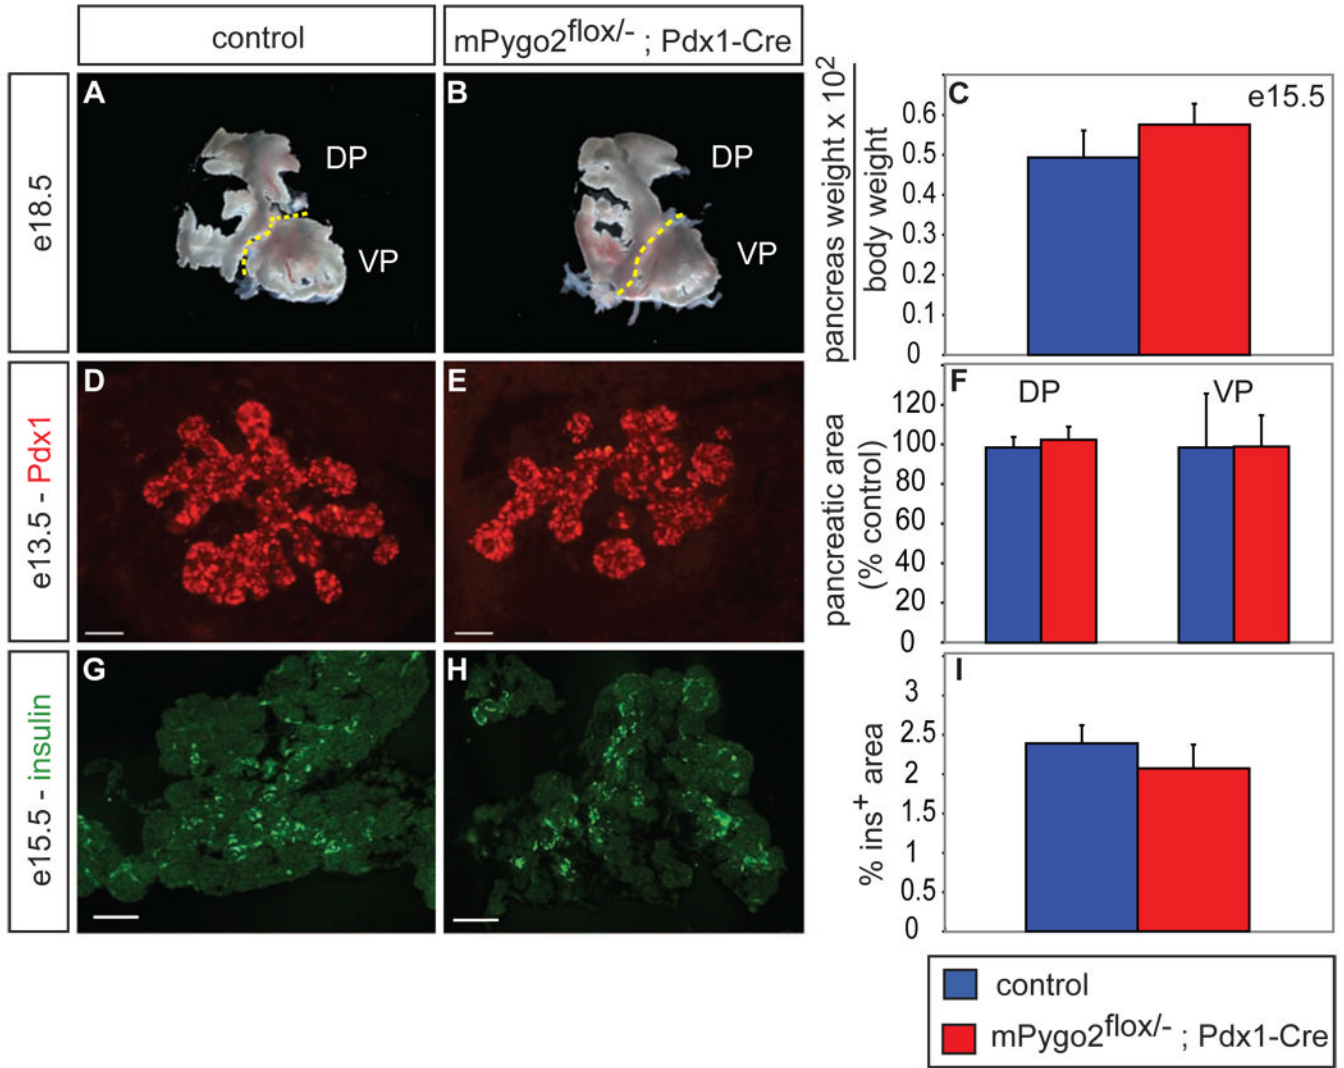

**Figure 8. Almost complete absence of epithelial mPygo2 after *Pdx1-Cre*-mediated recombination of the *mPygo2<sup>flox</sup>* allele**

(A) In *mPygo2<sup>flox</sup>* mice, exon 3 is flanked by *loxP* sites. Positions of the forward and reverse primers for detection of the unrecombined *mPygo2<sup>flox</sup>* allele are indicated. (B) The unrecombined *mPygo2<sup>flox</sup>* allele is equally detected in tail tip DNA from *mPygo2<sup>flox/-</sup>;Pdx1-Cre* and *mPygo2<sup>flox/-</sup>* mice. While also readily detectable in DNA from *mPygo2<sup>flox/-</sup>* pancreas after 30 PCR cycles, the unrecombined *mPygo2<sup>flox</sup>* allele is not amplified from *mPygo2<sup>flox/-</sup>;Pdx1-Cre* pancreas at e15.5. The faint band amplified from *mPygo2<sup>flox/-</sup>;Pdx1-Cre* pancreas after 33 PCR cycles most likely results from the presence of mesenchymal cells in e15.5 pancreas that are not targeted by the *Pdx1-Cre* transgene, but can also be explained

by residual unrecombined epithelial cells. **(C–H)** Immunofluorescence detection of mPygo2 (green) and Pdx1 (red) on pancreas sections of *mPygo2<sup>fllox/-</sup>;Pdx1-Cre* and control littermates at e13.5. While mPygo2 is expressed in the epithelium and mesenchyme of control embryos, mPygo2 is selectively absent from the epithelium in *mPygo2<sup>fllox/-</sup>;Pdx1-Cre* embryos. Residual mPygo2<sup>+</sup> cells are rarely observed in the epithelium. Scale bar = 50 μm.

**Figure 9. Normal pancreas development in *mPygo2<sup>flox/-</sup>;Pdx1-Cre* mice**

(A,B) Examination of gross pancreas morphology at e18.5 reveals a normal sized dorsal pancreas (DP) and ventral pancreas (VP) in *mPygo2<sup>flox/-</sup>;Pdx1-Cre* (*mPygo2<sup>Δpan/-</sup>*) embryos. The dashed yellow line indicates the separation between dorsal and ventral pancreas. (C) Likewise, the ratio between pancreas weight and total body weight is similar in *mPygo2<sup>Δpan/-</sup>* and control embryos at e15.5 (n=5). (D–F) The pancreatic epithelium was visualized by Pdx1 immunofluorescence staining (red in D,E). Morphometric quantification shows normal dorsal and ventral pancreatic epithelial areas in *mPygo2<sup>Δpan/-</sup>* embryos at e13.5 (F; n=4). (G–I) Insulin immunofluorescence staining (green in G and H) and morphometric quantification of the insulin (ins)<sup>+</sup> area over total pancreatic epithelial area at e15.5 reveals normal beta cell formation in *mPygo2<sup>Δpan/-</sup>* embryos (I; n=6). Scale bar = 50 μm.
