Abstract

A procedure for the coupling of aliphatic imines with allylic and allenic alkoxy lithium salts is described. The success of these studies was enabled by a unique reactivity profile of $\text{Ti}(\text{IV})$ isopropoxide/ $n\text{-BuLi}$ compared to well-known $\text{Ti}(\text{IV})$ isopropoxide/ R-MgX systems.

Nitrogen-containing small molecules have emerged as a subset of organic structures that display a range of pharmaceutically relevant properties.¹ As such, chemical methods that provide new approaches to the stereoselective assembly of diverse nitrogen-containing small molecules have great potential to affect the pace of discovery in medicine. Of the many robust methods available for the convergent synthesis of such molecules, embracing the reactivity of imines as electrophiles has proven to be a productive pursuit.² By a mechanistically distinct process, the reductive cross-coupling of imines with alkenes, alkynes and allenes has great potential to unlock unique and powerful convergent coupling reactions for the synthesis of stereodefined nitrogen-containing products. Until recently, many of these bond constructions were ill-defined, with only a handful of processes available for the regioselective coupling of highly activated imine-based systems with a small subset of alkynes.³ In our efforts to discover new cross-coupling reactions capable of forging C–C bonds between unactivated imines and unsymmetrical and electronically unactivated alkynes, alkenes and allenes, we have described a series of highly regio- and stereoselective metal-mediated coupling reactions for the synthesis of unsaturated 1,5-aminoalcohols,⁴ allylic amines,⁵ saturated 1,5-aminoalcohols⁶ and homoallylic amines⁷ (**1** → **2–5**; Figure 1). While these advances demonstrated coupling processes of potential significance in chemical synthesis, like other contributions in this general area of reaction methodology (reductive coupling chemistry), they were uniformly limited to a subset of imines – in this case aromatic imines. In an effort to increase the significance of these alkoxy-directed titanium-mediated reductive cross-coupling reactions of imines, we sought to identify a method suitable for the functionalization of *aliphatic* imines. Here, we describe a useful method for the activation of *aliphatic* imines via epititanation (**6** → **7**), and the application of these activated complexes in reductive cross-coupling reactions with allylic- and allenic alcohols.

The reduction of an aromatic imine by formation of an azametallacyclopropane, and subsequent hydrolysis, is a well-known process.⁸ To date, azametallacyclopropane formation has generally been accomplished in one of two ways: 1) by exposure of preformed aromatic imines to the combination of a titanium(IV) alkoxide and a reactive organometallic reagent (i.e. RMgX), or 2) by a metal-mediated redox process with suitably functionalized amines.⁹ For the former case, it has been documented that aliphatic imines are poor substrates for the process¹⁰ although the mechanistic details that lead to their poor behavior remain poorly understood. Deleterious side reactions, including pinacol-type coupling (homocoupling) and addition of the organometallic reducing agent to the imine have been observed. In studies aimed at overcoming these significant limitations, we explored the titanium-mediated reduction of imine **8**. As depicted in Figure 2, our preliminary study confirmed the poor reactivity of the Kulinkovich/Sato system for this process ($\text{Ti}(\text{O}i\text{-Pr})_4$, *i*-PrMgCl), but demonstrated a significant dependence of this reaction on the nature of the organometallic reducing agent employed. In this case, employing *n*-BuLi as the reductant¹¹ led to superior results. Aside from the differences in reactivity of the $\text{Ti}(\text{O}i\text{-Pr})_4$ /*n*-BuLi system in the reduction of aliphatic imine **8**, we observed a significant change in physical properties associated with the reaction media at elevated concentrations. As depicted in Figure 3, exposure of imine **8** to $\text{Ti}(\text{O}i\text{-Pr})_4$ / *n*-BuLi in THF (0.7 M in titanium) led to the formation of a free flowing solution. In contrast, treatment of imine **8** with $\text{Ti}(\text{O}i\text{-Pr})_4$ /*i*-PrMgCl in THF (0.5 M in titanium) led to the formation of a gelatinous suspension. While the unique reactivity of the *n*-BuLi-based system is of central interest to the studies presented here, the ability to maintain a free flowing solution at elevated concentrations of $\text{Ti}(\text{O}i\text{-Pr})_4$ is a notable property of the system.

Moving on to explore C–C bond forming processes with aliphatic imines, success in titanium-mediated prenylation of **8** was similarly dependent on the nature of the reducing metal used (Figure 4).¹² While the secondary Grignard reagents investigated led to little product formation (entries 1–2), *n*-BuMgCl was marginally effective (entry 3). Interestingly, organolithium reagents were uniformly more effective for this transformation, with *n*-BuLi providing the prenylated product **13** in 59% yield (entry 6). Due to the enhanced efficiency observed in this preliminary screen, and the practical advantages of *n*-BuLi, further study was dedicated to this reducing metal. Optimization of the prenylation was relatively straightforward, where simply employing two equivalents of aliphatic imine in the coupling reaction with **12** led to the formation of the homoallylic amine **13** in 80% yield.¹³

As illustrated in Figure 5 and Figure 6, this preparatively simple protocol to produce aliphatic imine-derived azametallacyclopropanes is useful for coupling reactions that extend beyond prenylation. Figure 5 highlights the compatibility of this process for the coupling of aliphatic imines with a variety of allylic alcohols. Eqs 1–4 describe coupling reactions of aliphatic imines that bear α -branching (eqs 1–4). Finally, aliphatic imines that lack α -branching are also competent reaction partners for coupling with allylic alcohols. As demonstrated in eq 5, the heptylimine **22** was converted to the prenylation product **23** in 92% yield.¹⁴

The presumed azametallacyclopropanes prepared by exposure of aliphatic imines to the combination of BuLi and $\text{Ti}(\text{O}i\text{-Pr})_4$ are also effective in cross-coupling reactions with allenic alcohols. As depicted in Figure 6, mono-, di- and trisubstituted allenes are all compatible with the process and deliver allylic amines containing a valuable 1,3-diene motif. Consistent with the trends in stereoselectivity observed in the related coupling reaction of aromatic imines, the present process was generally *E*-selective, with highest levels of stereoselection observed in coupling reactions of allenes bearing branched terminal substitution (i.e. **24** vs **26**; eqs 1–2). Finally isomeric allenes **28** and **30** are viable partners with imine **8** (eqs 3–4). In these cases, the production of dienes **29** and **31** occurred in a regiospecific fashion in 52 and 58% yield.

In conclusion, it has long been accepted that alkyl imines are particularly challenging substrates in reductive cross-coupling chemistry. In titanium alkoxide-mediated processes, alkylation of aliphatic imines with the reducing Grignard reagent typically employed in these processes has been cited as the root cause of this limitation. In an attempt to overcome this limitation, we initiated empirical studies to probe the structure/activity relationships of a range of reducing organometallic reagents in titanium alkoxide-mediated reduction of aliphatic imines. Initial studies led to the identification of *n*-BuLi as a particularly effective reagent in combination with Ti(O*i*-Pr)₄ for the net reduction of aliphatic imines. Subsequent to this observation, the reductive cross-coupling of a variety of aliphatic imines with allylic and allenic alcohols was accomplished. While the mechanistic underpinnings that have resulted in empirical success remain undefined, the current findings greatly impact the potential utility of metal-mediated reductive cross-coupling reactions for the assembly of stereodefined nitrogen-containing small molecules. Due to the significance of such molecules in biology and medicine, and the potential impact of stereoselective convergent coupling processes well-suited for their synthesis, we look forward to future developments that emerge from these findings.

13. (a) No evidence was found for the production of regioisomeric products (derived from reverse prenylation) (b) This reaction also produced 15% of the product derived from butyl addition to the imine (c) An interesting Mg-ion effect was observed in this coupling reaction: When one equivalent of $\text{MgBr}_2 \cdot \text{OEt}_2$ was added to this reaction (coupling of **8** with **12** under the optimized conditions with *n*-BuLi) the yield of **13** dropped to 47% (c) ^1H NMR spectra of the crude reaction mixtures resulting from attempted prenylation of imine **8** via procedures employing a 2° alkyl Grignard reagent and *n*-BuLi can be found in the Supporting Information.
14. A limitation of this coupling reaction, compared to our previously described allylation of aromatic imines, currently includes 2-halo-substituted allylic alcohols. Employing the reaction conditions used to generate the homoallylic amines in Figure 5 for the coupling of 2-bromo-propen-1-ol with imine **12** did not lead to appreciable quantities of the anticipated product of allyltransfer.
