EXPERIMENTAL
PATHOLOGY

Summary

Deletions in chromosome (chr.) 13q occur frequently in head and neck squamous cell carcinoma (HNSCC). Previous studies failed to identify common deleted regions in chr.13q, though several candidate tumour suppressor genes (TSGs) loci, e.g. BRCA2, RB1 and BRCAX have been localized in this chromosome, as well as no prognostic significance of the deletion has been reported. Thus, in the present study, deletion mapping of chr. 13q has been done in 55 primary HNSCC samples of Indian patients using 11 highly polymorphic microsatellite markers of which three were intragenic to BRCA2 gene, one intragenic to RB1 gene and another from BRCAX locus. The deletion in chr.13q was significantly associated with progression of HNSCC. High frequencies (27–39%) of loss of heterozygosity were found in 13q13.1 (BRCA2), 13q14.2 (RB1), 13q21.2–22.1 (BRCAX) and 13q31.1 regions. Deletions in the BRCA2 and RB1 regions were significantly correlated. The four highly deleted regions were associated with clinical stage and histological grades of the tumour as well as poor patient outcome. Deletion in the 13q31.1 region was only found to be associated with HPV infection. High frequencies (11–23%) of microsatellite size alteration (MA) were seen to overlap with the highly deleted regions. Forty per cent of the samples showed rare biallelic alteration whereas loss of normal copy of chromosome 13q was seen in five tumours. Thus, it seems that the putative TSGs located in the BRCAX and 13q31.1 regions as well as the BRCA2 and RB1 genes may have some cumulative effect in progression and poor prognosis of HNSCC. Significant association between deletion in BRCA2 and RB1 gene loci may indicate functional relationship between the genes in this tumour progression.

Head and Neck Squamous cell carcinoma (HNSCC) is an epithelial malignant disease arising from the mucosa of the upper aero-digestive tract (oral cavity, larynx, oropharynx, and hypopharynx). HNSCC is the fifth most common cancer worldwide (Parkin *et al.* 1999; Parkin *et al.* 2001). In South-Central Asia, 80% of HNSCC are found in the oral cavity and oropharynx (Sankaranarayanan *et al.* 1998; Parkin *et al.* 1999) and in most regions of India, cancer of the oral cavity is the leading malignancy accounting for 20% cancers in men and the third most common cancer in female (Sen *et al.* 2002). Epidemiological studies have linked tobacco, betel nut leaf quid, alcohol, some environmental factors and infection with oncogenic types of HPV to the development of HNSCC (D'Costa *et al.* 1998). Among HPVs, infection with high risk HPV-16 and 18 types are the most prevalent in the HNSCC tumours (D'Costa *et al.* 1998; Nagai 1999; Dahlgren *et al.* 2004).

The karyotypes of the HNSCC tumours are complex often near triploid and are composed of multiple numerical and structural abnormalities of the chromosomes (Sreekantaiah *et al.* 1994). Cytogenetic studies of HNSCC tumours have identified gradual increase of chromosomal aberrations from premalignant to malignant lesions and deletions in several chromosomal arms, e.g. 1p, 2q, 4q, 5q, 8p, 9p21-24, 10p, 10q, 11p, 13q, 17p, etc. (Jin *et al.* 1990; Hittleman *et al.* 1993; Sreekantaiah *et al.* 1994; Van Duke *et al.* 1994; Sauders *et al.* 2000).

Allelotyping studies (using microsatellite markers) of HNSCC have identified >25% loss of heterozygosity (LOH) in several chromosomal regions, e.g. 3p, 4q, 6p, 8p, 9p, 11q, 13q, etc. and among these regions, deletions in 11q, 13q and 14q were proposed to be associated with the development of carcinoma *in situ* (Nawroz *et al.* 1994; Califano *et al.* 1996) of this tumour. Deletion mapping of HNSCC tumours by different investigators have identified deletions in different regions of chr.13q, for example, Yoo *et al.* (1994) have seen highest (50%) deletion in the chr.13q14.1-14.3 region, whereas Maestro *et al.* (1996) have seen highest (30-65%) deletion in the chr.13q14.2-14.3 and 13q32-ter regions. On the other hand, Gupta *et al.* (1999) has identified three highly deleted regions at the chr.13q12.1 (25-30%), 13q14.3 (47-85%) and 13q34 (50%) regions. Also, high frequency of LOH in the chr.13q13, and 13q14.3 regions has been reported by Li *et al.* (1994) and Kirkpatrick *et al.* (1997), respectively. Thus, there is an ambiguity in the localization of minimal deleted regions among the different investigators. The chr.13q is known to harbour two candidate tumour suppressor genes (TSGs), i.e. BRCA2 and RB1 at the 13q13.1 and 13q14.3 regions, respectively. Also, an unknown candidate TSGs'

locus, named as BRCAX, associated with the development of breast cancer is localized at 13q21 region (Kainu *et al.* 2000).

Besides LOH, microsatellite instability (MA) was detected in different cancers and it may represent a form of genomic instability (Arzimanoglou *et al.* 1998). In HNSCC, the occurrence of MA in the Indian patient population has been shown to be high compared to the Western patient population (Chakraborti *et al.* 2001). Recently, we have detected high frequencies of MA in and around the LOH regions of chr.3, 8 and 9 in primary HNSCC, which indicates the importance of MA in the development of this tumour (Dasgupta *et al.* 2002; Bhattacharya *et al.* 2003; Chakraborty *et al.* 2003; Tripathi (Bhar) *et al.* 2003).

Thus, in the present study detailed deletion mapping has been done to localize the candidate TSGs loci in chr.13q associated with the development of HNSCC using the (i) intragenic microsatellite markers of BRCA2 and RB1 genes; (ii) microsatellite markers from the BRCAX locus and other regions of chromosome 13q. The clinicopathological correlation as well as the prognostic significance of the deleted regions has also been analysed in this tumour.

Material and methods

Sample collection and clinical data

Fifty-five freshly operated tumour samples as well as matched benign tissues or in some cases peripheral blood leucocytes (PBL) were collected from patients admitted to Chittaranjan National Cancer Institute and Cancer Center & Welfare Home, Kolkata, India. All the samples were collected during the period of 1995-99 and informed consent was obtained from all the patients prior to the collection of the samples. No preoperative radiotherapy or chemotherapy was given to the patients. After collection the samples were frozen immediately and stored at -80 °C until further use. Tumor stage and grade were defined according to the tumour node metastasis (TNM) classification of Union Internationale Contre le cancer (UICC) (Harmer 1978). Detailed clinicopathological features of the patient are presented in Table 1. Overall patients' median age was 49.5 years (range 20-73 years).

Microdissection and DNA extraction

The normal cells present as contaminant in the specimens were removed by microdissection procedure and the samples containing >60% tumour cells were taken for DNA extraction as described by Dasgupta *et al.* (2002). DNA was extracted from the microdissected tissue sections and their corresponding normal tissue or PBL by proteinase-K (Sigma Chemicals,

St. Louis, MO, USA) digestion followed by phenol:chloroform extraction (Sambrook *et al.* 1989). When the adjoining normal tissue of the lesion was contaminated with infiltrating tumour cells, then PBL was taken for normal DNA extraction.

Selection of microsatellite markers

To determine if there was LOH or MA on chr.13, 11 highly polymorphic microsatellite markers were taken (Figure 1). Three markers namely D13S1701, D13S1699 and D13S1695 are intragenic to BRCA2 gene (Chunder *et al.* 2004), the marker D13S153 is in the intron 2 of RB1 gene (Ogawara *et al.* 1998) and D13S1308 is from BRCA-X locus (Chunder *et al.* 2004) (Figure 1). The information and primer sequence of the microsatellite markers were obtained from the website <http://www.ncbi.nlm.nih.gov>.

Analysis of microsatellite alterations

Polymerase chain reaction (PCR) was performed with all the markers in a 20 µl reaction volume containing 67 mM

Tris-HCl (pH 8.7), 16.6 mM (NH₄)₂SO₄, 1–2 mM MgCl₂, 4 pmol of each primer, 0.2 mM of each dNTPs, 50–100 ng of template DNA and 0.5 units of Taq DNA polymerase. One of the paired primers in the reaction mixture was end labelled with [³²P] ATP using T4-Polynucleotide Kinase as described by Nawroz *et al.* (1994) and Dasgupta *et al.* (2002). The PCR conditions were 95 °C for 5 min, then 30 cycles at 95 °C for 1 min, annealing at appropriate temp (50–60 °C) for 1 min and extension at 72 °C for 2 min followed by final extension at 72 °C for 7 min. The labelled PCR products were electrophoresed in 7% polyacrylamide gel containing 8 M Urea and auto-radiographed. This microsatellite analysis procedure used for the allelotyping could detect LOH and MA in the presence of 50% and 10–30% tumour DNA, respectively (Dasgupta *et al.* 2002).

The LOHs were interpreted for all informative cases by densitometric scanning (Shimidazu, CS-9000, Kyoto, Japan) of the autoradiographs. The allelic loss was recorded if there was a complete absence of one allele or if the relative band intensity of one allele was reduced at least 50% in the tumour in comparison to the homologous allele in the

statistical analysis was performed using statistical program SPSS (SPSS Inc. Chicago, IL, USA).

Results

Molecular abnormalities (LOH/MA) on chr.13q

Deletion mapping of chr.13q by 11 microsatellite markers in primary HNSCC samples showed microsatellite instability (LOH/MA) in 85% (47/55) of the tumours in at least one of the markers indicating importance of chr.13q in the development of this tumour (Figures 1 and 2). The preference for deletions in larger and smaller alleles was seen in 53 and 47% of the affected alleles, respectively (data not shown), which indicates that the deletion phenomenon was independent of the size of the allele as seen in our previous studies (Dasgupta *et al.* 2002). The overall allelic loss of chr.13q

Figure 2 Representative photographs of the autoradiograph showing (a) loss of heterozygosity, (b) microsatellite size alteration of one allele, (c) microsatellite size alteration of both allele and (c) loss of one allele and microsatellite size alteration of other allele at different marker loci on chr.13q in different head and neck squamous cell carcinoma samples. gradually increased with progression of the clinical stage and there was a significant correlation between the mean FAL index ($P < 0.01$) and progression of the tumour (Figure 3).

High frequencies of deletions have been detected in four chromosomal regions, i.e. 13q13.1 (D1: 33–39%), 13q14.2 (D2: 35%), 3q21.2–22.1 (D3: 27–33%) and 13q31.1 (D4: 31%) (Figure 1). High frequencies (11–23%) of MA have also been seen to overlap with the highly deleted regions (D1–D4) (Figure 1). The contraction and expansion of alleles were observed in 51 and 49% of the affected alleles, respectively (data not shown). Overall, molecular abnormalities (LOH/MA) in the D1 and D3 regions were seen in 59 and 55% samples, respectively (Figure 1). Interestingly, significant correlation (P -value: 0.042) has been found between deletions in the D1 and D2 regions.

Five samples (1542, 5184, 5219, 951 and 2785) showed LOH or MA at all the informative loci, indicating loss of normal copy of chr.13 in these tumours (Figure 1). Eight samples (558, 4200, 2073, 5090B, 615, 1640, 4702 and 1552) showed LOH and/or MA in more than two consecutive markers, particularly around the high LOH regions (Figure 1). No homozygous deletion was found in these samples. However, 40% (22/55) of the samples showed rare biallelic alterations (MA-2 or LOH + MA) in and around the high LOH regions.

Detection of HPV

Using consensus L1 primers, 73% (40/55) of the HNSCC samples were found to be positive for HPV infection (Figure 2). All the HPV positive samples were seen to be positive for HPV type-16 using both HPV type-16/18 specific primers. Significant correlation was found between HPV infection and deletion in the D4 region (P -value: 0.0003) and MA in the D1 region (P -value: 0.046) (Table 2).

Association of molecular abnormalities with clinicopathological variables and patient survival

Among the various clinicopathological parameters tested, deletions in the D1–D4 regions were significantly correlated (P -value: 0.00029–0.034) with both pathological grades and TNM stage of the tumours (Table 2). MAs in the D1 and D4 regions were seen to be significantly associated (P -value: 0.011–0.019) with TNM stage of the tumour, whereas MA in the D4 region was only found to be associated (P -value: 0.014) with clinical grade of the tumour (Table 2).

The clinical outcome of the HNSCC patients was investigated for a period up to 5 years. Log-rank test uncovered a statistically significant difference in overall patient survival between cases with LOH and cases without LOH for all the deleted regions (P -value: 0.00001–0.05) (Figure 4).

We used the Cox-proportional hazards model to determine which factors were jointly predictive of overall survival of the patients. Among the different clinicopathological variables used in our analysis, lymph node status (RR = 0.1388, P = 0.0159) and deletion in all the four highly deleted regions (D1: RR = 0.1705, P = 0.0053, D2: RR = 0.155, P = 0.0091, D3: RR = 0.1744, P = 0.004, D4: RR = 0.1940,

P = 0.0021) were significantly predictive of overall survival time (Table 3).

Discussion

In the present study, we have analysed the allelic alterations (LOH/MA) in 11 microsatellite loci spanning whole chr.13q in 55 primary HNSCC samples at different clinical and histological stages. We found gradual increase in the mean FAL index (Figure 3) from stage I to more aggressive stage IV tumours, which is an indication of the accumulative nature of the deletions occurring in different chr.13q regions during progression of HNSCC. All the four highly deleted regions (D1–D4) were associated with higher stages and grades of the tumour as well as poor patient outcome (Table 2, Figure 4), which is supportive to the fact, that chr.13q deletion is a later event in progression of the disease and is an important prognostic determinant. In addition, according to multivariate analysis, deletions in the D1–D4 regions along with positive lymph node were significantly predictive of overall survival (Table 3). We have not analysed the microsatellite alterations of chr.13q in dysplastic lesions and CIS of head and neck due

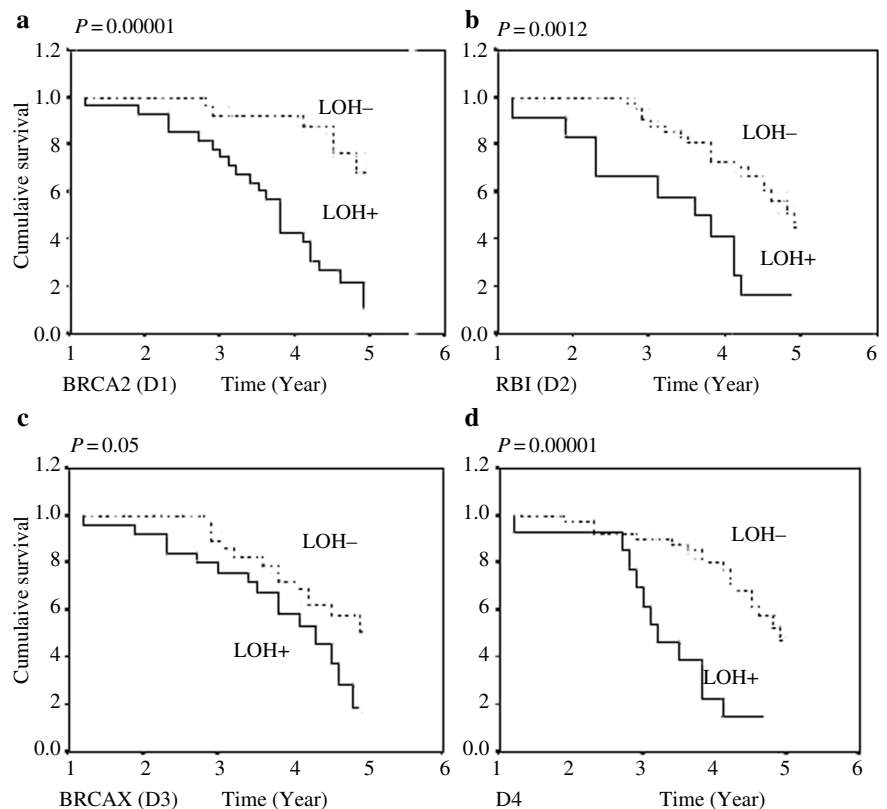

Figure 4 Kaplan–Meier 5-year survival probability curves with cumulative survival of head and neck squamous cell carcinoma patient by loss of heterozygosity (LOH) status in (a) D1 (BRCA2), (b) D2 (RB1), (c) D3 (BRCA-X) and (d) D4 region. Survival time was defined as the time from surgery to the patient's death, known recurrence or the last time the patient was known to be alive. The dotted line represents survival probability without LOH and smooth line represents with LOH probability.

Tobacco	0.3870	0.00001
HPV	0.5311	0.00001

to low incidence of such alterations in stage I/II tumours. However, Califano *et al.* (1996) showed the association between chr.13q deletion and the development of carcinoma *in situ* (CIS) in head and neck cancer using the microsatellite markers D13S133 and D13S170 from the chromosomal 13q14.3 and 13q31.1 regions, respectively. In our analysis, D13S170 marker showed high deletions mainly in the stage III/IV tumours (Figure 1). This discrepancy might be due to the difference in sample preparation, methodology used and ethnicity.

It is evident from Figure 5 that the deletions in the D1 and D2 regions overlap with the deletions reported previously in some HNSCC as well as other tumours. Deletions in the D3 and D4 regions have not yet reported earlier in HNSCC, while deletions in these regions have been reported in breast carcinoma and ovarian and fallopian tube cancers (Jongsma *et al.*

2002; Chunder *et al.* 2004). The significant association between deletions in the D1 and D2 region indicates that deletion in one region may impose selective pressure on the other regions to be deleted or size altered for development of the disease. The distance between the D1 and D2 is about 17.1 Mb and there are several samples in our study where either D1 or D2 alterations have been seen. This indicates that D1 and D2 are not epiphenomena due to large deletion. The microsatellite markers analysed in the D1 and D2 regions are intragenic to the putative TSGs BRCA2 and RB1, respectively. The co-operativity between BRCA2 and RB1 loci in HNSCC has not yet been reported earlier. In parathyroid carcinoma, tumours that showed loss of RB1 by allelotyping also showed loss of BRCA2 (Shattuck *et al.* 2003). Similar results have also been reported in prostate cancer (Cooney *et al.* 1996; Latil *et al.* 1996; Melamed *et al.* 1997). The overall 59% LOH seen in HNSCC samples in our study is comparable to that has been seen in early onset breast tumours of Indian Patients (Chunder *et al.* 2004). Also, high frequency of LOH has been reported in the BRCA2 loci using flanking microsatellite markers in oesophageal carcinoma, hepatocellular carcinoma and ovarian/fallopian tube carcinoma (Kuroki *et al.* 1995; Hu *et al.* 2002; Jongsma *et al.* 2002) (Figure 5). However, Gupta *et al.* (1999) suggested that neither BRCA2 nor RB1 were associated with the development of HNSCC. Kirkpatrick *et al.* 1997 had seen infrequent deletion in the microsatellite markers flanking to the BRCA2 gene in HNSCC. On the other hand, Maestro *et al.* (1996) have found overall 65% (28/43) LOH in the RB1 locus using a VNTR marker in HNSCC, but they did not found any changes in the expression pattern of the gene using both immunohistochemical and RT-PCR techniques, suggesting the involvement of any other candidate

Figure 5 Illustration showing the approximate location of highly deleted regions of chr.13q in head and neck squamous cell carcinoma and other human cancers in different studies.

TSG in this region. Similar conclusion has also been made by Ogawara *et al.* (1998) in this tumour. However, no one has sequenced the RB1 cDNA as well as genomic region of the gene in HNSCC to see whether the functional RB1 protein has been produced or not. Thus, the discrepancy of the association of BRCA2 and RB1 between our study and other Western studies in HNSCC might be due to the difference in ethnicity and aetiological factors. However, we have not analysed the mutation as well as methylation of BRCA2 and RB1 genes to see if these inactivation mechanisms of TSGs have any role in the down-regulation of these genes. A candidate TSG known as DICE1 has been found to be located in chr.13q14.1–13q14.2 regions, but its association with HNSCC tumours has not yet been analysed (Li *et al.* 2003). Ogawara *et al.* (1998) also reported a significant correlation between the LOH in chr.13q14.3 and lymph node metastasis in HNSCC contrary to that has been seen in our analysis (Table 2). This discrepancy might be due to the presence of normal cell contaminants in the surgical specimens used in the allelotyping study of Ogawara *et al.* (1998). Till date no biochemical correlation between BRCA2 and RB1 has been established, however, both the proteins could interact in the BRCT domain (transactivation) of BRCA1 protein associated with the cell cycle regulation and DNA repair (Welsh & King 2001). Thus, it suggests that inactivation of BRCA2 and RB1 genes might develop gross chromosomal abnormalities in later stages of HNSCC for selective growth advantage of the tumour and poorer outcome of the patients (Figure 4).

Deletion in the D3 (13q21.2–22.1) region is about 14.1 Mb wide and encompasses the Common Fragile Sites FRA13B and FRA13C at 13q21.2 and 13q22.2 regions, respectively, and also harbours a candidate breast cancer susceptibility locus BRCAX at 13q21.33 region (Gilles *et al.* 1996; Kainu *et al.* 2000; Thorland *et al.* 2003). In cervical carcinoma, HPV-16 integration site has been detected in the FRA13B and FRA13C regions (Wentzensen *et al.* 2004), though we have not seen any association between the deletion in this region and HPV infection in HNSCC. It seems that in HNSCC, HPV may not integrate in this region. Similar to our data, Ogawara *et al.* (1998) have seen 31% LOH using the D13S176 marker (used in our study) at 13q21.2 region in HNSCC. Using the D13S1308 marker (BRCAX: 13q21.33) comparable frequency of deletion has been reported in early and late onset breast tumours of Indian patients (Chunder *et al.* 2004). Moreover, high frequency (67%) of LOH has been reported in 13q21 region in ovarian and fallopian tube cancer indicating the location of a candidate TSG in this region (Jongsma *et al.* 2002) (Figure 5). No candidate TSG has yet been identified in this region. However, a significant association has been found between deletion in the BRCAX locus with ATM

and TP53 loci in early and late onset breast tumours, respectively, indicating the possible function of the candidate TSG in the BRCAX locus in cell cycle regulation and DNA repair pathways (Chunder *et al.* 2004). The deletion in the D4 region (13q31.1) is comparatively high (31%) in our study than other studies using the same microsatellite marker D13S170 (Yoo *et al.* 1994). However, high LOH (69%) has been reported in 13q22–31 regions in ovarian and fallopian tube cancer (Jongsma *et al.* 2002) (Figure 5), indicating the location of candidate TSG in this region. No candidate TSG has yet been identified in this region. The significant association of deletions in D3 and D4 region with different clinicopathological parameters including poor patient outcome indicates the presence of candidate TSGs in these regions (Table 2, Figure 4).

The occurrence of high MA in and around the high LOH regions of chr.13q seen in our study (Figure 1) is comparable to that has been seen in our previous allelotyping studies of other chromosomes in HNSCC (Chakraborty *et al.* 2003). Though, the actual significance of MA in the development of the tumour is not clear, still MA has been suggested to be important parameters for molecular detection of cancers (Mao *et al.* 1994). The presence of comparatively high frequency (40%) of rare biallelic alterations in the highly deleted region indicate that the LOH/MA in one allele of this region may impose selective pressure on the other allele of the same locus for deletion or size alteration. In the later stages of the tumours (stage III and IV), loss of normal copy of the chr.13 and interstitial alterations suggest that these chromosomal alterations are needed for progression of the disease. Similar phenomenon has been reported in HNSCC in the allelotyping studies of other chromosomes and chr.13 also (Maestro *et al.* 1996; Dasgupta *et al.* 2002; Bhattarcharya *et al.* 2003; Chakraborty *et al.* 2003; Tripathi (Bhar) *et al.* 2003). The high prevalence of HPV infection seen in our study is comparable (74%) to that have been seen by Balaram *et al.* (1995). The significance of the association among the HPV infection and deletion in the D4 region and MA in the D1 region is not clear, but it seems that HPV might have some role in the occurrence of genomic instability and tumour progression (Gillison *et al.* 1999).

Thus, it can be concluded that the deletions in the D1–D4 regions are needed for the development of later stages of HNSCC and can be used as prognostic indicators. The loss of function of known and putative TSGs in these regions may have cumulative effect in this tumour development. Along with these deletions, other molecular changes in the chromosome such as MA, interstitial alterations and loss of normal copy of chr.13 may impose selective pressure for growth advantage of the tumour.

Acknowledgements

Authors are grateful to Director, Chittaranjan National Cancer Institute (CNCI), Kolkata for encouragement and support, Dr S. Gupta, Director, Cancer Center and Welfare Home, Kolkata for providing tumour samples and Dr N Chunder for technical help. We are also grateful to Prof H. Z. Hausen and Dr E. M. de Villiers for the gift of HPV type 16/18 plasmids. Financial support was provided by research grants from the Department of Biotechnology, Govt. of India (Grant Number: BT/MB/05/002/94).
