### Abstract

Reactive oxygen species (ROS) are ubiquitous in life and death processes of cells<sup>1</sup>, with a major role played by the most stable ROS, hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). However, the study of H<sub>2</sub>O<sub>2</sub> in live cells has been hampered by the absence of selective probes. Described here is a novel nanoprobe (“nanoPEBBLE”) with dramatically improved H<sub>2</sub>O<sub>2</sub> selectivity. The traditional molecular probe, 2', 7'-dichlorofluorescein (DCFH), which is also sensitive to most other ROS (hydroxyl radical, superoxide, nitric oxide, peroxyxynitrite, hypochlorous acid and alkylperoxyl radical), as well as from enzymes such as peroxidases. The blocking is based on the combination of multiple exclusion principles: time barrier, hydrophobic energy barrier, size barrier. However, H<sub>2</sub>O<sub>2</sub> sensitivity is maintained down to low nM. The surface of the nanoprobe was engineered to address biological applications, and the power of this new nanoPEBBLE is demonstrated by its use on RAW264.7 murine macrophages. These nanoprobe may provide a powerful chemical detection/imaging tool for investigating biological mechanisms related to H<sub>2</sub>O<sub>2</sub>, or other species, with high spatial and temporal resolution.

H<sub>2</sub>O<sub>2</sub> is a key player in intracellular signaling<sup>2,3</sup>, host defense and phagocytosis<sup>4,5,6,7</sup>, wound detection and healing<sup>8</sup>, as well as in the initiation of several pathophysiological cascades that terminate in cell death or adaptation<sup>9,10</sup>. H<sub>2</sub>O<sub>2</sub> is a by-product from other ROS related reactions, such as the dismutation of the superoxide radical anion (O<sub>2</sub><sup>·-</sup>) under the mediation of superoxide dismutase. It is also a common precursor for the further generation of other, more

damaging, ROS, such as hydroxyl radical ( $\cdot\text{OH}$ ), hypochlorous acid (HOCl) and peroxynitrite ( $\text{ONOO}^-$ )<sup>11,12,13</sup>.  $\text{H}_2\text{O}_2$  is a relatively stable ROS, amenable to measurement, and, as such, has drawn much interest. However, specific and readily deployable tools for reliable and precise physiological/intracellular measurements of  $\text{H}_2\text{O}_2$  are still lacking.

Many ROS sensitive molecular probes have severe limitations, such as poor selectivity and instability, thus often leading to spontaneous oxidation (Supplementary figure 1)<sup>14,15</sup>. Further complications, such as the inability of specific probes to permeate biological membranes and the potential interference by unwanted enzymatic reactions, need to be considered for quantitative measurements under physiological conditions. DCFH (2',7'-dichlorofluorescein) dye is highly sensitive and is one of the most widely used probes for the detection of ROS and oxidative stress in biological systems<sup>16,17,18</sup>. For intracellular measurements, the non-fluorescent and lipophilic precursor molecule, DCFDA (2',7'-dichlorofluorescein diacetate), is used to freely pass into the plasma membrane. The DCFDA dye then converts into the hydrophilic DCFH, inside the cell, by losing two acetate groups due to esterase activity. DCFH can readily generate the strongly fluorescent and hydrophilic product, 2',7'-dichlorofluorescein (DCF), upon oxidation by ROS generated inside of cells. Although this dye has often been used to monitor  $\text{H}_2\text{O}_2$ , its poor selectivity strictly limits the utility of the measurements to systems that are relatively free from interferences. Furthermore, its pH sensitivity is a well known drawback<sup>19</sup>. Also, its use often depends on a catalytic activity of peroxidases, which can complete the transition to DCF even without ROS, and thus hurting the accuracy of detection<sup>16,17</sup>. Those limitations hamper its application in most biological situations.

Nanoparticle platforms provide a working solution that addresses many of the problems identified above. Our group has developed nanoparticle based biosensors, termed PEBBLES (Photonic Explorers for Biomedical uses with Biologically Localized Embedding)<sup>20,21,22</sup>, for the intracellular detection of a large number of biologically important analytes. NanoPEBBLE sensors provide several important advantages over conventional sensors such as molecular probes: minimal physical/chemical invasiveness, minimal interference between probe and cell ingredients, a wider choice of probe materials, synergistic detection schemes, biological targeting, autofluorescence background suppression, and a ratiometric measurement capability<sup>23</sup>. Here we describe an added benefit: induced selectivity.

Recently, several attempts to improve  $\text{H}_2\text{O}_2$  detection have been reported, based on either chemical modification of the ROS probes or nanoparticle-based approaches. Gong *et al.*<sup>24</sup>, Dickinson *et al.*<sup>25</sup>, Maeda *et al.*<sup>26</sup> and Setsukinai *et al.*<sup>14</sup> suggested various chemical derivatizations of DCFDA. Lee *et al.*<sup>27,28</sup> developed a polymer nanoparticle based on a peroxalate chemiluminescence (POCL)<sup>29</sup>, which is a well known chemiluminescence technique for  $\text{H}_2\text{O}_2$  detection. Kim *et al.*<sup>30</sup> and Poulson *et al.*<sup>31</sup> reported nanoparticles that embed peroxidases in hydrophilic polymer matrices. Both approaches are based on the selectivity of peroxidases and their catalytic effect. In spite of these advances, some limitations still remain, such as imperfect selectivity, interferences by enzymes and by non-ROS chemicals, unverified particle biocompatibility, leaching from particles, and insufficient dynamic ranges of detection.

In contrast, the approach given below utilizes the nanoparticle as a screening device that empowers high  $\text{H}_2\text{O}_2$  selectivity to an otherwise non-selective probe, DCFH. Such induced selectivity can be achieved by a delicate complementarity of properties between the nanoparticle matrix and the embedded molecular probe (Scheme 1). In addition, this nanoprobe has other typical benefits of nanoPEBBLES, such as biocompatibility, protection of content and targeting capability.

Ormosil nanoplatforms, which are bio-inert, relatively hydrophobic but still water-suspendable, with a 100 nm size (Supplementary figure 2), were synthesized by a previously

described method<sup>32,33</sup>. The nanoparticle surface is readily modifiable by amine functionalization (resulting in about 20 mV of zeta potential, indicating a positive surface charge). DCFDA was loaded into preformed Ormosil particles by a solvent displacement technique (Supplementary figure 3)<sup>34,35</sup>, wherein hydrophobic dye molecules and particles are dissolved in a volatile organic solvent first, mixed with aqueous media and then the solvent is evaporated. The resulting nanoparticle retains the dye molecule in its inactive/lipophilic form, DCFDA. We discovered that the DCFDA dye shows H<sub>2</sub>O<sub>2</sub> sensitivity without conversion to the activated hydrophilic intermediate (DCFH), in contrast to previous reports<sup>16–18</sup> (Table 1 and Supplementary figure 4). The DCFDA nanoprobe (0.1 mg/mL) displayed an increase in fluorescence intensity over time, upon addition of H<sub>2</sub>O<sub>2</sub>. The fluorescence intensity value reached a plateau after very long time (supplementary figure 5). The plateau value varied monotonously with H<sub>2</sub>O<sub>2</sub> concentration. The early-time rate of fluorescence generation also depends on H<sub>2</sub>O<sub>2</sub> concentration, as demonstrated in Table 1. The nanoprobe detected H<sub>2</sub>O<sub>2</sub> over a concentration range of 10 – 100 μM—a significantly wider detectable range than previous probes<sup>27,30,31</sup>. These DCFDA nanoprobe showed negligible dye leaching, confirming that the H<sub>2</sub>O<sub>2</sub> response was not from released dye molecules in solution (Figure 1).

The H<sub>2</sub>O<sub>2</sub> selectivity of the DCFDA nanoprobe and the DCFDA free dye has been examined by monitoring the change in fluorescence intensity upon exposure to various ROS interferents, such as ·OH, O<sub>2</sub><sup>·-</sup>, ·NO, ONOO<sup>-</sup>, HOCl, and ROO· (alkylperoxyl radical) (Table 2). The DCFDA free dye was prepared by solubilizing DCFDA in a trace amount of DMSO and diluting it in excess aqueous medium. The tests were performed as previously reported for the DCFH dye probe<sup>14</sup>. We note that when the DCFH dye was used as a H<sub>2</sub>O<sub>2</sub> probe, it suffered very large interferences from most ROS<sup>14</sup>. For instance, the fluorescence increase of the DCFH dye due to ·OH, ONOO<sup>-</sup> and ROO· was 40, 35 and 4 times that due to H<sub>2</sub>O<sub>2</sub>, respectively, under the same testing conditions as for Table 2.

The DCFDA nanoprobe, in comparison to DCFDA dye, showed a significantly enhanced selectivity towards H<sub>2</sub>O<sub>2</sub> over other ROS. Upon exposure to these ROS, DCFDA free dye showed noticeable increases in fluorescence intensity, except for ROO·. In contrast, the DCFDA nanoprobe exhibited significantly less changes (see Table 2). In the case of ·OH interference, the slight decrease in the nanoprobe response just reflects the reduced concentration of H<sub>2</sub>O<sub>2</sub>, by the reaction to produce ·OH, suggesting negligible interference from ·OH itself. Notably, ·OH has the shortest lifetime (nsec or shorter) among all the ROS<sup>36</sup>. Our previous study on ·OH sensing nanoprobe showed that ·OH could only be detected at the surface of nanoprobe, but not inside them. This suggests the general principle that nanoparticle matrixes may filter species based on lifetime, thus achieving improved selectivity towards longer-lived ROS. In the case of the HOCl interference, the decrease in the nanoprobe's fluorescence may be because of a pH change in the testing solution, due to HCl production from HOCl<sup>19</sup>. The H<sub>2</sub>O<sub>2</sub> response of the DCFDA nanoprobe shows a monotonic pH dependent behavior (Supplementary figure 6)

The ROS like O<sub>2</sub><sup>·-</sup>, ·NO, ONOO<sup>-</sup>, HOCl, and ROO· (alkylperoxyl radical) are *moderately* unstable ROS molecules, with lifetimes of msec or longer. Exclusion by short lifetime alone may not be sufficient to explain why they are not detected by the nanoprobe. Note that our previous studies have shown that singlet oxygen (<sup>1</sup>O<sub>2</sub>), with a lifetime of only about 2 μsec in aqueous media, can be successfully detected with the same Ormosil-based nanoprobe<sup>37</sup>. It is well known that organic solvents greatly stabilize <sup>1</sup>O<sub>2</sub>, resulting in extension of lifetime<sup>38</sup>. We hypothesize that the relatively hydrophobic Ormosil matrix must offer a similarly favorable environment for lipophilic ROS, such as <sup>1</sup>O<sub>2</sub> and H<sub>2</sub>O<sub>2</sub>. On the other hand, it is reasonable to assume that the Ormosil matrix would behave as a hydrophobic energy barrier, reducing the stability of most other polar ROS above. In the presence of ROO·, neither the free DCFDA dye

nor the nanoprobe exhibited recognizable fluorescence generation, in contrast to the DCFH dye probe<sup>14</sup>.

Another important advantage of using DCFDA encapsulated in nanoprobe is the avoidance of unwanted enzymatic interactions. The DCFDA nanoprobe showed no interference from horseradish peroxidase (HRP) but the DCFD free dyes showed significant interference (Table 2). Typically, the ROS assay using DCFH dye is performed in association with HRP<sup>16,17</sup>, for faster and more vivid detection, despite the fact that DCFH can be oxidized by HRP alone, without ROS<sup>16,17</sup>. Although this effect is not a significant drawback for general ROS detection, it can cause a very significant error in the H<sub>2</sub>O<sub>2</sub>-specific quantification. The matrix resistance to HRP interference is due to the large size of the HRP, being too large to penetrate into the Ormosil matrix. The same size exclusion may also eliminate potential confounding interactions from other enzymes or macromolecules. For example, the nanoprobe would be free from unwanted conversion of DCFDA to hydrophilic DCFH by the intracellular esterase, retaining their H<sub>2</sub>O<sub>2</sub> selectivity.

Based on the improved H<sub>2</sub>O<sub>2</sub> selectivity, H<sub>2</sub>O<sub>2</sub> generation from stimulated macrophages, which are well known for oxidative bursts, could be evaluated quantitatively. The surfaces of the DCFDA nanoprobe were engineered for *in vitro* measurement as follows: First, the DCFDA nanoprobe was labeled with a secondary fluorophore, Alexa Fluor 568 succinimidyl ester, because otherwise the nanoprobe is invisible until oxidation (Figure 2-a). Second, a membrane penetrating peptide, cysteine terminated TAT peptide (TAT-cys), was conjugated onto the surface of the nanoprobe, so as to deliver them directly to the cytosol<sup>39,40</sup>. As the DCFDA nanoprobe is pH sensitive (Supplementary figure 6), the nanoprobe must be actively delivered to the cytosol, bypassing phagocytotic uptake of macrophages, which is associated with significant acidification<sup>41</sup>.

The generation of H<sub>2</sub>O<sub>2</sub> from RAW264.7 murine macrophage cells, stimulated by a macrophage stimulant, *N*-formyl-Methionyl-*L*-Leucyl-*L*-Phenylalanine (fMLP)<sup>42</sup>, was monitored by DCFDA nanoprobe. Two control experiments were performed in parallel, one with the nanoprobe without TAT on the surface, so as to observe the effect of cytosolic delivery, and the other with the TAT-conjugated nanoprobe but without the addition of fMLP, so as to confirm that the response was induced by an oxidative burst. Macrophages without incubation with nanoprobe and without addition of fMLP were used to determine the autofluorescence background of the cells.

The fluorescence intensity changes of the nanoprobe were monitored over 6 hours after addition of fMLP, until the fluorescence was stabilized (Figure 2-b). The TAT conjugated nanoprobe, with stimulation, showed a fast increase of emission intensity for 1 hour, then the rate of increase slowed down until 4 hours, and stabilization occurred later on. The quantity of H<sub>2</sub>O<sub>2</sub> detected by the nanoprobe was assessed by comparison with the final product, DCF (from Sigma-Aldrich), applying a 1:1 stoichiometry in the reaction between H<sub>2</sub>O<sub>2</sub> and DCFDA dye molecules (overall, DCFDA+H<sub>2</sub>O<sub>2</sub>→DCF+H<sub>2</sub>O), based on a literature method<sup>15,43,44</sup> (Supplementary figure 7). Based on the Alexa 568 fluorescence, we estimated the concentration of nanoprobe in the cells to be about 12 mg/mL. This guarantees that there were enough DCFDA nanoprobe inside each cell for a reliable measurement. The H<sub>2</sub>O<sub>2</sub> concentration detected by the TAT conjugated nanoprobe, with fMLP stimulation, was equivalent to 18 nM. This result shows that low nM concentrations of H<sub>2</sub>O<sub>2</sub> can indeed be successfully detected in live cells by these nanoprobe. The nanoprobe without TAT exhibited a significantly reduced response to H<sub>2</sub>O<sub>2</sub>, which may imply that the nanoprobe's sensitivity towards H<sub>2</sub>O<sub>2</sub> was hindered by the phagocytotic acidification.

In summary, the improved H<sub>2</sub>O<sub>2</sub> selectivity of the DCFDA Ormosil nanoprobe is an outcome of a synergistic combination of three different matrix exclusion principles: time barrier, hydrophobic energy barrier, and size barrier. The resultant high specificity is assisted further by negligible dye leaching and by a wide dynamic range, thus enhancing the accuracy and applicability of the measurements. It appears that these DCFDA nanoprobe may provide a powerful chemical detection/imaging tool for investigating biological mechanisms related to H<sub>2</sub>O<sub>2</sub>, with high spatial and temporal resolution. Similar principles and nanoprobe platforms may be applied to the determination of other important biochemical species.

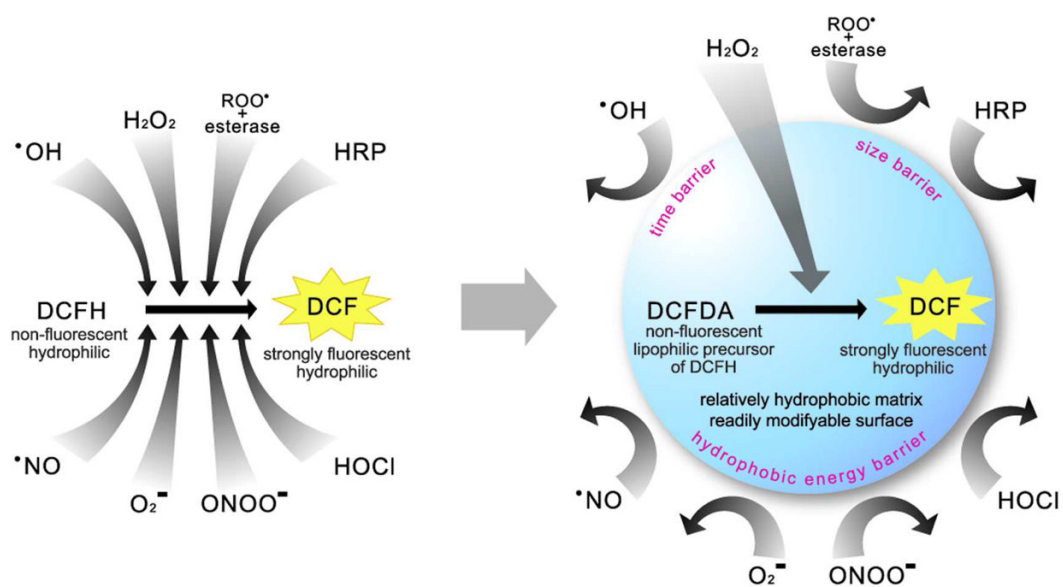

**Figure 1.** Negligible dye leaching from DCFDA nanoprobe. Filtrate of DCFDA nanoprobe did not respond to  $\text{H}_2\text{O}_2$ , indicating that the reaction between DCFDA dye and  $\text{H}_2\text{O}_2$  was confined to the inside of the nanoparticle matrix. Note that the change of filtrate's fluorescence values are so small that they are barely visible in the chart. This Figure validates the hypothesis of induced selectivity by nanoencapsulation.

**Figure 2.**

*In vitro* H<sub>2</sub>O<sub>2</sub> detection performed with DCFDA nanoprobes. a) Confocal image showing cellular uptake of DCFDA nanoprobes. The nanoprobes were incubated with RAW264.7 macrophage cells overnight. The nanoprobes were delivered to the cytosol by the TAT peptide function. The cells were stained by Calcein-AM (green colored, ex: 488 nm, em: 525 nm) and the nanoprobes were visualized by a secondary label, Alexa 568 (red colored, ex: 568 nm, em: 600 nm). b) Fluorescence increase over time due to H<sub>2</sub>O<sub>2</sub> generation from macrophages upon stimulation with fMLP: TAT-conjugated nanoprobes (◆), control without TAT (■), and control without stimulation (▲). The DCFDA nanoprobes showed a significantly larger increase of fluorescence from stimulated cells than from the control (caused by auto-oxidation or natural H<sub>2</sub>O<sub>2</sub> generation).

**Scheme 1.**

Schematic representation of induced  $\text{H}_2\text{O}_2$  selectivity by encapsulating DCFDA into relatively hydrophobic Ormosil nanoparticles. The left scheme shows that DCFH (activated form) can be oxidized by a variety of interferents. The right scheme shows that a relatively hydrophobic nanoparticle matrix encapsulating DCFDA (precursor form) can filter the interferences, thus only allowing penetration of  $\text{H}_2\text{O}_2$ , resulting in high selectivity towards this specific analyte.

**Table 1**

The DCFDA nanoprobe's  $\text{H}_2\text{O}_2$  sensitivity vs concentration. DCFDA nanoprobe shows a fluorescence generation that increases monotonically with the  $\text{H}_2\text{O}_2$  concentration.

$\text{H}_2\text{O}_2$ concentration	Fluorescence increase over 5 minutes
87 $\mu\text{M}$	5045 $\pm$ 585 %
8.7 $\mu\text{M}$	543 $\pm$ 79 %
870 nM	94 $\pm$ 17 %
87 nM	41 $\pm$ 5 %
8.7 nM	17 $\pm$ 6 %
0 nM	2 $\pm$ 2%

**Table 2**

DCFDA nanoprobe resistance to interferences from other ROS and HRP. The fluorescence generation upon introduction of various ROS interferents is compared between a solubilized DCFDA free dye solution (dissolved in a trace amount of DMSO and then diluted in an excess amount of aqueous media) and the DCFDA nanoprobe solution. Note, however, that the activated free dye, DCFH, is much more sensitive to  $\text{ROO}^\cdot$  (in Supplementary figure 8-f).

Interfering ROS	Fluorescence increase over 5 minutes	
	DCFDA free dye	Nanoprobe
$\cdot\text{OH}^a$	$24.1 \pm 0.3 \%$	$-6.8 \pm 0.0 \%$
$\text{O}_2^{\cdot-}{}^b$	$53.3 \pm 4.2 \%$	$0.0 \pm 0.9 \%$
$\cdot\text{NO}^c$	$26.6 \pm 3.3 \%$	$-0.4 \pm 0.9 \%$
$\text{ONOO}^-{}^d$	$199.4 \pm 17.9 \%$	$15.3 \pm 2.4 \%$
$\text{HOCl}^e$	$55.2 \pm 6.0 \%$	$-26.8 \pm 6.1 \%$
$\text{ROO}^\cdot{}^f$	$0.0 \pm 0.8 \%$	$0.0 \pm 0.1 \%$
$\text{HRP}^g$	$556.5 \pm 16.8 \%$	$1.9 \pm 0.1 \%$

<sup>a</sup>Generated from Fenton reaction ( $\text{Fe}^{2+} + \text{H}_2\text{O}_2$ ), ferrous chlorate (final 1  $\mu\text{M}$ ) and  $\text{H}_2\text{O}_2$  (final 8.7  $\mu\text{M}$ ). Note that the fluorescence increase here results from both  $\cdot\text{OH}$  radical and  $\text{H}_2\text{O}_2$ .

<sup>b</sup>Generated by ionization of  $\text{KO}_2$  in aqueous medium, (final 100  $\mu\text{M}$   $\text{O}_2^{\cdot-}$ )
