## Abstract

**Objective**—To identify genetic modifiers of  $\beta$ -blocker (BB) response and long-term survival in heart failure (HF).

**Background**—Differences in BB treatment effect between Caucasians and African Americans with HF have been reported.

**Methods**—Prospective cohort study of 2,460 patients (711 African American; 1,749 Caucasian) enrolled between 1999 and 2007. 2039 (81.7%) were treated with BB. Each was genotyped for  $\beta$ 1-adrenergic receptor (*ADRB1*) Arg389>Gly and G-protein receptor kinase 5 (*GRK5*) Gln41>Leu polymorphisms, which are more prevalent among African Americans than Caucasians. Primary endpoint was survival time from HF onset.

**Results**—There were 765 deaths during follow up (median 46 months). BB treatment increased survival in Caucasians (Log Rank P=0.00038) but not African Americans (Log Rank P=0.327). Among patients not taking BB, *ADRB1* Gly389 was associated with decreased survival in Caucasians (HR = 1.98, 95% CI = 1.1 - 3.7, P = 0.03) while *GRK5* Leu41 was associated with improved survival in African Americans (HR = 0.325, CI = 0.133 - 0.796, P = 0.01). *ADRB1* Gly389 *GRK5* Gln41Gln African Americans derived similar survival benefit from BB therapy (HR = 0.385 95% CI = 0.182 - 0.813, P = 0.012) as *ADRB1* Gly389 *GRK5* Gln41Gln Caucasians (HR = 0.529, 95% CI = 0.326 - 0.858, P=0.0098).

**Conclusions**—These data demonstrate that differences caused by  $\beta$ -adrenergic receptor signaling pathway gene polymorphisms, rather than race, are the major factors contributing to apparent differences in BB treatment effect between Caucasians and African Americans; proper evaluation of treatment response should account for genetic variance.

### Introduction

Heart failure affects approximately 5 million Americans, with over half a million new cases diagnosed every year (1). Abnormalities of cardiac  $\beta$ -adrenergic signaling that contribute to the pathophysiology of heart failure include increased circulating epinephrine levels and down-regulation or functional uncoupling of cardio-toxic  $\beta$ 1-adrenergic receptors (2,3). Accordingly,  $\beta$ -blockers, which antagonize catecholamine-stimulated beta adrenergic receptor signaling in the heart and elsewhere, represent one of the most important non-surgical therapeutic options for this disease, reducing morbidity and mortality (4,5). There is a class I indication for  $\beta$ -blocker treatment in heart failure (6). However, individual responses to  $\beta$ -blocker treatment vary widely and there is a need to identify non-responders within the broader clinical group that shows aggregate benefit, as well as to predict responders within groups where treatment effects are less clear.

Variability in heart failure risk and clinical course is objectively revealed by population surveys and prospective clinical trials that have identified ethnic differences in disease incidence, progression, and response to specific therapies (7-9). Accordingly, the American College of Cardiology/American Heart Association guidelines for evaluation and management of heart failure in the adult concluded that "heart failure progresses more rapidly in black than white patients" (6). The mechanisms responsible for these types of differences have not been clearly identified, and undoubtedly include social influences, access to care, and the quality of care (10). Individual genetic factors may also play a role (11). Evidence is accumulating in support of specific genetic loci that contribute to the over-representation of other complex diseases, such as hypertension and type 2 diabetes mellitus, in individuals of African heritage (12-16). A genetic or pharmacogenomic basis for differences in drug effect between individuals of African and European descent has also been proposed (17), supported by associations between variable drug clearance and functionally significant polymorphisms of genes encoding enzymes important for drug metabolism, cytochrome P450 (CYPB6) and N-acetyltransferase (NAT2) (18-20). Thus, ethnically diverse populations exhibit differences in drug response that may be due, in part, to variations within genes essential to the drug effect.

In evaluating the potential for genetic variation to influence heart failure outcome, it is notable that functional polymorphisms are common in the genes encoding the  $\beta$ -blocker target,  $\beta$ adrenergic receptors (ADRB1 and ADRB2), and a gene that critically regulates  $\beta$ -adrenergic receptor signaling, G-protein receptor kinase 5 (GRK5) (21,22). Previous pharmacogenomic studies have proposed that the  $\beta$ 1-adrenergic receptor (ADRB1) Arg389>Gly (23) and Gprotein receptor kinase 5 (GRK5) Gln41>Leu (22) polymorphisms, both of which are overrepresented in African Americans, may play roles in determining individual clinical responses to  $\beta$ -blockade in heart failure. The biological mechanisms for the effects of both alleles were established by expressing recombinant polymorphic proteins in cultured cells and in transgenic mice (22,24). However, studies of their impact on heart failure outcome in different ethnic groups, and comparisons of these two putative genetic risk factors to standard clinical risk factors for heart failure progression, have not been performed. Here, we report the results of a prospective longitudinal study examining the impact of ADRB1 and GRK5 genotype on  $\beta$ blocker modulation of long-term outcome in subjects with systolic heart failure who presented to the specialized heart failure/transplant programs of two major United States urban medical centers.

## Methods

#### **Study Subjects**

Subjects presenting to the heart failure referral programs at the University of Cincinnati or the University of Pennsylvania were prospectively recruited into one of two non-interventional

longitudinal genomics studies of heart failure funded by the NHLBI (P50 HL77101 and R01 HL88577). African American inclusion at >25% of the total cohort was part of the study design approved by NHLBI, and subgroup analysis of outcomes in Caucasians and African Americans was prespecified. Human study protocols were approved by Institutional Review Boards of the University of Cincinnati and the University of Pennsylvania. All subjects provided written informed consent. Enrollment criteria were age between 18 and 80 years and documented systolic heart failure with a left ventricular ejection fraction of less than 40%. The study recruited 2,460 heart failure patients, of which 711 (29%) were African American. 1,783 subjects (1164 Caucasian Americans and 619 African Americans) were enrolled between 2000 and 2007 in Cincinnati, and 677 subjects (585 Caucasian Americans and 92 African Americans) were enrolled in Philadelphia between 2003 and 2005. The cohorts were combined to provide a sufficient number of African Americans to power an analysis of racial subgroups. Racial classification was self-reported. The study endpoints were death or cardiac transplantation. Median follow-up was 46.3 months.  $\beta$ -blocker use was determined by the subjects' physicians (66% carvedilol, 24% metoprolol, 10% other  $\beta$ -blockers) and defined as continuous therapy for at least 6 months. Medication usage was confirmed at hospital clinic visits by personal interview. Follow-up data for each study subject was obtained at least yearly, either by personal interview, by mail, or by phone conversation.

#### Genotyping

Genomic DNA for genotyping was isolated and extracted using the Gentra Puregene genomic DNA purification kit (Qiagen, Valencia, CA). The DNA segments containing the region of interest were amplified with the polymerase chain reaction (PCR). PCR primers were designed using Primer3 online software (http://fokker.wi.mit.edu/cgi-bin/primer3/primer3\_www.cgi) (25), and pyrosequencing primers were designed using the Pyrosequencing SNP Primer Design Version 1.01 software (http://www.pyrosequencing.com). Before use, PCR primer sequences were screened across the human genome using the NCBI Blast program to ensure their specificity for the gene of interest. PCR and pyrosequencing were performed as previously described (26). Primers and conditions are listed in Supplemental Table 1. *GRK5* Gln41Leu genotyping was performed by pyrosequencing (University of Cincinnati cohort) or using a Sequenome MassArray platform (University of Pennsylvania cohort) with conservative genotype calls in 99.8% of samples. *ADRB1* Arg389Gly genotyping was performed using Assays-on-Demand (Applied Biosystems, Foster City, Calif) assay number C\_8898494\_10 according to the manufacturer's directions.

#### **Statistical Analysis**

Student's t-tests and chi-square tests were used to assess significant differences in variables between ethnic groups and between genotype classes within ethnic groups. Hardy-Weinberg Equilibrium (HWE) was assessed in each ethnic group separately. The primary outcome was time to transplantation or all-cause mortality through 350 months. Differences in time from diagnosis to endpoint were assessed using Kaplan-Meier curves and Log Rank tests (27). Relative risks were obtained by Cox Proportional Hazards modeling using an additive genetic model after adjustment for age at diagnosis and sex. All analyses were carried out using the R Statistical Language (http://www.R-project.org) (28). An alpha level of 0.05 was used to designate significance.

## Results

#### **Clinical Characteristics of the Study Population**

Clinical characteristics of the heart failure study cohort, grouped by race, are in Table 1. The two racial groups were well matched in terms of age, height and weight, sex, and severity of left ventricular dysfunction. As has been noted previously (29,30) hypertension, renal

dysfunction, and cerebrovascular events are more common among African Americans with heart failure, but in this cohort, diabetes was only slightly more prevalent. Coronary artery disease and ischemic cardiomyopathy were more common in Caucasians with heart failure. As might be expected at tertiary referral centers specializing in heart failure, pharmacological treatment of heart failure was similar between the two ethnic groups, with ~80-85% of subjects receiving a  $\beta$ -blocker (approximately two-thirds treated with carvedilol, one fourth with metoprolol, and 10% another agent), ~75-80% receiving an ACE inhibitor, ~22% receiving an angiotensin receptor blocker, and slightly over 30% receiving an aldosterone antagonist. (Fewer than 50 subjects in each group were treated with hydralazine/isosorbide dinitrate.) Similar proportions of both ethnic groups received automatic implanted defibrillators (24-29%). However, only half as many (~7%) of African Americans underwent cardiac transplantation (averaging 74.7 months after diagnosis) as did Caucasians (~15%; averaging 67.3 months after diagnosis). Average survival time from first objective heart failure diagnosis was 79.9 +/- 78.1 months (mean +/- S.D.) for Caucasians, compared to 69.8 +/- 68.6 months for African Americans (P = 0.17). Together, these data demonstrate that this population of heart failure study subjects recruited from the comprehensive heart failure/transplantation programs of two metropolitan medical schools has similar clinical characteristics and ethnic differences as observed in previous large heart failure trials (1,6,9,29).

The impact of standard clinical risk factors on heart failure survival in the study cohort is shown in Table 2. All of the analyses presented in this table are univariate Cox proportional hazards models. Among Caucasians, increasing age, hypertension, coronary artery disease, and diabetes each approximately doubled the mortality risk, whereas among the smaller African American cohort only age and hypertension achieved significance as a risk factor for increased mortality, although the clear trend was for all three clinical factors to decrease survival. Male sex was a significant risk factor among African Americans, but not Caucasians. In contrast, the relationship between left ventricular ejection fraction at presentation and long-term clinical outcome was not consistent, as previously observed (29). The Cox proportional hazards models presented in the following sections are adjusted for age at heart failure onset and sex. Although other clinical factors were significantly associated with survival univariately, including age and sex in the Cox proportional hazards model greatly reduced or eliminated the significance of these variables' relationship with survival.

#### β-blocker Treatment Effects on Mortality in Heart Failure

The group mean benefit of  $\beta$ -blocker treatment in heart failure is not disputable (6). However, results of individual studies have varied, particularly regarding the effects of β-blocker treatment in African Americans (31,32). Factors that may have contributed to differing results include under-representation of African Americans in some trials (33), different effects of  $\beta$ blockers with unique pharmacological characteristics (32), and real mechanistic differences in the magnitude of treatment effect between ethnic groups, as has been reported with ACE inhibitors versus other vasodilator therapy (34,35). To determine if there were differences in apparent β-blocker treatment effect between Caucasians and African Americans within our study population, we examined mortality as a function of  $\beta$ -blocker treatment status in the overall heart failure cohort, and then separately in Caucasians and African Americans. A summary of the clinical characteristics stratified by  $\beta$ -blocker and race ethnicity is given in Table 3. In the combined cohort,  $\beta$ -blocker treatment significantly increased survival time ( $\beta$ blocker Untreated N=455,  $\beta$ -blocker Treated N=2038, Log Rank P=0.00074, Figure 1a) and reduced mortality risk (age- and sex- adjusted Hazard Ratio = 0.71, 95% CI = 0.566 - 0.887, P=0.003). The effects of metoprolol and carvedilol appeared similar (not shown). When the survival data were analyzed in the Caucasian subgroup, increased survival with  $\beta$ -blocker treatment (β-blocker Untreated N=351, β-blocker Treated N=1391, Log Rank P=0.00038, Figure 1a top inset) and reduced risk of death or transplant (age- and sex-adjusted HR = 0.679,

95% CI = 0.519 - 0.888, P=0.005) were again statistically significant. However, a  $\beta$ -blocker treatment effect on survival was not as clear in the African American subgroup ( $\beta$ -blocker Untreated N=98,  $\beta$ -blocker Treated N=611, Log Rank P=0.327, Figure 1a *bottom inset*), with a trend toward reduced risk (age- and sex-adjusted HR=0.698, 95% CI = 0.453 - 1.08, P = 0.1). These data show that the HR for  $\beta$ -blocker treatment effect on mortality between the two races are similar, but the effects did not achieve statistical significance in African Americans because the confidence intervals are much broader, notwithstanding adequate numbers of subjects and experimental endpoints. Therefore, we further examined survival as a function of β-blocker treatment status in the two ethnic groups by comparing mortality within each treatment group. Survival times were not significantly different between Caucasians and African Americans in  $\beta$ -blocker untreated subjects (Figure 1b; Caucasian N=351, African American N=98, 82.8 +/- 69.3 months for African Americans versus 71.0 +/- 73.4 months in Caucasians, P=0.46, Log Rank P=0.5213), whereas among subjects taking  $\beta$ -blockers, African Americans had shorter survival times than Caucasians (Figure 1c; Caucasian N=1391, African American N=611, 66.8 +/- 68.4 months in African Americans versus 82.2 +/- 79.5 months in Caucasians, P=0.057, Log Rank P=0.0005). Thus, the mortality benefit from  $\beta$ -blockade appears greater in Caucasians than African Americans from these clinical populations.

#### ADRB1 Gly389 in Heart Failure

We considered that the broader confidence intervals for  $\beta$ -blocker treatment effect in African Americans might indicate a greater degree of inter-individual variability in this subgroup, possibly as a consequence of genetic factors. We further noted that the only two functionally significant  $\beta$ -receptor pathway gene polymorphisms reported to affect the response to  $\beta$ blocker therapy in heart failure are both over-represented in African Americans (23,36). The first reported such polymorphism substitutes Gly for Arg at position 389, within the signal transduction domain of the major cardiac  $\beta$ -blocker target,  $\beta$ 1-adrenergic receptors (37). Therefore, we genotyped our cohort for this polymorphism and examined whether it was associated with difference in  $\beta$ -blocker treatment effect. Allele frequencies of the minor ADRB1 Gly389 allele were 0.298 in Caucasians and 0.392 in African Americans. Genotypes were in Hardy-Weinberg equilibrium (African American P = 0.67; Caucasian American P =0.98) and similar to the reported allele frequencies in normal subjects (Caucasians, 0.12-0.25 and African Americans, 0.23-0.38, respectively (21,36). Thus, as previously reported, this allelic variant is more common among African Americans than Caucasians, but its prevalence within racial sub-groups is similar between heart failure subjects and non-affected controls, supporting previous conclusions that this polymorphism does not, by itself, modify the risk of developing heart failure (38).

Functional allelic variants that are not independent risk factors for disease may nevertheless modify the course of that disease or its response to specific therapies. This may particularly apply to polymorphisms of  $\beta$ -receptor pathway genes in heart failure, because hyper-activation of cardiac catecholaminergic signaling occurs early in the course of the disease. In our study cohort, there were no differences in the clinical characteristics of heart failure subjects stratified by *ADRB1* genotype (Table 3). Before adjusting for clinical risk modifiers, the *ADRB1* Gly389 polymorphism tended to be associated with decreased heart failure survival times in subjects not taking  $\beta$ -blockers when examined for the overall cohort (Arg389 Homozygous N=543, Gly389 Carriers N=597, Log Rank P=0.0587; Figure 2a), or separately for Caucasians (Arg389 Homozygous N=422, Gly389 Carriers N=369, Log Rank P=0.0436; Figure 2a *top inset*), but not in African Americans (Arg389 Homozygous N=119, Gly389 Carriers N=223, Log Rank P=0.546; Figure 2a *bottom inset*). After adjusting for age- and sex-, however, the Gly389 association with increase mortality risk in  $\beta$ -blocker untreated subjects was clearly significant in the entire cohort (HR = 1.76, 95% CI = 1.09 – 2.85, P = 0.02) as well as in Caucasian Americans analyzed as a separate sub-group (HR = 1.98, 95% CI = 1.07 – 3.65, P = 0.03).

(The number of African Americans not taking  $\beta$ -blockers and carrying the minor allele [N=34] was insufficient to properly power this subgroup analysis.) These results suggest a modest benefit for being homozygous ("wild-type") Arg389 among  $\beta$ -blocker non-treated subjects, as has previously been reported (39).

Among subjects treated with the  $\beta$ -blockers carvedilol or metoprolol (as were approximately 90% of the treated subjects in our study), there was no significant association between survival and *ADRB1* Arg389Gly genotype in the entire cohort (Arg389 Homozygous N=396, Gly389 Carriers N=463, Log Rank P=0.7974, Figure 2b; age- and sex- adjusted HR = 0.953, 95% CI = 0.736 - 1.24, P = 0.501), or when ethnic groups were analyzed separately (for Caucasian Americans: Arg389 Homozygous N=299, Gly389 Carriers N=271, Log Rank P=0.421, Figure 2b *top inset;* adjusted HR = 0.884, 95% CI = 0.638 - 1.23, P = 0.46; for African Americans: Arg389 Homozygous N=96, Gly389 Carriers N=188, Log Rank P=0.3928, Figure 2b *bottom inset*; adjusted HR = 0.813, 95% CI = 0.515 - 1.28, P = 0.37). These data suggest that the Arg389 *ADRB1* genotype does not predict a treatment effect for carvedilol or metoprolol.

#### **GRK5** Leu41 in Heart Failure

The second adrenergic signaling polymorphism reported to affect the response to  $\beta$ -blocker therapy in heart failure substitutes Leu for Gln at position 41 of GRK5, one of the G-protein receptor kinases that desensitize cardiac  $\beta$ -adrenergic receptors (22,40). The GRK5 Leu41 variant exhibits greater desensitization than the more common "wild-type" GRK5 Gln41 (41). For this reason, we genotyped the heart failure cohort and examined whether possessing this polymorphism was associated with any difference in heart failure outcome or  $\beta$ -blocker treatment effect. Allele frequencies of the minor *GRK5* Leu41 allele were 0.017 for Caucasians and 0.231 for African Americans. Genotypes were in Hardy-Weinberg equilibrium (African American P = 0.63; Caucasians P = 0.39) and are similar to the reported allele distributions in normal subjects (0.013 and 0.23 respectively (22). Except for slight differences in age at enrollment, there were no differences in the clinical characteristics between subjects homozygous for wild-type *GRK5* Leu41 polymorphism verses those carrying at least one polymorphic *GRK5* Gln41 allele (Table 4).

In an aggregate analysis of  $\beta$ -blocker untreated subjects there was no evidence for an effect of *GRK5* Leu41 genotype on heart failure survival (Gln41 Homozygous N=390, Leu41 Carriers N=47, Log Rank P=0.8211; Figure 3a) or for decreased mortality risk (age- and sex-adjusted HR for death = 0.755, 95% CI = 0.399 – 1.43, P = 0.39). When the data were analyzed according to ethnic group, we found only 3 subjects in the Caucasian subgroup that carried a Leu41 allele, were not taking  $\beta$ -blockers, and achieved the mortality endpoint during the study period (Figure 3a *top inset*). Thus, we are underpowered for this analysis. Among  $\beta$ -blocker untreated African Americans however, in which nearly equal numbers of subjects carry a *GRK5* Leu41 allele verses are homozygous Gln41 "wild-type", the presence of at least one *GRK5* Leu41 was associated with longer survival (Gln41 Homozygous N=56, Leu41 Carriers N=35, Log Rank P=0.0181; Figure 3a, *bottom inset*), and with a significant decrease in mortality risk after adjustment for age and sex (HR = 0.325, CI = 0.133 – 0.796, P = 0.01).

Interestingly, when  $\beta$ -blocker treated subjects within the cohort were analyzed as a whole for consequences of the GRK5 polymorphism, a significant detrimental effect of GRK5 Leu41 was detected (Gln41 Homozygous N=1602, Leu41 Carriers N=272, Log Rank P=0.0052, Figure 3b). However, the apparent difference by genotype is actually attributable to the general difference in outcome observed between  $\beta$ -blocker treated Caucasians and African Americans (compare Figure 3b with Figure 1c), because the Leu41 variant is ten-times more common among African Americans, and there were only 10 Caucasian subjects that carried a Leu41 allele, were taking  $\beta$ -blockers, and reached the study endpoint (Figure 3b, *top inset*). In contrast, among  $\beta$ -blocker treated African American subjects (in whom there was roughly equal

distribution of homozygous Gln41 wild-type versus Leu41 carriers), there was no association between *GRK5* Gln41 polymorphism genotype and heart failure outcome (Gln41 Homozygous N=317, Leu41 Carriers N=227, Log Rank P=0.7166, Figure 3b *bottom inset*).

#### Heart Failure Risk Profiling Using Clinical and Genetic Factors

Genotyping of our study cohort for two functional  $\beta$ -AR signaling polymorphisms revealed one genotype, ADRB1 Arg389, that is associated with significantly decreased mortality risk in β-blocker untreated Caucasians, and another, GRK5 Leu41, that is associated with decreased mortality risk in  $\beta$ -blocker untreated African Americans, with no evidence for a multiplicative interaction between these ADRB1 and GRK5 variants. We considered that these genetic factors might contribute to the apparent differences in heart failure outcomes and  $\beta$ -blocker response observed between Caucasians and African Americans in our cohort, and re-examined outcome in subjects matched for these two polymorphisms, i.e. in ADRB1 Gly389 GRK5 Gln41Gln individuals. When ADRB1 Gly389 GRK5 Gln41Gln patients were analyzed, β-blocker treatment significantly increased survival time (β-blocker Untreated N=110, β-blocker Treated N=371, Log Rank P = 0.00058, Figure 4a) and reduced mortality risk (age- and sex- adjusted Hazard Ratio = 0.530, 95% CI = 0.357 - 0.788, P=0.0017) in the combined cohort. The same was true for  $\beta$ -blocker treatment in Caucasians ( $\beta$ -blocker Untreated N=87,  $\beta$ -blocker Treated N=256, Log Rank P = 0.0053, Figure 4a top inset; age- and sex- adjusted HR = 0.529, 95% CI = 0.326 - 0.858, P=0.0098). When this analysis was applied to African Americans without considering genotype, it had failed to show a  $\beta$ -blocker treatment effect in this cohort (see Figure 1a, right inset). However, when the ADRB1 Gly389 GRK5 Gln41Gln subgroup of African Americans was analyzed,  $\beta$ -blocker treatment enhancement of survival was evident  $(\beta$ -blocker Untreated N=22,  $\beta$ -blocker Treated N=111, Log Rank P = 0.0373, Figure 4a bottom inset), as was a significant reduction in mortality risk (age- and sex- adjusted HR = 0.385 95% CI = 0.182 - 0.813, P = 0.012). Survival times were similar in genotype-matched Caucasian and African American β-blocker untreated subjects (Caucasian N=87, African American N=22, Log Rank P= 0.2368, Figure 4b; age- and sex- adjusted HR = 1.46, 95% CI = 0.611 - 1003.51, P= 0.39) and  $\beta$ -blocker treated subjects (Caucasian N=256, African American N=111, Log Rank P= 0.2283, Figure 4c), although there was still a trend toward shorter survival times in  $\beta$ -blocker treated African Americans after adjusting for age and sex (adjusted HR = 1.55, 95% CI = 0.992 - 2.43, P= 0.054). Another way to conceptualize the interaction of genotype and  $\beta$ -blocker treatment is to examine the effect of genotype within treatment class. By comparing the ADRB1 Gly389 GRK5 Gln41Gln genotype to all other genotypes pooled, we found that genotype had no effect among  $\beta$ -blocker treated subjects (Caucasians: HR=0.854, P=0.35; African Americans: HR=0.829, P=0.39) but did have a significant effect among βblocker untreated Caucasians (Caucasians: HR=2.09, P=0.02; African Americans: HR=1.77, P=0.19). These data suggest that in this heart failure population differences caused by  $\beta$ adrenergic receptor signaling pathway gene polymorphisms, rather than race, are the major factor contributing to apparent differences in β-blocker treatment effect between Caucasians and African Americans.

## Discussion

The major finding of this study is that genetic polymorphisms of the major cardiac  $\beta$ -blocker target, the  $\beta$ 1-adrenergic receptor, and a kinase that terminates its signaling, GRK5, can significantly impact heart failure outcomes, and that adjusting for these gene variants abrogates the apparent ethnic differences in  $\beta$ -blocker treatment effect on heart failure survival.

In heart failure patients with similar clinical presentations, some will have a more rapid disease course, whereas disease progression is less aggressive in others (42,43), and the benefits of recent advances in pharmacological and mechanical therapies for heart failure have not been

equally shared among all patient groups. In particular, management of heart failure remains a challenge for the African American population. African Americans have a 50% higher prevalence of heart failure, with earlier and more severe onset of disease and decreased survival (9,44). There are many possible reasons for racial differences in health care outcome, including differences in heart failure etiology, clinical risk factors or management practices, as well as the absence of pre-specified analysis of African Americans as a separate sub-group in many large clinical trials and a tendency for African Americans to be under-represented in these studies (45). Our study was specifically designed to have proportional representation of African Americans and to minimize differences in clinical risk factors and management practices that may contribute to ethnic differences in heart disease. Thus, heart failure patients were recruited from two large municipal tertiary referral heart failure/transplant programs, affording a consistent standard of care that has been shown to reduce or eliminate ethnic differences in mortality (46). The two ethnic cohorts were well-matched for ventricular function, ACE inhibitor and  $\beta$ -blocker treatment, and AICD use. Nevertheless, African Americans had significantly higher mortality rates, a less clear response to  $\beta$ -blocker therapy, and were transplanted only half as often as Caucasians. For this reason, the endpoint for these studies was all-cause mortality, and our multi-variate risk factor analysis adjusted for differences in sex and age.

The mortality from treated heart failure exceeds that of most cancers, (47) and  $\beta$ -blockers are one of only two drug classes that increase survival (the other being ACE inhibitors).  $\beta$ -blockers are in general highly effective in prolonging survival in heart failure patients, but interindividual differences in treatment effect continue to complicate disease management. Therefore, our focus in these studies was on two critical components of the signaling pathway targeted by  $\beta$ -blockers, the  $\beta$ 1-adrenergic receptor itself (48), and GRK5, an abundant kinase in myocardium that terminates  $\beta$ -adrenergic receptor signaling (40,41,49). The  $\beta$ 1-adrenergic receptor, encoded by the *ADRB1* gene, is the major cardiac target of  $\beta$ -blockers. Unique to humans is a common polymorphic variation of ADRB1 encoding either Gly or Arg at amino acid 389, located within the intracellular G-protein coupling domain (23). This region of  $\beta$ 1adrenergic receptor is highly conserved between species, with the human Gly variant being the only known instance of divergence from Arg at this position. The functional consequence of introducing Gly is diminished coupling between the  $\beta$ 1-adrenergic receptor variant and Gas (50) and decreased responsiveness to  $\beta$ -blockers in genetic mouse models (51). Human studies have been inconsistent as to whether there are meaningful associations between this polymorphism and heart failure outcome (24,38,39,52-58). The more common Arg389  $\beta$ 1adrenergic receptor exhibits enhanced functional coupling, is less prevalent in African Americans, and is associated with a favorable response to the experimental  $\beta$ -blocker, bucindolol, whereas carriers of the Gly389 minor allele reportedly shows no survival benefit from bucindolol (23). An investigation of adrenergic receptor gene polymorphisms on cardiovascular outcomes in the Woman's Ischemia Syndrome Evaluation (39) found that carriers of the Gly389 allele were at increased risk for heart failure and all cause mortality. The current findings of a trend for improved heart failure survival in Caucasians homozygous for Arg389, and the experimental findings of Akhter, et al that Arg389 transgenic mice recover from ischemic insults faster than Gly389 mice (59), also suggest a more complex role for this β-receptor variant in primary myocardial disease than has generally been recognized.

The other polymorphism we evaluated is ten-times more common in African Americans than Caucasian Americans, substituting Leu for Gln at position 41 of GRK5. GRK5 helps to terminate  $\beta$ -adrenergic receptor signaling by phosphorylating and uncoupling agonist-occupied receptors from their Gas signal transducers (40,49). Amino acid 41 is in a putative regulatory domain for the kinase, and (as with the  $\beta$ 1-adrenergic receptor 389 polymorphism) GRK5 amino acid sequence is conserved at this position across human, bovine, mouse, rat, dog, and zebrafish homologs, except for the human variant (22). Compared to the "wild-type"

GRK5, the Leu41 variant promotes more rapid agonist-mediated desensitization, phosphorylation, and internalization of  $\beta$ 1-adrenergic receptor (41), and mimics  $\beta$ -blockers in genetic mouse models (22). In a previous report, which is the only report to date of this polymorphism in a human study, we described a pharmacogenomic interaction with  $\beta$ -blockers for the combined endpoint of cardiac transplant or death in a small cohort of African Americans with heart failure (22). Here, we have greatly expanded the number of heart failure subjects studies, doubling the number of African American study subjects to 711, and compared outcomes to almost 1,800 Caucasians recruited from the same two academic centers. In so doing, we demonstrate a significant increase in heart failure survival in African Americans carrying at least one GRK5 Leu41 allele.

Our findings that the gene modifier effects for the ADRB1 389 polymorphism have greater significance for Caucasians, and for the GRK5 41 polymorphism are significant only in African Americans do not necessarily indicate different disease mechanisms between these ethnic groups. Both the ADRB1 and GRK5 SNPs exhibit significant differences in prevalence between populations of European and African descent, and natural variations in polymorphism allele frequency between different ethnic groups can result in correspondingly different pathological roles for these genetic events in different study populations. For example, the 8q24 locus associated with prostate cancer is associated with a higher prevalence of this disease among African Americans not because of a greater individual gene effect in African American individuals, but because the risk allele occurs with greater frequency in this population, and thereby contributes to increased incidence (60). Thus, the most important aspect of the current results is not what impact specific adrenergic signaling pathway polymorphisms have on heart failure, because these effects have been shown to vary between different populations, with different treatment practices, and in different cardiovascular conditions (24,38,39,52-58). Instead, the take-home message is that SNPs such as these two that clearly alter functional pathways in experimental systems have the potential to produce variability of disease prognosis and outcome in the same manner as clinical risk modifiers. Therefore, proper evaluation of disease risk and treatment response should account for genetic variance, either by matching subjects by relevant genotype as herein, or by including relevant genotypes in multi-variate models.
