### Abstract

High resolution localized surface plasmon resonance (HR-LSPR) sensors were combined with matrix assisted laser desorption ionization mass spectrometry (MALDI-MS) for the first time. LSPR sensors provide real-time label-free detection of molecular adsorption. Subsequent MALDI-MS analysis enables identification of the adsorbed molecules. This synergistic LSPR-MS approach was applied to the detection and identification of amyloid beta oligomers which play an important role in the molecular pathogenesis of Alzheimer's Disease.

### Introduction

The ability to detect and identify small quantities of biomolecules is essential for characterizing ligand-receptor interactions and ultimately elucidating the molecular basis of disease. Real-time, label-free detection techniques based on quartz crystal microbalances (QCM), microcantilevers, optical cavity resonators, propagating surface plasmon resonance (SPR),<sup>1</sup> and localized surface plasmon resonance (LSPR) spectroscopy<sup>2-4</sup> are widely used to measure the thermodynamics and kinetics of binding. These techniques are analyte general and require receptor functionalized surfaces for specificity. In order to identify unknown molecules bound to the surface, a complementary analytical technique is needed, such as matrix assisted laser desorption ionization mass spectrometry (MALDI-MS). The advantages of integrating propagating SPR sensors with MALDI have been previously demonstrated.<sup>5-6</sup> We report here the first experiments combining real-time, high resolution LSPR (HR-LSPR) and MALDI (See Figure 1). The techniques were applied to the detection of amyloid-beta derived diffusible ligands (ADDLs) which play an important role in the molecular pathogenesis of Alzheimer's Disease.<sup>7</sup>

ADDLs are neurotoxic oligomers of amyloid beta-protein (A $\beta$ ), intermediate in size between monomers and the fibrils found in the senile plaques of Alzheimer's patients. ADDLs specifically target synapses<sup>8</sup> and selectively block long term potentiation.<sup>9</sup> In transgenic

Alzheimer's mouse models, 12-mers of A $\beta$  develop when memory failure first occurs; injection of these isolated 12-mers into normal mice causes memory deficiency.<sup>10</sup> In human patients, there is a strong correlation between the presence of Alzheimer's Disease and the concentration of ADDLs in cerebrospinal fluid and cerebral cortex tissue.<sup>11–13</sup> Measuring A $\beta$  oligomer concentrations and studying their aggregation rates is therefore important for understanding pathology and developing diagnostics and therapeutics.

LSPR shift assays detect molecular adsorption to noble metal nanoparticles. These nanoparticles intensely absorb and scatter light at wavelengths that depend on the nanoparticle size, shape, composition and local refractive index.<sup>2–4</sup> Molecular adsorption to the nanoparticles increases the local refractive index, and leads to a red-shift in the extinction spectrum. With improvements in instrumentation and software, real-time LSPR shifts can now be monitored in solution with picometer spectral resolution.<sup>3,4</sup> Indeed the sensitivity is sufficiently high to detect the conformational changes that accompany calcium binding to calmodulin.<sup>4</sup> LSPR shift assays have also been used to detect ADDL concentrations down to 100 fM by measuring the LSPR wavelength in nitrogen before and after ADDL binding.<sup>13</sup>

To demonstrate the combination of HR-LSPR and MALDI-MS, we first used HR-LSPR to monitor binding of ADDLs to an anti-ADDL antibody (IgG, NU-1). Next, we acquired MALDI spectra from ADDLs on a stainless steel plate. Finally, we acquired MALDI spectra from an LSPR substrate after first recording real-time LSPR.

## Experimental Methods

### Preparation of Amyloid ADDLs

ADDLs were prepared according to previously published protocols.<sup>7</sup> A $\beta$ <sub>1–42</sub> peptide (California Peptide Research, Napa, CA) was dissolved in hexafluoro-2-propanol (HFIP) and aliquoted to microcentrifuge tubes. HFIP was allowed to evaporate overnight in a fume hood, after which residual traces of HFIP were removed by drying for 15 min in a SpeedVac (Savant Instruments) at 6 mTorr. The tubes were stored desiccated at –80°C. To prepare the soluble oligomer solution, an aliquot of A $\beta$ <sub>1–42</sub> was dissolved in neat, cold dimethylsulfoxide (DMSO; freshly opened vial) to make a 5 mM solution. The DMSO stock was immediately diluted into cold phenol-free F12 medium (Life Technologies, Gaithersburg, MD) to make a 100- $\mu$ M A $\beta$  solution. This solution was then incubated at 4 °C for 24–30 hours, centrifuged at 14,000 $\times$ *g* for 10 min, and the supernatant was collected. Protein concentration was determined using the Coomassie blue assay, with the monomer A $\beta$ <sub>1–42</sub> peptide as the molar reference. SDS-PAGE separation of these ADDLs shows a series of oligomers including higher order oligomers > 50 kDa.<sup>7</sup> SDS-PAGE studies with cross-linked ADDLs suggest that pentamers and hexamers are more stable configurations.<sup>14</sup>

### Nanosphere Lithography (NSL)

Silver nanoprisms attached to a glass substrate were prepared using nanosphere lithography (NSL).<sup>15</sup> Nanospheres (Interfacial Dynamics Corporation, Portland OR, d=390 nm) were drop coated onto a #2 18 mm glass coverslide to create a close-packed hexagonal monolayer. Silver was then deposited through the triangular spaces in the sphere mask to a height of 80 nm. The spheres were removed by attaching a layer of tape to the sample and then peeling it off, followed by sonicating the sample in ethanol for 10 seconds. The sample was then functionalized with a self-assembled monolayer (SAM) by incubation in an ethanolic solution of 0.75 mM octanethiol and 0.25 mM 11-mercaptoundecanoic acid (MUA) for at least 24–48 hrs. The SAM protects the nanoprisms by reducing the effect of solvent annealing as well as providing carboxyl groups onto which biomolecules can be covalently linked.

## HR-LSPR

Silver nanoprism substrates, prepared by NSL, were placed in a home built flow cell. Unpolarized light from a BPS100 lamp (BWTEK Inc., Newark, DE) was focused on the substrate (1 mm spot size), and transmitted light was analyzed with a BRC711E photodiode array spectrometer (BWTEK Inc., Newark, DE). A clear region on the substrate, made by masking with Kapton tape during silver deposition, was used as a spectral reference. Transmittance at each wavelength was calculated as  $T = (\text{sample-dark}) / (\text{reference-dark})$ , and extinction was calculated as  $-\log_{10}(T)$ . A program written in Labview (National Instruments, Austin, TX) acquired spectra at 1 s intervals, calculated the maximum wavelength by fitting a 100 nm spectral region around the peak to a fourth order polynomial, and displayed  $\lambda_{\text{max}}$  in real-time. Solutions were injected into the flow cell with a syringe. To switch solutions, the solution within the flow cell was aspirated with the syringe, and a new solution was added; spectral acquisition was paused during the roughly 10 s that this process took.

The binding curves for each step were fit to a single exponential with a linear drift correction term:  $y(t) = y_{\text{sat}} - b \exp(-t/\tau) - c t$ . The linear correction term accounted for the particle shape annealing in aqueous solvent, and was less than 0.001 nm/s in all cases. The total LSPR shift due to adsorption of biomolecules to the LSPR surface varies from sample to sample by  $\pm 30\%$  due to differences in nanoparticle morphology and initial  $\lambda_{\text{max}}$ , which is known to affect the sensitivity of nanoparticles to refractive index changes.

## MALDI on stainless steel plate

The ADDLs were spotted onto a MALDI plate using the sandwich method with sinapinic acid as the matrix. A sinapinic acid stock solution (SA) was prepared as 10 mg/mL sinapinic acid in a solvent of 50% (v/v) acetonitrile, 49.95% water, 0.05% trifluoroacetic acid. 0.5  $\mu\text{L}$  SA was pipetted onto the stainless steel plate and aspirated to leave a thin film. After drying, 0.5  $\mu\text{L}$  of ADDLs solution was added, and 0.5  $\mu\text{L}$  of SA was added to the droplet and allowed to dry. The mass spectra were acquired on a MALDI time of flight (TOF) instrument, Axima CFR (Shimadzu, Tokyo, Japan/Kratos, Manchester, UK) which uses a 337 nm nitrogen laser. The instrument was calibrated using mass calibration standards of bovine insulin and insulin oxidized B chain.

## MALDI on an LSPR sample

The LSPR sample consisted of silver nanoprisms on a glass slide prepared by NSL. The nanoprisms had been previously exposed to ADDLs, and the adsorption was monitored in real-time using HR-LSPR. The sample was then spotted with 1  $\mu\text{L}$  SA and allowed to dry. On some spots, we also co-deposited 5 pmols of bovine insulin and insulin oxidized B chain as calibration standards. Subsequently, the sample was attached to a stainless steel MALDI plate using kapton tape and introduced into the MALDI instrument.

## Results and Discussion

Figure 2 shows an HR-LSPR sensorgram of ADDLs binding to silver nanoprisms fabricated using nanosphere lithography. The nanoprism substrate was incubated in 10 mM phosphate buffered saline (PBS) at pH 7.4, followed by ADDLs (10  $\mu\text{M}$  in  $\text{A}\beta$ ), a PBS rinse, and a final incubation in 200 nM anti-ADDLs. All binding curves were fit to a sum of an exponential plus a linear drift term:  $y(t) = y_{\text{sat}} - b \exp(-t/\tau) - c t$ . Upon incubation with ADDLs, the LSPR extinction shifted by 5.0 nm with a 24 s exponential time constant ( $\tau$ ) due to adsorption. Rinsing in PBS resulted in a small blue-shift (0.4 nm) due to removal of weakly bound ADDLs. Subsequent adsorption of antibody resulted in an additional 6.8 nm shift ( $\tau = 725$  s). Figure 2b shows the real-time tracking of the peak wavelength. Figure 2c shows extinction spectra at each stage of ADDLs binding. A control experiment using bovine serum albumin (BSA, MW

66 kDa) resulted in a similar initial shift of 5.0 nm ( $\tau=19$  s), but minimal antibody adsorption (0.52 nm), see Figure 2d and 2e. These results indicate that a similar amount of BSA and ADDLs adsorb to the nanoprisms, and at a similar rate, but that the antibody binds specifically to the ADDLs functionalized surface. The signal to noise ratio of these measurements is high ( $\sim 500$ ) and measurements can be made over many hours with no photobleaching. Although previous researchers have used propagating SPR to examine A $\beta$  oligomerization,<sup>16</sup> this marks the first time that LSPR sensors detected real-time binding of ADDLs and antibody.

ADDLs were spotted onto a stainless steel MALDI plate along with the MALDI matrix, sinapinic acid (SA). Approximately 35 pmol of A $\beta$  was deposited per spot. MALDI spectra were acquired on an Axima CFR instrument (Shimadzu, Tokyo, Japan). In addition to the A $\beta$  peak, we observed a second set of peaks shifted by 16 mass units (see supplemental Figure S1). Previous researchers have also observed this peak, and attributed it to oxidation of the methionine.<sup>17</sup> It is reported that high concentrations of the oxidized species of A $\beta$  are found in senile amyloid plaques, although *in vitro*, it is less prone to oligomerization and fibrillization.<sup>17,18</sup> The oxidized ADDLs are reported to have decreased toxicity over periods of less than 24 hours, with restored toxicity after 96 hours.<sup>17,18</sup>

The MALDI spectrum also displays a series of oligomers up to at least 30-mers (see supplemental Figure S2). The observed ions are likely a combination of intact molecular ions, fragments from larger oligomers, and gas phase aggregates. Indeed, post source decay of the dimer into monomer was observed using reflectron mode (see supplemental Figure S3). Hung and coworkers published the first MALDI spectra of A $\beta$  oligomers up to octomers.<sup>19</sup> Their studies of A $\beta$  peptides and oligomers adsorbed to hydrophobic C-6 modified surfaces showed that the GxxxG peptide repeat sequence of A $\beta$  is important in oligomerization. Replacing any of the glycines in those repeat sequences with leucine residues reduced both the amount of oligomerization and toxicity of the A $\beta$ . The present results demonstrate that even larger oligomers can also be observed with MALDI. Work is ongoing to acquire MALDI from electrophoretically separated ADDLs as well cross-linked ADDLs and isotope labeled ADDLs to elucidate the aggregation and dissociation mechanisms in the MALDI spectra.

We next performed MALDI directly on an LSPR sample after adsorption of ADDLs (Figure 3). Figure 3a shows real-time binding of 5  $\mu$ M ADDLs to an LSPR substrate. The shift is  $\sim 6.5$  nm ( $\tau=49$  s); the reduced adsorption rate compared to Figure 2 may be due to lower concentration, while the similar total shift indicates that the surface saturates after long incubation times at 5  $\mu$ M concentration. Next, we pipetted 1  $\mu$ L SA onto the substrate and allowed it to dry. The number of moles of ADDLs on the nanoprisms spotted with matrix is estimated to be approximately 4 orders of magnitude less concentrated than on the samples directly drop coated onto the MALDI plate (Figure S2). As a result, oligomers are obscured by background. The monomer peak is clearly observed and resolved into two peaks due to normal and oxidized A $\beta$ . Such posttranscriptional modifications could not be resolved using LSPR alone.

## Conclusion

The LSPR-MS approach offers detection and identification capabilities similar to the established SPR-MALDI approach.<sup>5,6</sup> In addition, LSPR systems display less interference from bulk refractive index changes,<sup>20</sup> observation of protein conformational changes,<sup>4</sup> and higher spatial resolution down to single particles.<sup>2</sup> Nanoparticles also provide advantages for mass spectrometry because nanoparticles may also be suspended in solution and concentrated through centrifugation.<sup>21</sup> In addition, nanoparticles have been reported to enhance desorption and ionization processes in MALDI imaging.<sup>22,23</sup>

In conclusion, we have demonstrated the first use of MALDI-MS on an LSPR sample. The LSPR provided real-time binding data, while the MALDI allowed the identification of normal and oxidized A $\beta$  in ADDLs. Integrating LSPR with MS therefore represents an important advance in the analytical capability of LSPR. We expect complementary LSPR and MS analysis will be important in the *in vitro* analysis of A $\beta$  aggregation and interaction with biomolecules, as well as the characterization and analysis of A $\beta$  in tissue samples and cerebral spinal fluid.<sup>13,24</sup>
