Abstract

Mitochondria are central players in the pathophysiology of ischemia-reperfusion. Activation of plasma membrane G-coupled receptors or the Na, K-ATPase trigger cytosolic signaling pathways that result in cardioprotection. Our working hypothesis is that the occupied receptors migrate to caveolae, where signaling enzymes are scaffolded into signalosomes that bud off the plasma membrane and migrate to mitochondria. The signalosome-mitochondria interaction then initiates intramitochondrial signaling by opening the mitochondrial ATP-sensitive K⁺ channel (mitoK_{ATP}). MitoK_{ATP} opening causes an increase in ROS production, which activates mitochondrial protein kinase C epsilon (PKC ϵ), which inhibits the mitochondrial permeability transition (MPT), thus decreasing cell death. We review the experimental findings that bear on these hypotheses and other modes of protection involving mitochondria.

Keywords

mitochondrial K_{ATP} channel; protein kinase C; reactive oxygen species; permeability transition; signaling pathways

1. Mitochondria : the target for ischemia-reperfusion injury and cardioprotection

Mitochondria are effectors of both ischemia-reperfusion injury (IRI) and cardioprotection. As pointed out 30 years ago by Jennings and Ganote [1], the heart is strictly aerobic and consequently extremely vulnerable to a decrease in oxygen supply. Thus, ischemia causes profound and immediate mitochondrial derangements. These include cessation of ATP synthesis, inhibition of respiration, and a drop in $\Delta\Psi$. This is accompanied during ischemia by cellular changes, especially an increase in Ca²⁺ and phosphate, and, during reperfusion, by large increases in reactive oxygen species (ROS) originating from the respiratory chain [2,3]. Together, these factors promote opening of the mitochondrial permeability transition (MPT),

a high-conductance pore in the inner mitochondrial membrane, which is the main cause of necrotic cell death in IRI [4–8]. Consequently, as pointed out by Weiss, et al. [4], cardioprotection by preconditioning or postconditioning must ultimately involve the prevention of MPT.

In addition to their role as mediators of cell death, mitochondria have been shown to be major effectors of diverse self-defense mechanisms, including ischemic pre- and post-conditioning [7,9–11]. These and other conditioning protocols have been shown to require opening of the mitochondrial ATP-sensitive K⁺ channel (mitoK_{ATP}) and inhibition of MPT opening. Since cardioprotection involves both mitoK_{ATP} opening and a decrease in MPT opening, it is reasonable to hypothesize that these two phenomena are part of the same signaling pathway. Indeed, this connection has been demonstrated [12], and will be discussed in this review.

This review describes our current understanding of the signaling mechanisms that originate at plasma membrane receptors, go to mitochondria, and terminate with MPT inhibition. For space reasons, we have not discussed mechanisms for the prevention of apoptosis. For different perspectives, readers are referred to excellent reviews by other authors [13–18].

2. Receptor-mediated signaling to open mitoK_{ATP}

2.1 G_i-protein coupled receptor (GPCR) pathways

Ischemic preconditioning (IPC) and ischemic postconditioning are receptor-mediated processes that are triggered by GPCR agonists released by the ischemic heart, primarily bradykinin, opioid peptides, and adenosine [19]. Other GPCR ligands, including acetylcholine, catecholemines, endothelin, and angiotensin II, are also cardioprotective [20-24], but they were found not to be physiological triggers of IPC [14]. A composite diagram of the GPCR signaling pathways is given in Fig. 1. GPCR signaling has been extensively studied by Downey and Cohen and their coworkers, and is the subject of an excellent review by these authors [14]. It should be emphasized that each G_i-coupled receptor ligand triggers its own unique signaling cascade. Opioids and acetylcholine instigate transactivation of the epidermal growth factor receptor (EGFR), leading to downstream activation of phosphtidylinostitol 3-kinase (PI3-K) and Akt. Bradykinin also induces activation of PI3-K and Akt, but without transactivation of EGFR. These two pathways then converge and ultimately lead to mitoKATP opening and production of ROS. The adenosine signaling pathway has not yet been fully characterized. MitoK_{ATP} opening is not involved during the *trigger* phase of adenosine preconditioning (i.e., when 5-HD administration brackets adenosine perfusion) [25], but mitoKATP opening is required during the mediator phase (i.e., when 5-HD administration precedes ischemia) [26-29].

Protection afforded by all of the trigger substances is blocked by PKC inhibitors, and PKC, probably PKC ε , is thought to be a common target of cardioprotective signaling [14]. It has been difficult to localize the critical PKC ε , because multiple PKC ε isoforms participate in cardioprotection [30]. In ouabain signaling, PKC ε acts proximally in conjunction with EGFR transactivation [31]. The adenosine A1 receptor is believed to directly stimulate PLC and PLD to activate PKC [21]. These PKCs are cytosolic. As discussed below, two PKC ε isoforms regulate mitoK_{ATP} and MPT at the level of the inner mitochondrial membrane [32]. Thus, the physiological effect of PKC ε activation depends entirely on its location and not on its biochemistry, which appears to be invariant.

2.2 Non-GPCR pathways of protection - digitalis

Cardiac glycosides are classic inhibitors of the plasma membrane Na^+/K^+ -ATPase, but this enzyme also has important non-canonical functions that are triggered by digitalis. Thus, ouabain interaction with the Na, K-ATPase activates src kinase, causing formation of a "binary

receptor" that phosphorylates and assembles other proteins into signaling modules that transmit signals to intracellular compartments [33,34]. Ouabain signaling has been shown to depend on mitoK_{ATP} opening and mitochondrial ROS production [35]. Ouabain is cardioprotective in rat heart [31,36,37], and this cardioprotection is blocked by the mitoK_{ATP} blocker 5- hydroxydecanoate (5-HD), the ROS scavenger N-2-mercaptopropionylglycine (MPG), and the src kinase inhibitor PP2 [36]. It is interesting to note that, whereas inhibition of the pump and consequent increase in intracellular Na⁺ and Ca²⁺ is required for positive inotropy, ouabain cardioprotection occurs at doses (about 10 μ M in rat) that do not produce significant enzyme inhibition [37] or increased contractility [31,36,37]. These distinctions further emphasize the dissociation of the pumping and signaling functions of Na,K-ATPase. Ouabain cardioprotection does not depend on guanylyl cyclase or PKG activities, showing that this signaling pathway differs from that triggered by GPCR agonists [36]. Ouabain-induced inotropy also requires mitoK_{ATP} opening and ROS production [36,38].

The rat heart Na,K-ATPase exhibits a low sensitivity to cardiac glycosides; however, we have observed qualitatively similar phenomena in the ouabain-sensitive rabbit heart. Thus, cardioprotection occurs at lower ouabain doses than those required for inotropy, and both cardioprotection and inotropy require mito K_{ATP} opening (S. Pierre, unpublished data).

3. From receptor to mitochondria by signalosomes

We propose that cardioprotective signals are transmitted to mitochondria by signalosomes, which are vesicular, multimolecular signaling complexes that are assembled in caveolae and deliver signals to the mitochondrial outer membrane (MOM) [39]. A diagram of the signalosome hypothesis is presented in Fig. 2.

3.1 Rationale

Signaling cascades such as the one portrayed in Fig. 1 must occur rapidly and precisely. We consider it unlikely that these spatio-temporal requirements can be met by random diffusional collisions. Cytosolic proteins are extensively hydrated, and the organization of this water causes a phase separation from bulk cytosolic water. Minimization of the phase boundary, in turn, causes proteins to coalesce within their common hydration phase [40]. If the proteins of the cardioprotective signaling pathway were randomly distributed in the cytosol, they too would coalesce within the hydration phase, with losses of directionality and specificity. Accordingly, we suggest that the signaling cascade is compartmentalized to promote metabolic channeling and that the entire reaction sequence moves through the cytosol as a unit. This hypothesis agrees with and extends the proposal by Ping and coworkers [41,42] that intracellular signaling involves assembly and regulation of multiprotein complexes.

3.2 The signalosome hypothesis

Upon activation, GPCR migrate to caveolae, where caveolins organize and compartmentalize receptors and signaling molecules [43–49]. Caveolae are 50–100 nm membrane invaginations that are rich in cholesterol, sphingolipids, and caveolin proteins [50]. EGFR, the Src family of tyrosine kinases, G-protein α -subunits, PKC isoforms, and transporters such as the Na/K-ATPase have been found to associate with caveolins, which also regulate the activity of many of these proteins [50–56]. Caveolar assembly of the signaling platform is followed by budding off and internalization [57]. Receptor endocytosis has been observed for both GPCRs [45,47, 58–60] and the α 1-subunit of Na,K-ATPase [61]. We propose, therefore, that the receptor-specific signaling platform is assembled in caveolae, then separates and internalizes as a signalosome. The signalosome migrates via the cytoskeleton to mitochondria, where it binds to receptors on the MOM, designated in Fig. 2 as R1 (for GPCR-induced signalosomes) and R2 (for ouabain-induced signalosomes). The terminal kinase of the signalosome

phosphorylates its specific receptor, which causes the signal to be transmitted across the MOM and intermembrane space to PKCɛ1 on the mitochondrial inner membrane. This is followed by the intramitochondrial signaling pathway described in Section 4 and Fig. 4.

3.3 Experimental evidence for signalosome-mediated mitoKATP opening

We developed protocols for purifying signalosomes from hearts subjected to various preconditioning or postconditioning protocols and then assayed their functional activity [39]. When the signalosome fractions were added to mitochondria from untreated hearts, they caused mito K_{ATP} opening, as shown in Fig. 3. Based on the finding that functionally active signalosomes were obtained from hearts exposed to bradykinin, ouabain, ischemic preconditioning, and ischemic postconditioning (Fig. 3), we conclude that this is a general mechanism of signal transmission. Signalosome preparations also inhibited MPT when added to mitochondria from untreated hearts. The signalosomes were dissolved by the cholesterol binding agent methyl- β -cyclodextrin and were resistant to Triton X-100. These properties support their origin in caveolae. Electron microscopy reveals that the signalosomes are 100–140 nm in diameter and can be decorated with immunogold labeled caveolin 3 antibodies [39]. The signalosome induced by bradykinin stimulation contains eNOS, guanylyl cyclase, and cGMP-dependent protein kinase (PKG), and we were able to demonstrate the participation of each of these enzymes in the mito K_{ATP} assay when proper substrates were supplied (Quinlan and Garlid, unpublished).

3.4 Signalosomes phosphorylate MOM receptors

As shown in Fig. 3, addition of signalosomes from preconditioned hearts to mitochondria from non- preconditioned hearts results in activation of the mitoK_{ATP}. Activity of signalosomes induced by GPCR-mediated protection (bradykinin, IPC, and postconditioning) is inhibited by KT5823, and we conclude that GPCR signalosomes use PKG as the terminal kinase that interacts with mitochondria. In contrast, the activity of signalosomes induced by ouabain is not inhibited by KT5823, in agreement with the finding that KT5823 does not block protection by ouabain [36]. Activity of the ouabain signalosome is inhibited by preincubation with εV_{1-2} and PP2 (both are required), indicating that the terminal kinases are PKC ε and Src kinase. We have found that recombinant PKG [32,62] or recombinant PKC ε plus Src (Quinlan and Garlid, unpublished) can also induce mitoK_{ATP} opening in isolated mitochondria.

That the signalosomes interact with the MOM was demonstrated by the finding that neither the signalosomes nor the recombinant terminal kinases induce $mitoK_{ATP}$ opening in mitoplasts lacking the MOM [32,39]. That signalosomes interact by phosphorylation was demonstrated by the finding that activity was blocked in the presense of the Ser/Thr phosphatase PP2A (Fig. 3). The ouabain signalosome was also blocked by tyrosine phosphatase, confirming the action of its Src kinase.

We have not yet determined the molecular identity of R1. R2 is an endogenous MOM MAP kinase, as revealed by Western blot showing increased phosphorylation of p38 MAPK (Thr 180/Tyr 182) after the heart was treated with ouabain and functional studies showing that the MAP kinase inhibitor SB203580 blocked mito K_{ATP} opening by the ouabain signalosome (Quinlan and Garlid, unpublished studies).

3.5 Signal transmission from MOM to PKC_E1

Signalosome-dependent mitoK_{ATP} opening is also blocked by the PKC ϵ inhibitors chererythrine and ϵV_{1-2} [62], confirming a role for PKC ϵ ("PKC ϵ 1" in Fig. 2), which is discussed in the next section. Signaling from R1 or R2 to PKC ϵ 1 is not prevented by MPG, and therefore this step does not involve ROS. This is all we know at this stage about the nature of the link between the MOM receptors and PKC ϵ 1.

The diagram in Fig. 4 summarizes several years of studies on intramitochondrial signaling [12,32,39,62–66]. The primary function of this pathway is to inhibit MPT opening, which is widely considered to be the cause of cell death after ischemiareperfusion [5,6,11].

4.1 Step one - opening mitoK_{ATP} by activation of PKCε1

Ischemic preconditioning, ischemic postconditioning, and pharmacological preconditioning by plasma membrane receptor agonists cause mitoK_{ATP} opening by activating a PKCɛ that is constitutively expressed in mitochondria and associated with the mitochondrial inner membrane [64]. The PKCɛ-specific peptide agonist ΨɛRACK and the PKCɛ agonists H₂O₂, NO, and phorbol 12-myristate 13-acetate (PMA) each open mitoK_{ATP} (see Fig. 5) [32]. That these agents were acting via PKCɛ ("PKCɛ1" in Fig. 4) was verified by showing that the PKCɛ-specific binding antagonist εV₁₋₂ blocked all four modes of PKCɛ activation of mitoK_{ATP} but did not block mitoK_{ATP} opening by diazoxide [32,64]. Neither the PKCɛspecific peptide antagonist, δV_{1-1} nor a scrambled analog of εV₁₋₂ had any effect on H₂O₂dependent mitoK_{ATP} opening. Moreover, the PKC inhibitor Gö6983, which inhibits PKCα, PKCβ, PKCγ, and PKCζ, did not block PKCɛ-dependent mitoK_{ATP} opening, excluding a role for these isoforms [62].

Jaburek, et al. [64] showed that $\Psi \in RACK$ and ϵV_{1-2} open mito K_{ATP} in liposomes reconstituted with partially purified mito K_{ATP} . Thus, mito K_{ATP} and PKC ϵ copurify and remain associated during multiple purification steps carried out in the presence of Triton X-100. This, together with the finding that PKC ϵ remains associated with mitochondria in mitoplasts [12], suggests that PKC ϵ and mito K_{ATP} are part of a functional complex. When given access in mitoplasts to the mitochondrial inner membrane ("MIM"), PP2A prevented mito K_{ATP} -dependent swelling induced by PKC ϵ agonists [32], and we conclude that PKC ϵ -dependent mito K_{ATP} opening requires phosphorylation, perhaps of mito K_{ATP} itself.

PKC ε requires anionic phospholipids for activity, a requirement met in this case by cardiolipin, which is abundant in mitochondria. PKC ε is activated physiologically by diacylglycerol (or phorbol ester) or by a sulfydryl oxidizing agent, such as H₂O₂ [67] or NO [32]. PMA or H₂O₂ open up one of the two zinc fingers in PKC ε [68,69]. Ψ ε RACK, PMA, H₂O₂, or NO cause conformational changes that expose the substrate domain on PKC ε and cause its binding to its RACK (receptor for activated C kinase [70]). Ψ ε RACK is a PKC ε -specific peptide agonist that acts by regulating intramolecular PKC ε binding, and ε V₁₋₂ is a PKC ε -specific peptide antagonist that acts by preventing protein-protein interactions between PKC ε and its binding protein [70–72]. Murriel and Mochly-Rosen [73] found that Ψ ε RACK protected cardiac cells from ischemic damage, whereas ε V₁₋₂ caused a loss of protection.

4.2 Step two - mitochondrial K⁺ uptake and its consequences

Once mito K_{ATP} is opened, the increase in K⁺ uptake leads to several changes in the matrix. Electrophoretic K⁺ influx is balanced by electrogenic H⁺ efflux driven by the respiratory chain. Uncompensated, this would cause an increase of matrix pH of about 2 pH units. Partial compensation is provided by electroneutral uptake of substrate anions, such as phosphate. The compensation is partial because the concentration of phosphate in the cytosol is much lower than that of K⁺, and this imbalance leads to matrix alkalinization [65,66,74].

Matrix alkalinization now releases the K^+/H^+ antiporter from inhibition by matrix protons [75], causing K^+ efflux to increase in response to increased K^+ uptake until a new K^+ steady state is achieved. The uncoupling caused by increased futile cycling of K^+ induces is about 3% of the maximum activity of the electron transport chain. This low level of uncoupling reflects

the low activity of mitoK_{ATP}, a property that is essential for mitochondrial survival. Thus, if we add sufficient valinomycin to double the mitoK_{ATP}-mediated K⁺ influx, the MOM ruptures with loss of cytochrome c[65].

Uptake of K⁺ salts and osmotically obligated water leads to increased matrix volume (" Δ V" in Fig. 4), which is the basis of the light scattering (LS) assay for mitoK_{ATP} activity [65]. LS is the only practical method to study this process in isolated mitochondria, because mitoK_{ATP}-dependent K⁺ flux is rapid (t_{1/2} ~ 30 s) and small in magnitude. This technique has been successfully employed by several laboratories to measure K⁺ flux in mitochondria [76–80].

MitoK_{ATP}-dependent matrix alkalinization plays an essential role in intramitochondrial signaling. It causes Complex I to produce increased amounts of superoxide and its products, H_2O_2 and hydroxyl anion radical [66]. As seen below, the ROS produced by this mechanism play two important roles in cardioprotection, through their ability to activate PKC ϵ .

We note that each of the consequences of $mitoK_{ATP}$ opening are due specifically to the increased K⁺ influx. Thus, valinomycin (approximately 1 pmol/mg mitochondria) duplicates the effects of KCO on K⁺ uptake, respiration, matrix alkalinization, volume increase, and ROS production [65,66].

4.3 Step three - activation of PKCε by endogenous ROS

4.3.1 ROS activation of PKCɛ2 and inhibition of MPT—The increased ROS activates a second mitochondrial PKCɛ, "PKCɛ2" in Fig. 4, which inhibits the mitochondrial permeability transition ("MPT") in a phosphorylation-dependent reaction [12]. H₂O₂ and NO, but not superoxide, also activate PKCɛ2 and inhibit MPT [12,32]. The dichotomy between protective and damaging ROS was strikingly demonstrated in an experiment in which 100 μ M H₂O₂ plus 2 μ M free Ca²⁺ were used to induce MPT opening in heart mitochondria. This ROS-induced MPT opening was inhibited when the mitochondria were first conditioned with 2 μ M H₂O₂ [12]. Thus, cardioprotective mitoK_{ATP} opening leads to inhibition of MPT, and, therefore, to reduction of cell death after ischemia-reperfusion injury [5,6,11].

The evidence for two distinct mitochondrial PKC ϵ is that the specific agonist $\Psi\epsilon$ RACK can activate PKC ϵ 1 and open mitoK_{ATP}, but it cannot activate the PKC ϵ that regulates MPT [12]. This establishes a clear difference between the two PKC ϵ s. Our tentative explanation for the observation is that PKC ϵ 2 faces the matrix side of the inner membrane. $\Psi\epsilon$ RACK is an anionic peptide that cannot enter the matrix, whereas ϵ V₁₋₂, which inhibits both PKC ϵ 1 and PKC ϵ 2, can readily enter the matrix.

4.3.2 ROS activation of PKCɛ1 and feedback mitoK_{ATP} **opening**—The mitoK_{ATP}-dependent increase in ROS plays an additional role in cardioprotection. Note in Fig. 4 that PKCɛ1 is bypassed when KCOs are administered to the heart; however, we have found that PKCɛ1 is soon activated by mitoK_{ATP}-dependent ROS, leading to a persistent phosphorylation-dependent open state of mitoK_{ATP} [32]. These data define a new, positive feedback loop for mitoK_{ATP} opening, whose existence, which has been suggested by a number of authors [81–83], means that mitoK_{ATP} may be either upstream or downstream of PKCɛ, depending on the triggering stimulus. We suggest that feedback phosphorylation of mitoK_{ATP} is the mechanism of memory, which is seen with all PC triggers [84,85]. Thus, cardioprotective stimuli can be washed away from the system and the perfused heart remains protected from a major ischemic assault, thanks to phosphorylation of mitoK_{ATP}. We infer, but have not demonstrated, that mitoK_{ATP} opening is eventually reversed by an endogenous phosphatase ("PP2A" in Fig. 4) within the intermembrane space. For example, PP2A has been found in mitochondria where it is activated by proapoptotic factors [86].

4.4 Intramitochondrial signaling and the literature

The model in Fig. 4 helps to support and extend results of previous studies. Jiang et al [87] observed PKC and 5-HD regulation of the human cardiac mitoKATP in lipid bilayers. Garg and Hu [88] showed that PKC^c modulates mitoK_{ATP} activity in cardiomyocytes and COS-7 cells. Penna et al [89] demonstrated that protection by postconditioning protection involves a redox mechanism and persistent activation of mitoKATP and PKC. Facundo et al. [80] showed that H2O2 induces mitoKATP activity in isolated mitochondria, but did not identify participation of PKCE. Zhang et al. [90] found that superoxide anion activated mitoKATP in planar bilayers, and we showed that this effect is mediated, not by superoxide, but by H_2O_2 acting indirectly via PKCe1 [32]. Sasaki, et al. [91] suggested that NO may open mitoK_{ATP} directly; however mitoK_{ATP} opening by NO is blocked by εV_{1-2} [32], showing that NO opens mitoK_{ATP} indirectly through PKCE1. Several authors have shown that exogenous and endogenous NO are cardioprotective and have attributed this effect to MPT inhibition [92-95]. Brookes, et al. [92] showed that NO inhibited MPT and cytochrome c release in isolated liver mitochondria. We showed that this effect occurs via activation of PKCc2 [32]. Korge, et al. [96] found that diazoxide prevented MPT opening and cytochrome c loss, and that both effects were mimicked by the PKC activator PMA and blocked by 5-HD. Kim, et al. [97] found that a cytosolic extract, together with cGMP and ATP, blocked MPT in isolated mitochondria, an effect that was blocked by PKG inhibition. Forbes, et al [98] and Pain, et al [85] found that N-acetylcysteine or MPG reversed the protective effect of diazoxide in perfused hearts. Our data suggests that blockade of protection occurred because mitoKATP-dependent ROS was scavenged and unavailable to activate PKCc2 and inhibit MPT. Lebuffe, e al [81] found that PMA-induced protection was blocked by 5-HD and that this block was reversed by coadministration of H_2O_2 and NO. This is also consistent with the model of Fig. 4 in that H_2O_2 and NO can bypass the blocked mito K_{ATP} and act directly on PKC ε 2, thereby inhibiting MPT and protecting the heart.

5. Other mitochondrial mechanisms of cardioprotection

5.1 K_{ATP} channel openers (KCO)

KCOs have been shown to be cardioprotective in all species examined [99,100]. The ability of KCOs to open mito K_{ATP} in their therapeutic dose range was described in 1996 [101]. Diazoxide was 1000 times more potent in opening mito K_{ATP} than in opening sarc K_{ATP} , making diazoxide a valuable tool to determine whether cardioprotection was mediated by the sarcolemmal or the mitochondrial K_{ATP} channel. It was found that diazoxide was as effective as cromakalim in protecting the heart. Moreover, diazoxide protection, unlike that mediated by cromakalim, was not accompanied by APD shortening, thus demonstrating that cardioprotection was not due to sarc K_{ATP} opening. These findings led to the hypothesis that mito K_{ATP} is the receptor that mediates the cardioprotective effects of KCOs [101,102]. KCOs act on the regulatory sulfonylurea receptors (SUR) of K_{ATP} channels. Pinacidil, cromakalim, and nicorandil are effective openers of cardiac K_{ATP} through their action on SUR2A, but ineffective on pancreatic beta cell K_{ATP} , which uses SUR1. Conversely, diazoxide is an effective open mito K_{ATP} and protect the heart [65,101,102,104–108].

5.2 glycogen synthase kinase -3β (GSK-3β)

The GSK-3 β inhibitors lithium and SB 216763 are cardioprotective. IPC and diazoxide cause phosphorylation and inactivation of GSK-3 β [83,109], suggesting that GSK-3 β may be downstream of mitoK_{ATP}. Inhibition of GSK-3 β has no effect on MPT opening in isolated mitochondria [32], suggesting that the GSK isoform that interferes with cardioprotection resides outside of mitochondria. Importantly, cardioprotection by GSK-3 β inhibition is blocked

by 5-HD [110], indicating that the ultimate deleterious effect of GSK-3 β activity may be to cause mitoK_{ATP} inhibition.

5.3 Amobarbital

Amobarbital, administered 1 min before 25 min global ischemia, is cardioprotective in rat, causing marked improvement of contractile function and reduction of infarct size [111]. Amobarbital is a short-acting barbiturate that is a classic, reversible inhibitor of Complex I at the rotenone site. Amobarbital treatment was associated with preservation of cytochrome *c* [111], which is otherwise released after ischemia-reperfusion, due in part to oxidative degradation of cardiolipin [112]. Cardioprotection by amobarbital is consistent with the authors' overall hypothesis that ROS arising from Complex III during ischemia causes mitochondrial damage that contributes to myocardial injury during reperfusion [113].

5.4 Bromoenol lactone (BEL)

BEL, administered before global ischemia, is cardioprotective in rat [114] and rabbit [115], causing marked reduction of infarct size. BEL is a specific inhibitor of calcium-independent phospholipase A(2) (iPLA2), which is the major phospholipase A(2) in myocardium and is present in heart mitochondria [115]. Ischemia causes fatty acid accumulation in the heart, caused by phospholipases-mediated degradation of membrane phospholipids [112,116,117]. Protection by BEL was reversed, in both rat and rabbit hearts, by the simultaneous perfusion of 5-HD, implying participation of mitoK_{ATP}.

5.5 Hydrogen sulfide

 H_2S , administered before global ischemia, is cardioprotective in rat [118–120]. H_2S is synthesized in the heart and other tissues by cystathionine λ -lyase. Cytoplasmic [H_2S] is determined by the balance between its constitutive production and its oxidation by mitochondria. When tissue oxygen levels fall, H_2S oxidation decreases, and [H_2S] increases, and Olson, et al. [121] consider H_2S to be the oxygen sensor of cells. Protection by H_2S was abolished by chelerythrine, implicating participation of PKC [119]. Infarct size reduction by H_2S was also abolished by glibenclamide and 5-HD, implicating participation of mitoK_{ATP} in H_2S protection [120]. H_2S increased the open probability of sarcolemmal K_{ATP} in cardiomyocytes [122] and may have a similar effect on mitoK_{ATP}.

5.6 Mitochondrial aldehyde dehydrogenase (ALDH2)

An activator of ALDH2, administered before global ischemia, is cardioprotective in rat, causing marked reduction of infarct size [123]. This recent discovery was the result of a directed proteomic search. The authors speculate that protection by ALDH2 activation is due to its metabolism of cytotoxic aldehydes, such as 4-hydroxynonenol.

5.7 Ca²⁺-activated mitochondrial K⁺ channel (mitoK_{Ca})

NS1619, an activator of the large conductance mitoK_{Ca} is cardioprotective in guinea pig, and protection is blocked by the inhibitor paxilline [124–126]. Sato, et al [127] found that there was no cross-talk between mitoK_{ATP} and mitoK_{Ca} — that is, paxilline blocked effects of NS1619 but not diazoxide, and 5-HD blocked effects of diazoxide but not NS1619. Cao et al. [125] observed similar absence of cross-talk in cardioprotection experiments. The latter findings suggest distinct channels with distinct pharmacology and suggest that these two channels constitute alternative mechanisms for raising matrix K⁺ and generating ROS.

6. Summary

Recent years have brought robust advances in our understanding of cardiac signal transduction during cardioprotection against ischemia-reperfusion and the pivotal role of mitochondria in these processes. This review exposes our current understanding of the mechanistic link between plasma membrane receptors and MPT, the ultimate mitochondrial target of cardioprotection. We suggest that interaction of the cardioprotective ligand with its receptor induces the formation of a signaling platform that is scaffolded by caveolins, that contains the activated enzymes of the pathway, and that is delivered to mitochondria as a signalosome. We believe that the signalosome mechanism [39] provides a means to resolve the mystery of receptor-specificity described by Downey, et al. [14]: "*It is still a mystery how identical Gi proteins, when activated by binding of the different agonists to their individual receptors, can initiate such distinct signaling pathways.*"

This review also points to several areas that require further investigation as to how signalosomes are directed to mitochondria, how cytoskeleton is involved, and what receptors are involved at the mitochondrial level. Even in light of these questions, the elucidation of the interactions among signaling components and mitochondria is a valuable tool for understanding the molecular controls in the decision between cell survival and cell death.

Figure 1. GPCR-mediated signaling to mitochondria

Occupation of the GPCR leads to activation of PI3-kinase, phosphorylation of phosphatidylinositol bisphosphate, and activation of the phosphatidylinositol-dependent kinases (PDKs) [128]. PDKs then phosphorylate Akt, which initiates the remainder of the cytosolic signaling pathway: endothelial nitric oxide synthase (eNOS) is phosphorylated, leading to production of NO. NO stimulates guanylyl cyclase, and the cGMP produced activates protein kinase G (PKG) [129], which causes mitoK_{ATP} opening [62,130–132].

Figure 2. Signal transmission by signalosome

It is proposed that interaction of bradykinin (and other GPCR agonists) or ouabain with their plasma membrane receptors induces formation of a vesicular caveolar signaling platform (signalosome) that phosphorylates receptor (R1 and R2) on the mitochondrial outer membrane (MOM). The terminal kinase of the bradykinin signalosome is PKG. The terminal kinases of the ouabain signalosome are PKC ϵ and Src kinase. Following phosphorylation of the MOM receptor, the signal is transmitted across the intermembrane space to activate PKC ϵ on the mitochondrial inner membrane. PKC ϵ , in turn opens mitoK_{ATP} by a phosphorylation reaction [32].

Garlid et al.

Figure 3. Signalosomes from treated hearts induce mito K_{\rm ATP} opening in mitochondria from untreated hearts

Shown are changes in "MitoK_{ATP} activity (%)" when signalosome fractions from rat hearts treated with bradykinin, ouabain, ischemic preconditioning, or ischemic postconditioning were added to assay mitochondria from untreated rat hearts. Ischemic preconditioning consisted of two 5 min ischemia-reperfusion cycles, and ischemic postconditioning consisted of six 10 s cycles of ischemia-reperfusion. Also shown are the effects of PP2A (11 ng/mL) and KT5823 ("KT", 0.5 μ M) added to the assay. Note that PP2A cannot cross the MOM of intact mitochondria, so its effect is on the MOM. Data are averages ± SD of 3 to 4 independent experiments. The figure is from Quinlan, et al. [39].

Garlid et al.

Figure 4. The intramitochondrial signaling pathways

The pathways leading to mitoK_{ATP} opening, ROS production, and MPT inhibition are shown. Signals arising from Gi-coupled receptors are delivered to mitochondria via the terminal kinase PKG. Signals arising from ouabain action upon the Na-K ATPase are delivered to mitochondria via two terminal kinases, PKCɛ and Src. The terminal kinases are localized in the signalosomes. PKG phosphorylates an unknown MOM receptor, "R1", whereas PKCɛ and Src act in conjunction to activate a distinct MOM receptor, "R2". These MOM receptors transmit the signal by an unknown mechanism to PKCɛ1 located at the inner membrane. The activated PKCɛ1 phosphorylates and opens mitoK_{ATP}. PKCɛ1 activity is likely to be counteracted physiologically by Ser/Thr protein phosphatases (PPase) such as PP2A. MitoK_{ATP} opening via PKCɛ1 or by K_{ATP} channel openers such as diazoxide causes K⁺uptake, increased matrix pH, and increased H₂O₂ production from Complex1. H₂O₂ produced by mitoK_{ATP} activity now diffuses and activates both PKCɛ1 and PKCɛ2. PKCɛ2 inhibits MPT, thus reducing cell necrosis and infarct size. The figure is from Costa and Garlid [32].

Figure 5. PKC ϵ -mediated mitoK_{ATP} opening

Changes in mitochondrial matrix volume (V) are plotted versus time. Rat heart mitochondria (0.1 mg/ml) were suspended in standard assay medium [32]. H_2O_2 (2 μ M) or Ψ cRACK (0.5 μ M) were added to medium in the presence of ATP (0.2 mM) approximately one second after the mitochondria. Other additions to the assay medium were 5-HD (0.3 mM) and ϵ V₁₋₂ (0.5 μ M). Traces are representative of at least 5 independent experiments. The figure is from Costa and Garlid [32].
