Abstract: The first in class proteasome inhibitor bortezomib (B) received its initial regulatory approval for therapy of patients with multiple myeloma (MM) in the relapsed/refractory setting. Modulation of proteasome function, however, is also a rational strategy for chemosensitization, and a variety of agents have shown synergistic activity with bortezomib pre-clinically, including anthracyclines. This formed the basis for evaluation of a regimen of bortezomib with pegylated liposomal doxorubicin (PLD). PLD+B, in a phase I study, induced a predictable and manageable toxicity profile, and showed encouraging anti-MM activity. In a recent international, randomized phase III trial, PLD+B demonstrated a superior overall response rate and response quality compared to bortezomib alone, as well as a longer time to progression, duration of response, progression-free survival, and overall survival. Sub-analyses revealed benefits in almost all clinically relevant subgroups, including several which would be considered to have high-risk disease. These findings have led to the establishment of the PLD+B regimen as one of the standards of care for patients with relapsed and/or refractory myeloma. Efforts are now underway to build on this combination further by adding other active anti-myeloma agents. In this review, we will discuss the role of PLD+B as an important addition to our therapeutic armamentarium for patients with MM.

Keywords: multiple myeloma, relapsed/refractory, pegylated liposomal doxorubicin, bortezomib, Doxil[®], Velcade[®]

Introduction to management strategies incorporating bortezomib and anthracyclines in multiple myeloma

In May 2003, bortezomib (B) (Velcade[®]; Millenium Pharmaceuticals), a first in class proteasome inhibitor, received accelerated approval by the Food and Drug Administration (FDA) for use in patients with multiple myeloma (MM) who had received at least 2 prior lines of therapy, and had progressive disease on the most recent therapy.¹ In March 2005, this approval was amended to allow the use of bortezomib for patients with MM after 1 or more prior lines of therapy.² In the relapsed or primary refractory setting, single-agent bortezomib has provided response rates of 27% to 43%, with median times to progression of 6.2 to 7.0 months.^{3–5} To improve these outcomes, combinations of bortezomib with other agents active in MM have been explored. Among these drug classes are anthracyclines, whose efficacy in treating myeloma was established with the combination of vincristine-doxorubicin-dexamethasone in the 1980s.^{6–11} Pre-clinical studies combining bortezomib and doxorubicin have demonstrated the ability of each drug to reduce chemoresistance to the other, and indeed these drugs have shown synergy in combination.

Unfortunately, the administration of continuous infusion doxorubicin is complicated by the requirement for central line placement which increases the risks of infections and thrombosis, while doxorubicin itself is associated with the risks of neutropenia and cardiotoxicity. In an effort to maintain the efficacy of doxorubicin, while improving its tolerability, a pegylated, liposomal form of doxorubicin (PLD, Doxil®; Johnson and Johnson) was developed. With a half-life of approximately 79 hours, a single 60- to 90-minute administration of pegylated liposomal doxorubicin is comparable in efficacy to continuous infusion doxorubicin, but has a lower incidence of neutropenia, alopecia and cardiac toxicity.^{12,13}

The pre-clinical synergy observed between proteasome inhibitors and anthracyclines led to the development of clinical trials investigating the use of these drug classes in combination. In this review, we discuss treatment strategies using bortezomib together with PLD in patients with relapsed and refractory MM.

Mechanism of action

Doxorubicin

Doxorubicin, an anti-tumor anthracycline antibiotic produced by the soil fungus *Streptomyces peucetius*, has been used in a number of malignancies including MM. Its cytotoxicity is thought to result in large part from inhibition of the DNA repair enzyme, topoisomerase II.^{14,15} It also intercalates into double-stranded DNA, producing structural changes that interfere with DNA and RNA synthesis.^{16–18} Doxorubicin and other anthracyclines also chelate iron, thereby generating reactive oxygen species, such as oxygen free radicals, hydroxyl radicals, and hydrogen peroxide, that cleave DNA, messenger mRNA, proteins, and lipids. The formation of oxygen free radicals and the peroxidation of lipids also contribute to the cardiac toxicity that is characteristic of non-liposomal anthracyclines.^{19,20}

Bortezomib

Bortezomib is a dipeptide boronic acid analog which targets the ubiquitin-proteasome pathway (UPP) by inhibiting the function of the 26S proteasome complex. Inhibition of the UPP blocks protein and transcription factor degradation, leading to accumulation of misfolded/damaged proteins, and inducing heat shock stress responses within the cell.^{21,22} Bortezomib mediates its cytotoxic effects via alterations in multiple pathways including inhibition of nuclear factor kappa-B (NF-κB) signaling. In the quiescent cell, NF-κB is bound to the inhibitory protein IκB, rendering it inactive. However, with phosphorylation, ubiquitination, and

degradation of IκB by the ubiquitin-proteasome pathway, NF-κB is released from the bound state and translocates from the cytoplasm to the nucleus. Activated NF-κB initiates an immune/inflammatory response via increased gene transcription of multiple cytokines, and also contributes to cellular resistance to apoptosis and chemotherapy resistance. Bortezomib inhibits IκB degradation, thereby suppressing NF-κB activity and contributing to apoptosis.^{21,23–26} Bortezomib's anti-tumor activity is also mediated by a number of pro-apoptotic pathways including accumulation of p53, p21 and p27, activation of c-Jun N-terminal kinase (JNK), inhibition of the interleukin (IL)-6-induced Ras/Raf/mitogen-activated protein kinase (MAPK) pathway, and interference with the anti-apoptotic effects of Bcl-2.^{26–32} Additionally, preclinical studies with bortezomib have demonstrated a reduction in levels of cytokines (IL-6), angiogenesis factors (vascular endothelial growth factor), and growth factors (insulin-like growth factor-1), which among other effects inhibits adhesion of myeloma cells to bone marrow stromal cells.^{23,25,26,28}

Rationale for combination

One of the mechanisms of doxorubicin resistance is via up-regulation of NF-κB expression.^{31,32} As bortezomib suppresses the activity of NF-κB, chemo-resistance to PLD induced by this mechanism would be abrogated by using these drugs in combination.²⁹ Bortezomib may also sensitize myeloma cells to DNA damage by down-regulating the transcription of DNA repair enzymes, as demonstrated in in vitro studies as well as by gene expression profiling.³⁰ P-glycoprotein, encoded in the multi-drug resistance gene 1 (MDR1), functions as a cell membrane transporter responsible for the efflux of toxins including multiple chemotherapy agents.^{6,27} Preliminary data suggest proteasome inhibition decreases expression of P-glycoprotein, and subsequently bypasses a well-defined mechanism of multi-drug resistance.³³ Cell adhesion mediated drug resistance (CAM-DR) also contributes to the development of resistance to conventional chemotherapeutics, and in addition to suppression of NF-κB activity, bortezomib may overcome CAM-DR.³⁰

Anthracyclines, in turn, may also overcome bortezomib resistance by inhibiting the mitogen-activated protein kinase phosphatase (MPK-1) pathway. One of several mechanisms of proteasome inhibitor-induced apoptosis is via activation of JNK. However, bortezomib induces MPK-1, which can dephosphorylate and inactivate JNK. Anthracyclines have been shown to inhibit MPK-1 activity, potentially contributing to the synergy of doxorubicin and bortezomib.³⁴ Combination studies of bortezomib and anthracyclines in in vitro

and in vivo models have demonstrated improved inhibition of MPK-1, increased activation of JNK, and increased apoptosis. These preclinical observations led investigators to develop clinical trials evaluating the combination of bortezomib and PLD.³⁰

Pharmacology/pharmacokinetics

In a phase I study of PLD+bortezomib (PLD+B), the pharmacodynamics of bortezomib were evaluated using an ex vivo assay of 20S-proteasome inhibition by measuring the chymotryptic proteasome protease activity.³⁵ Proteasome inhibition on Days 1 and 4 prior to PLD administration was 63.7%, and with the addition of PLD on days 8 and 11, mean proteasome inhibition increased to 67.4%. As might be expected, proteasome inhibition was lowest at the starting bortezomib dose of 0.9 mg/m², with no difference noted between the 1.05 and 1.50 mg/m² dose levels.

The $t_{1/2}$ of PLD was 80 hours and remained constant across escalating bortezomib dose cohorts; suggesting no significant alteration in the pharmacokinetic and pharmacodynamic profile of bortezomib and PLD when combining the two agents.³⁵

Efficacy studies

The combination of bortezomib and pegylated liposomal doxorubicin was first evaluated clinically in a phase I study led by Orłowski et al with 42 patients having any confirmed hematologic malignancy. Notably, the majority ($n = 24$) had MM.³⁵ Dose reductions and treatment delays were frequent at the 1.5 and 1.6 mg/m² dose levels of bortezomib, and therefore 1.3 mg/m² of bortezomib on days 1, 4, 8, and 11 in combination with 30 mg/m² of PLD on day 4 of a 21-day cycle was established as the optimal dosing regimen. Among 22 evaluable patients with MM, 36% achieved either complete remission (CR) or near CR, and another 36% achieved partial remission (PR). Prior to study enrollment, 13 patients had received anthracyclines to which their disease had either not responded, or initially responded but then derived no further benefit; among them, 38% achieved CR or near CR, and another 23% achieved PR. With extended follow-up, the median time to disease progression (TTP) among the 22 evaluable patients was 9.3 months, with a median time to re-treatment (TTRT) of 24.2 months, and median overall survival of 38.3 months. Both the median TTP and median TTRT compared favorably to outcomes seen on the patients' prior therapy.^{35,36} This experience led to a prospective, international, randomized, controlled phase III trial led by Orłowski et al comparing single-agent bortezomib with the

combination of PLD+B in patients with relapsed or primary refractory MM.³⁷ The results of this trial led the FDA to approve combination therapy with PLD+B in May 2007, for the treatment of bortezomib-naïve patients who had progressed after at least 1 prior line of therapy.³⁸ In this study, 646 patients, who had progressed after ≥ 1 line of therapy and were bortezomib-naïve, were enrolled and stratified according to β_2 -microglobulin and response to prior therapy (relapsed vs refractory). Patients on both arms were treated with 1.3 mg/m² of bortezomib on days 1, 4, 8 and 11 on a 21 day cycle, while patients on the combination arm also received 30 mg/m² of PLD on day 4 of each cycle. Patients were treated for up to 8 cycles or until complete response, disease progression, or unacceptable toxicity developed, though patients tolerating therapy were allowed to continue beyond 8 cycles if they showed continued disease response. The primary endpoint was TTP on an intent-to-treat population, while secondary endpoints were overall survival (OS), overall response rate (complete response + partial response) as defined by the European Blood and Marrow Transplant Group criteria, and safety profile.³⁹

Among patients treated with the combination of PLD+B, TTP was higher at 9.3 months, compared with 6.5 months among patients treated with bortezomib alone ($p = 0.000004$). Progression-free survival (PFS) was also longer in those treated on the combination arm than in those treated with bortezomib monotherapy (9.0 vs 6.5 months, $p = 0.000026$). An increase in the duration of response (DOR) from 7.0 to 10.2 months with combination therapy paralleled the improvements seen in TTP and PFS. Early follow-up of survival data also suggested an improvement in 15-month OS among those treated with PLD+B compared with those treated with bortezomib alone (76% vs 65%, $p = 0.03$). By intent-to-treat analysis, the overall response rate (ORR) was similar between monotherapy (41%) and combination therapy arms (44%) ($p = 0.43$); however, rates of CR + very good partial response (VGPR) were higher (19% vs 27%) with combination therapy ($p = 0.0157$). When only response-evaluable patients were included in the analysis, the overall response rate for bortezomib alone ($n = 310$) was 44% and that for PLD+B ($n = 303$) was 52% ($p = 0.05$).³⁷

Braccalenti et al have taken an alternative approach to evaluating the effect of adding PLD to the anti-tumor activity of B. In an ongoing study, 40 mg/m² of PLD given once every 21 days is added to bortezomib 1.3 mg/m² (on days 1, 4, 8, 11 for the first 8 cycles, and then on days 1, 8, 15, and 22) after either 8 cycles (cohort 1) or 3 cycles (cohort 2) of therapy. Among 5 patients enrolled in cohort 1, 4 had

objective responses with bortezomib and 1 had disease stabilization; the addition of PLD did not improve the quality of the responses achieved with bortezomib alone. In cohort 2, 9 of 17 evaluable patients had objective responses (52.9%) after 3 cycles of bortezomib monotherapy. Of these, 7 patients had conversion of their remission from either PR (4 patients) or near CR (3 patients) to CR. Though we await further follow-up of this study, its preliminary results provide further evidence that adding PLD to bortezomib enhances activity of the latter in certain patients.⁴⁰

Sub-group analyses from randomized phase III trial

A number of formal subgroup analyses were performed to compare the efficacy of PLD+B with bortezomib alone among elderly patients, those with high-risk disease, those having prior autologous stem cell transplant (ASCT) and early relapse after ASCT, those with previous anthracycline and thalidomide exposure, and those having one or multiple prior lines of therapy (Table 1). As described below, these subgroups all benefited from combination therapy. Subgroups that did not benefit from combination therapy were those with low β_2 -microglobulin and those with chromosome 13 deletion.

In a pre-specified subgroup analysis of 250 patients ≥ 65 years of age, the addition of PLD improved TTP from 205

days to 276 days ($p = 0.0056$, HR = 1.82, 1.18–2.79) and also improved DOR from 227 days to 311 days. ORR was also increased from 39% to 49% by combination therapy. The benefit of adding PLD in this older patient population was comparable to that seen in younger patients.⁴¹

A second pre-specified subgroup analysis evaluated the effect of adding PLD to bortezomib in patients with high-risk disease, where high-risk disease was defined as having either an elevated β_2 -microglobulin (≥ 5.5 mg/L) or primary refractory disease. TTP was significantly increased in the combination therapy arm, both among patients having an elevated β_2 -microglobulin (178 vs 276 days; $p = 0.0007$), as well as among those having primary refractory disease (189 days vs median not reached, $p = 0.0322$). Patients with an elevated β_2 -microglobulin also showed improvement in ORR (33% vs 49%), and DOR (211 vs 310 days).⁴²

The third pre-specified subgroup analysis compared patients with and without a history of prior ASCT. In patients without a prior history of ASCT, TTP increased from 197 to 331 days ($p = 0.0009$) with the addition of PLD, ORR improved from 39% to 45%, and DOR increased from 204 days to 394 days. Similar benefits in TTP (197 vs 276 days, $p = 0.0011$) and DOR (227 days vs 309 days) were also observed in patients who had had a prior ASCT.⁴³

Table 1 Subgroup analyses from phase III trial of bortezomib vs pegylated liposomal doxorubicin + bortezomib (PLD+B)

Subgroup	ORR (%)		TTP (days)		p value
	B	PLD+B	B	PLD+B	
Age ≥ 65 yrs	39	49	205	276	0.0056
β_2 -microglobulin ≥ 5.5 mg/L	33	49	178	276	0.0007
Primary refractory disease	48	43	189	MNR	0.0322
No prior ASCT	39	45	197	331	0.0009
Prior ASCT	46	50	197	276	0.0011
≥ 2 prior lines of therapy		N/A	186	276	<0.0001
1 prior line of therapy		N/A	199	330	0.036
Anthracycline naïve		N/A	197	282	0.015
Anthracycline exposed		N/A	197	295	0.0001
ISS stage 3		N/A	177	276	<0.0007
ISS stage 2		N/A	186	250	<0.004
ISS stage 1		N/A	223	331	0.067
TSD > 2 years		N/A	197	295	<0.0001
TSD ≤ 2 years		N/A	197	243	0.0033
Relapse < 12 months post ASCT	74	93 ($p = 0.01$)	205	276	0.13

Abbreviations: ASCT, autologous stem cell transplant; ISS, International Staging System; MNR, median not reached; N/A, not available; TSD, time since diagnosis; TPP, time to disease progression; ORR, overall response rate.

Bladé et al also presented a pre-specified analysis to assess the efficacy of combination therapy with PLD+B based on the number of prior lines of therapy and previous anthracycline exposure. The TTP was similar with PLD+B between those who had ≥ 2 lines of prior therapy (276 days) vs 1 prior therapy (330 days) (heterogeneity test, $p = 0.523$), as well as between those who were anthracycline-exposed (median 144 mg/m² in both treatment arms) or -naïve (heterogeneity test, $p = 0.716$). The incidence of symptomatic cardiac events was also comparable between treatment arms in each subgroup. There was a uniform benefit with PLD+B combination therapy in TTP regardless of the number of prior lines of therapy and anthracycline exposure.⁴⁴

The impact of treatment with prior thalidomide on outcomes of patients treated with PLD+B was also evaluated in a post hoc analysis of the phase III study by Sonneveld et al. Prior exposure to thalidomide did not affect TTP (295 days for thalidomide-naïve vs 270 days for thalidomide-exposed) or DOR (310 days for thalidomide-naïve vs 319 days for thalidomide-exposed). ORR was also comparable between the thalidomide-naïve and -exposed arms (48% vs 47%).⁴⁵ A second post hoc analysis by Sutherland et al evaluated the effect of International Staging System (ISS) disease stage and time since initial diagnosis (TSD; 2 cohorts: >2 years and ≤ 2 years) on outcomes of patients treated with PLD+B. There was a consistent benefit in TTP across ISS stages 2 (HR = 1.8, $p < 0.004$) and 3 (HR = 2.1, $p < 0.007$) but not ISS stage 1 (HR = 1.6, $p = 0.067$). TSD did not affect the benefit in TTP (>2 years, HR 1.83; ≤ 2 years, HR = 1.75).⁴⁶

A post hoc analysis of outcomes of patients, who had an early relapse (<12 months) after ASCT, was also performed (Kumar et al). Among these patients, the 12-month post-randomization survival was significantly higher in those treated with combination therapy (93% vs 74%, $p = 0.01$). TTP in the early relapse cohort also suggested improvement with combination therapy (205 vs 276 days), but did not reach statistical significance ($p = 0.13$, HR = 0.94). A similar benefit in TTP was noted among patients whose myeloma relapsed 12 months or later after ASCT, suggesting that the benefits of treatment with combination therapy were not affected by timing of relapse after ASCT. No differences in ORR (CR+PR) or VGPR rates were seen in patients with early vs late relapses, or between treatment arms within each group.⁴⁷

Safety/tolerability

Based on the risk of dose reductions and delays at higher dose levels of bortezomib (PLD was maintained at a fixed

dose level) during the phase I study of PLD+B, a dosing schedule of bortezomib 1.3 mg/m² on days 1, 4, 8, and 11, and PLD 30 mg/m² on day 4 on a 21-day cycle was determined to be the most feasible for multiple cycle administration.³⁵ Neutropenia and thrombocytopenia were the most common reasons for therapy-related dose delays, followed by diarrhea and fatigue.³⁵

In the phase I study, 43% of patients experienced \geq grade 3 thrombocytopenia, and 40% and 17% respectively experienced \geq grade 3 lymphopenia and neutropenia. The most notable infectious complications were febrile neutropenia (10%) and pneumonia (14%).³⁵ By comparison, 23% of patients in the PLD+B arm of the phase III study developed \geq grade 3 thrombocytopenia and 29% had \geq grade 3 neutropenia (Table 2). Though the incidence of \geq grade 3 neutropenia was nearly twice that seen among those treated with bortezomib alone (15%), the incidence of febrile neutropenia was comparable between study arms (2% vs 3%). Rates of thrombocytopenia were also similar.³⁷

Peripheral neuropathy (PN) is one of the most common toxicities of single-agent bortezomib, with an incidence of grade 1–4 events seen in 36% of patients and grade 3–4 events in 8% in the APEX trial.⁴ In the phase I study of PLD+B, where doses of bortezomib up to 1.5 mg/m² were evaluated, an incidence of 55% (12% grade 3–4) was observed.³⁵ However, in the phase III study of bortezomib vs PLD+B, where 1.3 mg/m² of bortezomib was given to all patients, rates of peripheral neuropathy were comparable to those seen in previous clinical trials of single-agent bortezomib.³⁷ Rates of peripheral neuropathy were also comparable between treatment arms of this study (PN grades 1–4: 39% and 35% respectively; \geq grade 3: 9% and 4%), despite an equivalent number of median cycles of therapy ($n = 5$) and similar cumulative dose of bortezomib (monotherapy, 24.4 mg/m²; combination, 23.2 mg/m²). This suggests that PLD added no further neurotoxicity to bortezomib.³⁷

Reducing the potential for cardiac toxicities with doxorubicin was one of the most important reasons for the development of PLD. Data from the phase III study of bortezomib vs PLD+B showed that 7% and 9% of patients respectively had a fall in their left ventricular ejection fraction by $\geq 15\%$, suggesting that PLD does not add significant risk of cardiotoxicity to bortezomib. Congestive heart failure was seen in 3% of patients on each treatment arm.³⁷ In addition, in a pre-specified analysis by Bladé et al evaluating the role of prior anthracycline exposure, there was no increase in the incidence of symptomatic cardiac events with prior anthracycline exposure.⁴⁴

Table 2 Grade 3–4 adverse events in phase III trial of bortezomib vs pegylated liposomal doxorubicin + bortezomib (PLD+B)

Adverse event	Bortezomib (%) N = 318	PLD+B (%) N = 318	p value
All drug-related adverse events	165 (52)	217 (68)	<0.001
Thrombocytopenia	49 (16)	71 (23)	0.249
Neutropenia	46 (15)	94 (29)	<0.001
Febrile neutropenia	2 (2)	3 (3)	n/a
Peripheral neuropathy	39 (9)	35 (4)	n/a
Cardiotoxicity	7 (3)	10 (2)	n/a
Thromboembolic events	1 (1)	1 (1)	n/a
Diarrhea	14 (4)	22 (7)	0.034
Palmar plantar erythrodysesthesia	0 (0)	15 (5)	<0.001

In the phase III study, the addition of PLD to bortezomib resulted in a statistically significant increase in the incidence of nausea, vomiting, and diarrhea.³⁷ Diarrhea (10%), bowel obstruction (7%), and lower gastrointestinal bleeding (5%) were also seen in the phase I study of PLD+B.³⁵ Finally, palmar plantar erythrodysesthesia, now known as hand-foot syndrome, was noted in 21% of patients (all grade 1–2) in the phase I study and 16% of patients in the phase III study.^{35,37} It required discontinuation of PLD in 5% of patients on the latter study.

In subset analyses of the phase III study, the effect of age, prior stem cell transplant, and high-risk disease on the incidence of adverse events was evaluated.^{41–43} With the exception of an increased incidence of grade ≥ 3 neutropenia among patients ≥ 65 years old, age did not impact the development of adverse events with combination therapy. Similarly, having primary refractory myeloma, a history of prior ASCT, or a serum β_2 -microglobulin ≥ 5.5 mg/L, did not affect rates or severity of adverse events encountered with PLD+B.^{42,43}

PLD+B-based combinations in relapsed/refractory disease (Table 3)

Given the established activity of dexamethasone in combination with bortezomib as well as anthracyclines, Jakubowiak et al evaluated the addition of 40 mg of dexamethasone on days 1–4 to PLD+B in the relapsed/refractory setting.⁴⁸ In this study, patients were treated on a 21-day cycle of therapy for up to 6 cycles. Among 18 evaluable patients, who had received a mean of 3.6 prior regimens, the ORR was 55%, and 33% achieved CR/nCR. Grade 3/4 neutropenia and thrombocytopenia were each seen in 7 patients; pneumonitis was seen in 5 patients and, unfortunately, resulted in 1 death.⁴⁸

The combination of thalidomide-PLD-dexamethasone (ThaDD) has also provided noteworthy results, with an

ORR of 75.5%, and CR rate of 30% in the relapsed/refractory setting.⁴⁹ Building on this regimen, Offidani et al sought to improve these response rates further by adding bortezomib (ThaDD-V). In the induction phase of this feasibility study, patients received 100 mg of thalidomide daily with PLD 30 mg/m² iv on day 4, dexamethasone 20 mg on days 1 to 2, 4 to 5, 8 to 9, 15 to 16, and bortezomib 1.3 mg/m² on days 1, 4, 8, and 11 of every 28 days. Patients then alternated taking bortezomib 1 mg/m² iv days 1, 8, 15 with dexamethasone 20 mg on days 1 to 2, 8 to 9, 15 to 16, and thalidomide 100 mg daily with dexamethasone 40 mg on days 1 to 4, every other cycle for a total 6 cycles, as consolidation therapy. Finally, patients received thalidomide 100 mg daily as a maintenance regimen until disease relapse. The ORR seen in 20 evaluable patients was 80%, of which 40% achieved either CR or stringent CR.⁵⁰ However, as 9 of the 20 patients developed grade 2–3 peripheral neuropathy, the authors subsequently amended their protocol to reduce the dose intensity of both bortezomib and thalidomide.^{50,51}

Chanan-Khan et al have also evaluated the combination of thalidomide, B, and PLD, but with a steroid-sparing approach. In this phase II study, patients were given 1.3 mg/m² of bortezomib on days 1, 4, 15, and 18 together with 20 mg/m² PLD on days 1 and 15; 200 mg thalidomide was given daily with low-dose warfarin prophylaxis. Among 17 evaluable patients, the ORR was 65%, and CR rate was 23%; PFS was 10.9 months. Among this heavily pre-treated population, responses were seen regardless of the prior therapies that patients had received. Grade 2 palmar plantar erythrodysesthesia developed in 2 patients, and 1 patient had grade 3 cellulitis. Importantly, no thromboembolic events were noted with this combination; and no patients developed evidence of cardiotoxicity, regardless of exposure to prior anthracyclines.⁵²

Table 3 Pegylated liposomal doxorubicin + bortezomib combinations in relapsed/refractory setting

Author	Phase of study	Regimen	Dose	Evaluable pts (#)	PR (%)	CR/nCR (%)	PFS/TTP (med. months)

Abbreviations: B, bortezomib; D, dexamethasone; M, melphalan; PLD, pegylated liposomal doxorubicin; T, thalidomide; PR, partial response; CR, complete response; nCR, near complete response; ORR, overall response rate; PFS, progression-free survival; TTP, time to disease progression.

Presently, Chari et al are evaluating the addition of melphalan to PLD+B in a phase I/II dose escalation trial.⁵³ Based on preliminary data from this study, 4 evaluable patients have been enrolled and treated at the first dose level, on which they have received PLD 10 mg/m² and melphalan 5 mg/m² on day 1, and bortezomib 0.7 mg/m² on days 1, 4, 8 and 11, on a 28-day cycle. A maximum of 6 cycles are planned. At the time of publication, 1 patient had achieved nCR and 2 patients had stable disease. No DLTs were reported, though 1 patient had transient grade 3 neutropenia.⁵³ Further updates of this study are necessary before conclusions may be drawn about this regimen.

Conclusions

The management of MM has changed rapidly over the past 10 years with increased understanding of the biology of the ubiquitin proteasome pathway, mechanisms of chemoresistance to this pathway, and methods of targeting it for treatment. Combination therapy with PLD+B is an important therapeutic option for patients with relapsed or refractory myeloma that provides superior outcomes to single-agent bortezomib, including improved 15-month OS rates. As patients with relapsed or refractory MM have often previously received anthracyclines, thalidomide, and/or autologous stem cell transplant, it is significant that PLD+B improves patient outcomes irrespective of these prior exposures. The lack of further benefit seen with adding PLD to bortezomib in patients with low β_2 -microglobulin and deletion of chromosome 13 suggest that bortezomib may be solely responsible for the responses seen in these subgroups of patients.

The tolerability profile of PLD+B is noteworthy. Treatment emergent peripheral neuropathy is a common

clinical challenge in patients with MM. That PLD is able to improve patient outcomes without exacerbating symptoms of neuropathy adds to its usefulness. This steroid-sparing combination is also a valuable choice for patients with poorly controlled diabetes mellitus and those who are otherwise steroid intolerant. It is equally important that in a disease with a median age at diagnosis of 70 years, this combination does not increase the risk of cardiotoxicity compared with bortezomib alone.⁵⁴ Finally, the lack of need for prophylactic anticoagulation, which is in contrast to immunomodulatory derivative (Imid[®])-steroid combinations, is advantageous for patients at risk for falls, or with other bleeding tendencies. While these advantages are important, clinicians must be vigilant for the gastrointestinal toxicities, neutropenia, stomatitis, and hand-foot-syndrome that can be seen with PLD+B, so that these may be promptly addressed if they develop.

Ongoing phase II studies are currently evaluating the combination of PLD+B with such agents as dexamethasone, thalidomide, and melphalan in the relapsed/refractory setting. These trials have a limited number of patients and follow-up to date; however mature data may suggest additional treatment options in the future.

Because of its significant activity in the relapsed/refractory setting, with manageable and non-overlapping toxicities, PLD+B is also being evaluated as induction therapy prior to ASCT. This Cancer and Leukemia Group B (CALBG) study led by Orlowski et al enrolled 63 patients with symptomatic MM requiring therapy on the same B-PLD schema utilized in the phase 3 study. Preliminary response data on 29/63 patients demonstrated a CR/nCr rate of 28% and ORR of 79%. Stem cell collection, in a limited

number of evaluable patients, was not compromised.⁵⁵ If longer follow-up confirms these promising results, this steroid-sparing combination may provide an effective option for patients with improved tolerability over other currently used regimens.

In future clinical trials of PLD+B, it will be useful to assess whether fluorescence in situ hybridization (FISH), conventional cytogenetics, and/or molecular profiling can be used to determine which patients are most likely to benefit from this regimen.
