Abstract

Background: Selenium, an essential micronutrient, has received considerable attention for its antioxidant properties. In addition, selenium may affect several cardiometabolic risk factors, such as glucose homeostasis and lipid concentrations. However, the effects of selenium intake on the lipid profile in selenium-replete populations, such as the United States, are largely unknown.

Objective: We examined the relation of serum selenium concentrations with serum lipids in a representative sample of US adults.

Design: This was a cross-sectional analysis of 5452 men and women aged ≥ 20 y participating in the third National Health and Nutrition Examination survey. Serum selenium was measured by atomic absorption spectrometry.

Results: The multivariable adjusted differences in total cholesterol, LDL cholesterol, HDL cholesterol, apolipoprotein B (apo B), and apolipoprotein A-I (apo A-I) comparing the highest with the lowest quartile of serum selenium were 16.6 mg/dL (95% CI: 11.6, 21.4 mg/dL), 10.9 mg/dL (95% CI: 6.4, 15.4 mg/dL), 3.2 mg/dL (95% CI: 1.6, 5.0 mg/dL), 8.9 mg/dL (95% CI: 5.6, 12.2 mg/dL), and 6.9 mg/dL (95% CI: 1.7, 12.1 mg/dL), respectively. Participants in the highest quartile of serum selenium had 10% higher concentrations of triacylglycerols than did participants in the lowest quartile (ratio of triacylglycerol concentrations: 1.10; 95% CI: 1.05, 1.17). The difference in the ratios of LDL cholesterol to HDL cholesterol and apo B to apo A-I that compared the highest with the lowest selenium quartiles were 0.11 (95% CI: -0.02, 0.25) and 0.03 (95% CI: 0.00, 0.06), respectively.

Conclusion: Elevated serum selenium was associated with elevated serum concentrations of total cholesterol, LDL cholesterol, HDL cholesterol, triacylglycerols, apo B, and apo A-I among US adults, a selenium-replete population. Experimental studies are needed to determine cause and effect relations and the potential mechanisms underlying these associations.

INTRODUCTION

Selenium, an essential micronutrient, has received considerable attention for its antioxidant properties mediated through glutathione peroxidases and other selenoproteins (1,2). Glutathione peroxidase synthesis, however, plateaus with increasing selenium concentrations. In the United States, a country with relatively high selenium intake, 99% of US adults have serum selenium concentrations > 95 ng/mL (3), well above the concentration needed to maximize the activity of glutathione peroxidases. In selenium-replete populations such as the United States, other effects of selenium not related to its antioxidant properties may thus be the primary determinants of the beneficial or harmful effects of selenium intake population-wide.

In rats, selenium supplementation increased LDL-receptor activity and mRNA expression (4) and decreased β -hydroxy- β -methylglutaryl coenzyme A reductase mRNA expression, resulting in lower concentrations of total cholesterol, LDL cholesterol, and apolipoprotein B (apo B) (5). As a consequence, it was proposed that selenium intake may beneficially affect the lipid profile (4,5). In humans, randomized trials of the effect of selenium intake or supplementation on lipid concentrations are limited to studies in which selenium was given in combination with other vitamins or minerals (6,7) or to small short-term studies (8,9). Observational studies of the association between selenium and lipids are inconsistent, finding positive associations of serum selenium with total cholesterol (6,10-14), with LDL cholesterol (10,14), or with HDL cholesterol or the ratio of HDL cholesterol to total cholesterol (HDL cholesterol:total cholesterol) (8,14-17). Those studies were conducted mostly in populations with relatively low serum concentrations of selenium, and their generalizability to a selenium-replete population is uncertain (6-17).

Recent randomized and observational evidence indicate that high selenium exposure in selenium-replete populations may increase diabetes risk (18-20). Because of current interest in selenium for chronic disease prevention, it is important to understand the full range of effects of high selenium exposure on cardiovascular risk factors, including lipids. The objective of this analysis was thus to evaluate the association of serum selenium concentrations with serum lipid concentrations in US adults with the use of data from the third National Health and Nutrition Examination Survey (NHANES III).

SUBJECTS AND METHODS

NHANES III, conducted from 1988 to 1994, used a stratified multistage probability cluster design to obtain a representative sample of the civilian noninstitutionalized US population (21). For the present study, we selected 7129 participants from NHANES III, aged ≥ 20 y, who participated in the morning medical examinations and fasted ≥ 9 h. We then excluded 114 women who were pregnant at the time of the survey; 339 participants with missing serum selenium data; 179 participants with missing lipid concentrations or with triacylglycerols > 400 mg/dL, precluding LDL-cholesterol estimation; 538 participants with missing values on other variables of interest; and 507 participants with a history of cardiovascular disease or cancer. The final analyses were based on a total of 5452 NHANES III participants. In NHANES III, apolipoprotein A-I (apo A-I) and apo B were measured only during 1988–1991; therefore, apolipoprotein concentrations were only available on 2589 participants.

NHANES III study protocols were approved by the National Center for Health Statistics Institutional Review Board. Oral and written consent was obtained from all participants.

Data collection and measurements

The laboratory procedures and quality control methods for serum measurements of selenium, lipids, and apolipoprotein were described before (22,23). To measure serum selenium, whole blood was collected in containers previously screened for selenium contamination. After clotting and centrifugation, serum was collected, frozen at -20°C , and shipped to the laboratory. Serum selenium was measured with the use of atomic absorption spectrometry (22,24,25). The limit of detection was 8 ng/mL. The between-assay CV for quality control-pooled samples analyzed throughout the duration of the survey ranged from 4.0% to 6.4% (22).

Serum lipids were measured at the Lipoprotein Analytic Laboratory at the Johns Hopkins University in Baltimore, MD. Total cholesterol, triacylglycerols, and HDL cholesterol were measured with the use of a Hitachi 704 Analyzer and reagents from Roche/Boehringer Mannheim Diagnostics (Indianapolis, IN), and LDL-cholesterol concentrations were calculated with the use of the Friedewald formula (26). Apo A-I and apo B were measured by radial immunodiffusion or rate immunonephelometry, and results were converted to values based on the World Health Organization-International Federation of Clinical Chemistry and Laboratory Medicine International Reference Materials (23).

Other laboratory procedures were described in detail (22). In brief, serum C-reactive protein was measured by latex-enhanced nephelometry, a low-sensitivity assay, serum creatinine by the Jaffé-modified kinetic method, and serum cotinine by HPLC and atmospheric-pressure chemical ionization tandem mass spectrometry.

Information about age, sex, race-ethnicity, education, family income, menopausal status, cigarette smoking, alcohol consumption, physical activity, history of cardiovascular disease and cancer, use of cholesterol-lowering medication, and use of vitamin-mineral supplements was based on interview questionnaires (21). Body mass index (in kg/m^2) was calculated. Diabetes mellitus was defined as a plasma glucose ≥ 126 mg/dL, a self-report of a physician diagnosis of diabetes, or current medication use. Glomerular filtration rate was estimated by the formula from the Modification of Diet in Renal Disease Study after alignment of serum creatinine concentration with the assay used to develop the formula (27,28).

Statistical methods

Participants were divided into quartiles of serum selenium concentration based on the weighted population distribution. Serum triacylglycerol concentrations were markedly right skewed and were \log_{10} transformed for statistical analyses. We used multivariable linear regression to estimate the differences (95% CIs) in concentrations of serum total cholesterol, LDL cholesterol, HDL cholesterol, \log_{10} -triacylglycerols, apo B, apo A-I, ratio of LDL cholesterol to HDL cholesterol, and ratio of apo B to apo A-I (apo B:apo A-I) comparing the 3 highest quartiles of serum selenium with the lowest quartile. Because triacylglycerols were \log_{10} -transformed, the results of the regression models for triacylglycerols are reported as ratios in triacylglycerol concentrations, comparing the 3 highest quartiles of serum selenium with the lowest quartile. To further explore the shape of the relation between serum selenium and serum lipids, we used restricted cubic splines with knots at the 5th, 35th, 65th, and 95th percentiles of the serum selenium distribution (29).

We fitted 3 models with progressive levels of adjustment. Model 1 was adjusted for age, sex, and race-ethnicity. Model 2 was further adjusted for education, family income, menopausal status, cigarette smoking, serum cotinine, alcohol consumption, physical activity, and body mass index. Model 3 was further adjusted for use of cholesterol-lowering medication, vitamin-

mineral use, glomerular filtration rate, C-reactive protein, diabetes mellitus, thyroxin, and thyroid-stimulating hormone.

The association of serum selenium concentrations as a continuous variable with serum concentrations of LDL cholesterol, HDL cholesterol, and triacylglycerol was determined for subgroups defined by sex, age, race-ethnicity, smoking status, alcohol consumption, body mass index, vitamin-mineral supplement use, and cholesterol-lowering medication use. From those models we estimated the difference in lipid concentrations comparing the 80th (137.7 ng/mL) with the 20th (111.4 ng/mL) percentile of the selenium distribution, assuming a linear dose-response relation between selenium and LDL cholesterol, HDL cholesterol, and logtriacylglycerols. Although we used a comparison between the 80th and 20th percentiles, the statistical significance of these analyses would be the same if we had used other percentiles for comparison. *P* values for the interactions were obtained with the use of Wald tests. Data were analyzed with the use of SUDAAN (version 9.0; Research Triangle Institute, Research Triangle Park, NC) to account for the NHANES weights and complex design.

RESULTS

The mean serum concentration of selenium in study participants was 125.7 ng/mL. On average, participants with higher selenium concentrations were more likely to be men, non-Hispanic white, and high school educated (Table 1). Serum selenium concentrations were inversely associated with body mass index, C-reactive protein, and the prevalence of smoking.

Higher serum concentrations of selenium were associated with higher concentrations of serum lipids and apolipoproteins. The multivariable-adjusted differences in total cholesterol, LDL cholesterol, HDL cholesterol, apo B, and apo A-I, comparing the highest with the lowest quartile of serum selenium were 16.6 mg/dL (95% CI: 11.6, 21.4 mg/dL), 10.9 mg/dL (95% CI: 6.4, 15.4 mg/dL), 3.2 mg/dL (95% CI: 1.6, 5.0 mg/dL), 8.9 mg/dL (95% CI: 5.6, 12.2 mg/dL), and 6.9 mg/dL (95% CI: 1.7, 12.1 mg/dL), respectively (Table 2). After multivariable adjustment, participants in the highest quartile of serum selenium had 10% higher concentrations of triacylglycerols than did participants in the lowest quartile (ratio of triacylglycerol concentrations: 1.10; 95% CI: 1.05, 1.17) (Table 3). Spline regression models showed relatively linear increases in serum lipids and apolipoproteins by serum selenium concentrations (Figure 1). The multivariable-adjusted differences in LDL cholesterol:HDL cholesterol and apo B:apo A-I, comparing the highest with the lowest quartile of serum selenium, were 0.11 (95% CI: -0.02, 0.25) and 0.03 (95% CI: 0.00, 0.06), respectively (Table 4).

When the associations of serum selenium concentrations with serum LDL cholesterol, HDL cholesterol, and triacylglycerols were evaluated by study subgroups (Figure 2 and Figure 3), none of the interactions were statistically significant except for the interaction of serum selenium and sex on serum HDL cholesterol ($P < 0.001$) and the interaction of serum selenium and race on serum HDL cholesterol ($P = 0.03$).

DISCUSSION

In this large cross-sectional study, conducted in a representative sample of the US population, serum selenium concentrations were positively associated with serum concentrations of total cholesterol, LDL cholesterol, HDL cholesterol, apo B, apo A-I, and triacylglycerols. The associations were moderately strong and relatively linear, and they persisted after adjustment for age, sex, race, thyroid hormone concentrations, supplement use, or other traditional cardiovascular risk factors. The rigorous methods and the detailed quality control procedures

of NHANES III, the large sample size, and the representative nature of the population sample add to the strength of these findings.

Serum selenium concentrations were also positively associated with total-cholesterol concentrations in several cross-sectional studies conducted in Denmark (11), France (6,14), Italy (13), Norway (only among women) (12), and Spain (10). In those studies, average serum concentrations of selenium ranged from 76 ng/mL (10) to 125 ng/mL (12). Three small studies conducted in the Netherlands ($n = 82$) (30), Portugal ($n = 126$) (15), and Finland and Japan ($n = 60$) (31) reported no relation between serum concentrations of selenium and total cholesterol. Another small study of Japanese women ($n = 127$) found a positive relation of serum concentrations of selenium with total cholesterol among premenopausal women but not among postmenopausal women (32). Finally, in 142 women from Korea (16), participants in the highest selenium quartile had lower concentrations of total cholesterol, although the associations were not adjusted by age, and selenium concentrations were inversely related to age in that study. Except in a few small studies that were subject to greater random variability, the association of selenium with total-cholesterol concentrations seems largely consistent across populations.

Few studies have evaluated the association of serum selenium with the different components of the lipid profile, and the relations appear to differ across studies. For instance, 1 study reported a positive association between selenium and LDL cholesterol (10), whereas 2 studies reported no association (14,17); 2 studies reported a positive association with HDL cholesterol (14,17), whereas 2 other studies did not (11,13). Small sample sizes and selective reporting of findings may explain some of those inconsistencies. Moreover, none of the studies that evaluated triacylglycerols found a positive association with serum selenium concentrations (6,11-13). Specifically, the SU.VI.MAX study found no association between selenium and triacylglycerols. Selenium concentrations in the SU.VI.MAX study ($\bar{x} \pm SD$: 89.6 \pm 15.8 ng/mL in men; 85.7 \pm 15.0 ng/mL in women) were substantially lower than those in NHANES III. This finding could reflect a differential association of selenium with serum lipids in selenium-deficient compared with selenium-replete populations.

Evidence from randomized clinical trials on the effects of selenium supplementation on the lipid profile is limited. In 2 large trials, selenium supplementation was administered in combination with other vitamins and minerals (6,7), and the effects of selenium cannot be isolated. The SU.VI.MAX study randomly assigned participants to 100 μ g selenium, 120 mg vitamin C, 30 mg vitamin E, and 20 mg zinc or to placebo and followed them for 7.5 y. At the end of follow-up, women in the active intervention group had higher concentrations of total cholesterol and men were more likely to use lipid-lowering medication than were participants in the placebo group (6). In the Shandong Intervention Trial in Linqu County, China, 204 adults receiving 37.5 μ g selenium, 250 mg vitamin C, and 100 IU vitamin E for 7.3 y had higher concentrations of total cholesterol and LDL cholesterol at the end of follow-up than did participants receiving placebo (7). No differences were observed in HDL-cholesterol concentrations. Two small trials have evaluated the lipid effects of selenium alone in supplements. In China, 40 healthy tin miners were randomly assigned to supplements with 300 μ g selenium or placebo and followed for 1 y (9). At the end of follow-up, cholesterol concentrations were higher in the selenium group (153 \pm 91.2 mg/dL) than in the placebo group (145 \pm 95.7 mg/dL), although this difference was not statistically significant. Finally, a small Finnish trial randomly assigned 27 healthy medical students to selenium (96 μ g/d) or to placebo for 2 wk. This short course of selenium had no effect on concentrations of total cholesterol, HDL cholesterol, or triacylglycerol or on HDL cholesterol:total cholesterol (8).

The mechanisms underlying the association of serum selenium with lipid concentrations are unclear. Selenium could affect lipid concentrations, although the mechanisms proposed so far

point to decreasing total-cholesterol concentrations with increasing selenium. In rats, supplementation with 1 $\mu\text{g/g}$ Se increased LDL-receptor activity and mRNA expression, an effect hypothesized to be mediated through type I 5'-iodothyronine deiodinase. Iodothyronine deiodinases are selenoproteins involved in activating thyroxine to triiodothyronine, which increases LDL-receptor gene expression (4). In our study, the association between selenium and lipid concentrations did not change after adjustment for concentrations of thyroid-stimulating hormone and thyroxine. Also in rats, supplementation with 1 ppm selenium decreased apo B concentrations and mRNA expression of β -hydroxy- β -methylglutaryl coenzyme A reductase, the rate-limiting enzyme in hepatic cholesterol synthesis (5,33).

Alternatively, increased selenium and lipid concentrations could be the consequence of a common exposure. Selenium is incorporated into selenoproteins as selenocysteine (1,34). Selenoproteins, including glutathione peroxidases, iodothyronine deiodinases, selenoprotein P, and thioredoxin reductase, are responsible for the biological functions of selenium (1,3). Above selenium levels needed to maximize serum selenoprotein concentration and activity (70–90 ng/mL Se in serum or plasma), increases in serum selenium, however, reflect the nonspecific incorporation of selenomethionine replacing methionine in albumin and other serum proteins (3,35,36). Because 99% of the NHANES III participants had serum selenium > 95 ng/mL (3), variation in selenium concentrations in our study population probably reflect variation in selenomethionine concentrations but not selenoprotein activity. The association between selenium and lipid concentrations could then be driven by a common dietary factor or by general overnutrition, but this association was not modified after adjustment for body mass index or use of vitamin-mineral supplements.

Because of our cross-sectional design, we cannot determine the cause and effect relation of the association between selenium and lipid concentrations. Mechanistic studies, conducted in populations with different selenium repletion status, are needed to establish the causal effect of selenium on lipid concentrations. In the United States and in other populations with high selenium exposure, those studies will help clarify the potential chronic toxicity of selenium concentrations in the high-normal range. Indeed, selenium is known to have a relatively narrow therapeutic range, and its toxicity is partly related to the ability of some selenium compounds to generate reactive oxygen species (37-39). The tolerable upper intake amount for selenium has been set at 400 $\mu\text{g/d}$ by the Institute of Medicine to avoid visible symptoms of selenium toxicity in sensitive persons (3). Unfavorable effects of selenium on serum lipids and possibly on diabetes risk (18-20) in selenium-replete populations, such as the United States, could explain the lack of beneficial effects of selenium on coronary heart disease in studies conducted in the United States (40-43).

In conclusion, high serum concentrations of selenium were associated with high serum concentrations of total cholesterol, LDL cholesterol, HDL cholesterol, triacylglycerols, apo B, and apo A-I among US adults, a selenium-replete population. Ongoing trials of selenium supplements should monitor serum lipid and apolipoprotein concentrations (44,45). Additional studies are also needed to determine cause and effect relations and potential mechanisms across a wide range of selenium exposures.

FIGURE 1. Serum lipid and lipoprotein concentrations by serum selenium concentrations, Third National Health and Nutrition Examination Survey. Dose-response lines are based on restricted cubic spline transformations with 4 knots. Results were adjusted for education, family income, postmenopausal status for women, cigarette smoking, serum cotinine, alcohol consumption, physical activity, body mass index, cholesterol-lowering medication use, vitamin-mineral supplement use, glomerular filtration rate, C-reactive protein, diabetes mellitus, thyroid-stimulating hormone, and thyroxine.

**FIGURE 2.**

Differences in serum concentrations of LDL cholesterol and HDL cholesterol comparing the 80th (137.7 ng/mL) with the 20th (111.4 ng/mL) percentile of the serum selenium distribution. Differences (95% CI in parentheses) in concentrations of serum LDL cholesterol and HDL cholesterol were derived from multiple linear regression models that included serum selenium concentrations as a continuous variable. Differences were adjusted for age, sex, race-ethnicity, education, family income, postmenopausal status for women, cigarette smoking, serum cotinine, alcohol consumption, physical activity, body mass index, cholesterol-lowering medication use, vitamin-mineral supplement use, glomerular filtration rate, C-reactive protein, diabetes mellitus, thyroid-stimulating hormone, and thyroxine. The area of each square is proportional to the inverse of the variance. Horizontal lines represent 95% CIs. None of the *P* values for the interactions was statistically significant at the 0.05 level, except for the interaction of serum selenium and sex on serum HDL cholesterol ($P < 0.001$) and the interaction of serum selenium and race on serum HDL cholesterol ($P = 0.03$). Although we used a comparison between the 80th and 20th percentiles, the statistical significance of these analyses would be the same if we had used other percentiles for comparison.

**FIGURE 3.**

Ratios of serum triacylglycerol concentrations comparing the 80th (137.7 ng/mL) with the 20th (111.4 ng/mL) percentile of the serum selenium distribution. Ratios (95% CI in parentheses) of triacylglycerol concentrations were derived from multiple linear regression models that included serum selenium concentrations as a continuous variable. Ratios were adjusted for age, sex, race-ethnicity, education, family income, postmenopausal status for women, cigarette smoking, serum cotinine, alcohol consumption, physical activity, body mass index, cholesterol-lowering medication use, vitamin-mineral supplement use, glomerular filtration rate, C-reactive protein, diabetes mellitus, thyroid-stimulating hormone, and thyroxine. The area of each square is proportional to the inverse of the variance. Horizontal lines represent 95% CIs. None of the *P* values for the interactions was statistically significant at the 0.05 level. Although we used a comparison between the 80th and 20th percentiles, the statistical significance of these analyses would be the same if we had used other percentiles for comparison.

Table 1
 Baseline characteristics of the study population by quartile (Q) of serum selenium concentrations ($n = 5452$)¹

	Q1 (<113.7 ng/mL)	Q2 (113.7–123.6 ng/mL)	Q3 (123.7–134.6 ng/mL)	Q4 (≥134.7 ng/mL)	P for trend
Age (y)	42.8 ± 0.9 ²	42.5 ± 0.6	43.2 ± 0.9	43.5 ± 0.9	0.46
Sex, male (%)	41.0 (2.2) ³	43.7 (1.9)	52.2 (2.0)	54.2 (1.7)	<0.001
Race (%)					
Non-Hispanic white	68.3 (2.7)	76.4 (2.2)	78.9 (1.4)	83.3 (2.4)	<0.001
Non-Hispanic black	16.9 (1.1)	10.4 (0.8)	7.8 (0.7)	6.8 (1.0)	<0.001
Mexican American	5.3 (0.8)	5.5 (0.5)	5.8 (0.7)	4.4 (0.8)	0.50
High school education (%)	74.7 (1.9)	77.1 (1.8)	79.9 (1.8)	80.5 (1.7)	<0.001
Body mass index (kg/m ²)	27.0 ± 0.3	26.4 ± 0.3	26.4 ± 0.2	25.9 ± 0.2	0.01
Current smoking (%)	33.8 (2.0)	30.6 (2.2)	27.1 (1.8)	20.9 (1.8)	<0.001
Current alcohol consumption (%)	62.8 (2.5)	62.7 (2.3)	67.7 (2.1)	66.0 (3.4)	0.28
Hypertension (%)	27.6 (1.9)	25.2 (1.5)	27.3 (1.4)	28.9 (2.1)	0.45
Diabetes (%)	4.6 (0.6)	5.6 (0.9)	4.9 (0.6)	5.7 (0.9)	0.44
Vitamin-mineral supplement users (%)	41.7 (2.6)	41.3 (2.2)	40.5 (2.1)	42.1 (2.8)	0.97
C-reactive protein <0.03 mg/dL (%)	69.3 (2.4)	75.1 (2.0)	77.5 (1.9)	78.1 (2.2)	0.008
Serum selenium (ng/mL)	105.9 ± 0.4	118.9 ± 0.1	128.9 ± 0.2	147.0 ± 0.9	—

¹ Adjusted for age, sex, and race-ethnicity.

² $\bar{x} \pm$ SE (all such values).

³ SE in parentheses (all such values).

Table 2
Difference (95% CI) in serum lipid and lipoprotein concentrations by quartile (Q) of serum selenium concentrations ($n = 5452$)¹

	Q1 (<113.7 ng/mL)	Q2 (113.7–123.6 ng/mL)	Q3 (123.7–134.6 ng/mL)	Q4 (≥134.7 ng/mL)	P for trend
