Abstract

Prostate adenocarcinoma is the second leading cause of cancer death among men, due primarily to the fact that the majority of prostate cancers will eventually spread to the skeleton. Metastatic dissemination requires a complex series of coordinated events that result in cells that escape from the primary tumor into the circulation and eventually colonize a distant organ. The ability of these cells to evolve into macroscopic metastases depends strongly on their compatibility with, and ability to utilize, this new microenvironment. We previously showed that bone-metastatic prostate cancer cells exposed to human bone marrow respond by activation of cell survival pathways, such as PI3K/Akt, and that these events are mediated by the alpha-receptor for platelet-derived growth factor (PDGFR α). Our studies and others have shown that PDGFR α may be activated by mechanisms independent of PDGF ligand binding.

Here we provide conclusive evidence that soluble components of human bone marrow can activate PDGFR α through a mechanism that does not require the canonical binding of PDGF ligand(s) to the receptor. In particular, we found dimerization of PDGFR α monomers is not induced by human bone marrow, but this does not prevent both receptor phosphorylation and downstream signaling from occurring. To establish the relevance of this phenomenon *in vivo*, we employed a PDGFR α mutant lacking the extracellular ligand-binding domain. Our studies show that this truncated PDGFR α was able to restore bone-metastatic potential of prostate cancer cells as effectively as the full-length form of the receptor.

INTRODUCTION

Prostate adenocarcinoma is the second leading cause of cancer related death among men, despite a largely successful treatment of the primary tumor following early detection [1]. The main problem for therapy is that the majority of prostate cancers will eventually disseminate

⁴Corresponding author: Dr. Alessandro Fatatis, Department of Pharmacology and Physiology, Drexel University College of Medicine, 245 N. 15th Street – MS 488, Philadelphia, PA 19102, USA. afatatis@drexelmed.edu.

to the skeleton. This complication leads to a significant decline in quality of life and is currently untreatable, representing the main cause of death in patients with advanced disease [2].

Metastatic dissemination is a concerted multi-step process in which cancer cells spread from the primary tumor into the vasculature, survive in the circulation and reach distant organs [3]. Cancer cells that spread to secondary sites must initially adhere to the luminal surface of endothelial cells, and subsequently migrate in response to chemo-attractant cues produced by the tissue microenvironment [4] [5]. Further progression into clinically significant metastases depends strongly on the ability of cancer cells to support their survival and proliferation in the parenchyma of the secondary organ. In fact, it is widely agreed that cancer cells that fail to adapt to a specific organ microenvironment will either perish or remain dormant; where they are incapable of causing harm to the patient unless growth is resumed [6] [7].

Cancer cells that disseminate to the skeleton through the circulatory system encounter the bone marrow immediately following extravasation from the vascular sinusoids. Their propensity to grow into macroscopic secondary tumors is most likely dictated by favorable conditions offered by this tissue, such as compatible trophic factors [8] [9]. Thus, interference with these symbiotic interactions has been proposed as a powerful means to counteract skeletal metastases [10].

Effective therapies against skeletal metastases might be achieved by identification and blockade of molecular targets that result in disruption of the host/tumor relationship. To this end, we exposed bone-metastatic prostate cancer cells to bone marrow aspirates from human donors, and found that they responded by activation of downstream cell survival pathways, such as PI3K/Akt [11]. We also determined that these events are mediated by the alpha-receptor for platelet-derived growth factor (PDGFR α), a receptor tyrosine kinase expressed at higher levels in bone-metastatic cells than in cells that lack bone tropism [12]. In addition, we demonstrated that targeting PDGFR α with a humanized monoclonal antibody dramatically prevents the growth of skeletal lesions in an animal model of disseminated prostate cancer [13]. When PDGFR α was over-expressed in prostate cancer cells that lacked bone-metastatic potential, it restored their ability to survive during the first days following extravasation in the bone marrow. This allowed these cells to progress into secondary bone tumors that were comparable in number and size to those produced by metastatic cancer cells that endogenously express higher levels of the receptor [13]. The emphasis we place on the role of PDGFR α in prostate cancer progression and dissemination is also based on studies by other groups which reported detection of PDGFR α in human samples from both primitive prostate adenocarcinoma [14] [15] and bone secondary tumors [16]. While the contribution of PDGFR α in the promotion of skeletal metastases from prostate and breast cancers is progressively emerging [17] [18], studies focusing on the mechanisms of receptor activation and recruitment of downstream signaling pathways have provided some exciting results. In particular, recent evidence suggests that PDGFR α may be activated by novel mechanisms, alternative to the conventional binding of PDGF ligand(s) to the receptor. For instance, Lei and Kazlauskas have shown that generation of reactive oxygen species (ROS) is sufficient for Src kinase-mediated activation of PDGFR α [19]. Additional evidence demonstrates that PDGFR α associates with, and is activated in response to, infection by human cytomegalovirus [20]. In agreement with these studies, we have found that activation of PDGFR α by human bone marrow could occur despite blockade of the extracellular ligand-binding domain [11].

Here we provide conclusive evidence that the acellular fraction of human bone marrow can activate PDGFR α through a mechanism that does not require the canonical binding of PDGF ligand(s) to the receptor. In particular, we found that human bone marrow does not induce dimerization of PDGFR α monomers, but this does not prevent both receptor phosphorylation and downstream signaling from occurring. To establish the relevance of this phenomenon *in vivo*, we employed a PDGFR α mutant lacking the extracellular ligand-binding domain. Our

studies show that this truncated PDGFR α was able to restore bone-metastatic potential of prostate cancer cells as effectively as the full-length form of the receptor.

MATERIALS AND METHODS

Reagents

Both PP2 (4-Amino-5-(4-chlorophenyl)-7-(t-butyl)pyrazolo [1,5-a]pyrimidine) and NAC (N-acetyl-L-cysteine) were obtained from Calbiochem (San Diego, CA).

Cell Lines and Cell Culture—PC3-ML and PC3-N cell lines were derived from the parental PC-3 cell line (ATCC, Manassas, VA) as previously described [21]. DU145 cells were purchased from ATCC. All cell lines were cultured at 37°C and 5% CO₂ in DMEM supplemented with 10% fetal bovine serum (Hyclone, Logan, UT) and 0.1% gentamicin (Invitrogen, Carlsbad, CA). Cells were engineered to stably-express EGFP as described below.

Ectopic PDGFR α Expression—Human full-length PDGFR α (NM_006206) and its truncated form ($\alpha\Delta X$) were expressed in the identical lentiviral vector (America Pharma Source) used to obtain stably fluorescent cells as previously described [13]. The truncated PDGFR($\alpha\Delta X$) lacks amino acids 45-524, corresponding to the entire extracellular domain with the exception of the signal peptide (AA 1-44). Amino acid 45 in this truncated receptor corresponds to leucine 525 of the full-length form, which is the beginning of the transmembrane domain [22]. Cells were transduced using an MOI of 50 ifu/cell. As the lentiviral vector contains an EGFP-IRES site, the cells expressing PDGFR α were isolated and purified by flow cytometry and sorting based on their fluorescence intensity.

Human Bone Marrow Acquisition and Processing

Bone marrow samples from healthy male donors (ages 18–45) were supplied by Lonza Biosciences (Poetics™ Donor Program). Samples were shipped and maintained at 4° C throughout processing. Briefly, samples were centrifuged (1,500 rpm for 20 minutes) in order to separate the acellular and cellular phases. Supernatant containing the acellular phase was removed and filtered using 0.8 μ m and 0.22 μ m filters in succession followed by storage at –80° C.

In Vitro Experimental Protocols

Cells were starved from serum for four hours prior to being exposed to bone marrow or PDGF-AA (30ng/ml). Fifty micro-liters of processed bone marrow were administered to cells in 1ml of experimental medium for a final 1:20 dilution. PP2 was used at a concentration of 10 μ M and IMC-3G3 was used at a concentration of 20 μ g/ml. Receptor crosslinking experiments were carried out on ice and/or at 4°C using the chemical crosslinker BS₃ (Pierce) at a concentration of 2mM. Briefly, cells were incubated with either ligand or bone marrow for the time periods indicated, followed by incubation with BS₃ for 30m at 4°C. Crosslinking was then quenched by the addition of 20 mM Tris for five minutes at room temperature.

SDS-PAGE and Western Blotting

Cell lysates were obtained and SDS-PAGE and Western Blot analysis performed as previously described [23], with few modifications. Membranes were blotted with antibodies targeting phospho-Akt (Ser-473, Cell Signaling Technology), PDGFR α (R&D Systems) and total Akt (Cell Signaling). Primary antibody binding was detected using an HRP-conjugated secondary antibody (Pierce). Chemiluminescent signals were obtained using SuperSignal West Femto reagents (Pierce) and detected with the Fluorochem 8900 imaging system and relative software (Alpha Innotech). Densitometry analysis was performed using the UN-SCAN IT software (Silk

Scientific). Samples were run on the same gels for effective comparison of intensity levels. Each experiment was repeated at least three times and provided similar results.

Detection of PDGFR α phosphorylation

Cells were washed twice with ice cold PBS and lysed with immunoprecipitation buffer (50mM Tris, 150mM NaCl, 10mM NaF, 10mM sodium pyrophosphate, 1% NP40) supplemented with protease and phosphatase inhibitors (Protease Inhibitor Cocktail Set III, Phosphatase Inhibitor Cocktail Set II, Calbiochem). 750 μ g of cell lysates were incubated with agarose-conjugated anti-PDGFR α primary antibody (Santa Cruz) for one hour at 4°C. Immunoprecipitation was carried out according to the manufacturer's protocol, with immunoprecipitated protein run on a 7.5% polyacrylamide gel. Western blotting was carried out as previously described using an antibody directed against phospho-Tyrosine (Cell Signaling) or phospho-PDGFR α (Tyr-742, Cell Signaling). Equal loading was confirmed by stripping the membrane and blotting for total PDGFR α .

Animal model of metastasis—Five week-old male immuno-compromised mice (CB17-SCRF) were obtained from Taconic and housed in a germ-free barrier. At six weeks of age, mice were anesthetized with 100mg/kg ketamine and 20mg/kg xylazine and successively inoculated in the left cardiac ventricle with cancer cells (5×10^4 in 100 μ l of serum-free DMEM/F12). All cancer cells used in our *in vivo* studies were stably transduced using a lentiviral vector (America Pharma Source) expressing enhanced Green Fluorescent Protein (eGFP), either with an exogenous gene insert (full-length PDGFR α or its α AX truncated form) or as an empty-vector. PC3-ML and PC3-N cells expressing the empty-vector showed metastatic abilities identical to their wild-type counterparts, as established in our previous studies [11], [13]. As also previously described, the only soft-tissue organs that we find are harboring cancer cells at four weeks post-inoculation are the adrenal glands. However, these tumors remain contained in size and never produce tumor burden in the inoculated animals [13].

Mice were sacrificed at specified time-points following inoculation and tissues prepared as described below. All experiments were conducted in accordance with NIH guidelines for the humane use of animals. All protocols involving the use of animals were approved by the Drexel University College of Medicine Committee for the Use and Care of Animals.

Tissue Preparation—Bones and soft-tissue organs were collected and fixed in 4% formaldehyde solution for 24 hours and then transferred into fresh formaldehyde for additional 24 hours. Soft tissues were then placed either in 30% sucrose for cryoprotection or 1% formaldehyde for long-term storage. Bones were decalcified in 0.5M EDTA for 7 days followed by incubation in 30% sucrose. Tissues were maintained at 4°C for all aforementioned steps and frozen in O.C.T. medium (Electron Microscopy Sciences, Hatfield, PA) by placement over dry-ice chilled 2-methylbutane (Fisher, Pittsburgh, PA). Serial sections of 80 μ m in thickness were obtained using a Microm HM550 cryostat (Mikron, San Marcos, CA).

Fluorescence stereomicroscopy and morphometric analysis of metastases—Bright-field and fluorescent images of skeletal metastases were acquired using a SZX12 Olympus stereomicroscope coupled to an Olympus DT70 CCD color camera. Digital images were analyzed with ImageJ software (<http://rsb.info.nih.gov/ij/>) and calibrated for measurement by obtaining a pixel to millimeter ratio. Morphometric evaluation of skeletal tumors was conducted by analysis of serial cryosections, in which the largest representative tumor section for each metastasis was identified. A freehand tool was used to outline the border of each metastatic lesion, and the area was computed using the ImageJ 'measure area' function.

Statistics—Data shown in figures are representative of at least two experiments providing similar results. We analyzed number and size of skeletal metastases between groups using a two-tailed Student's *t*-test. A value of $P \leq 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

We have previously shown that the activation of the PI3K/Akt pathway in bone-metastatic prostate cancer cells exposed to human bone marrow aspirates depends mostly on PDGFR α signaling [11]. Furthermore, prostate cancer cells that lack bone-metastatic potential - and were less responsive to bone marrow - could activate Akt to the same extent of bone-metastatic cells following PDGFR α overexpression [13]. Therefore, our first series of experiments sought to ascertain whether the acellular fraction of human bone marrow would induce phosphorylation of PDGFR α - as is the case when this receptor binds, and is activated by, its proper PDGF ligands [24]. As done for our previous studies, we employed PC3-ML cells, a sub-population of the human PC3 cell line originally derived from a skeletal metastasis in a patient affected by prostate adenocarcinoma [25]. PC3-ML cells were originally selected for their invasiveness *in vitro* in concert with their bone-metastatic potential in animal models [21]. When these cells were exposed to bone marrow, PDGFR α phosphorylation was clearly detected and lasted at least 30 minutes (Fig.1A). The ability of bone marrow to phosphorylate PDGFR α could be consistently observed using aspirates withdrawn from different donors (Fig.1B, **top**).

Structural and functional studies have shown that PDGF binding induces dimerization of PDGFR; this allows the *trans*-phosphorylation of several conserved tyrosine residues on the juxtaposed intracellular portion of each receptor [26]. In addition to enhancing the catalytic activity of the kinase domain, this event creates docking sites for the binding and activation of signal transduction mediators containing SH2 domains, including members of the PI3K family [27]. At least eight tyrosine residues on PDGFR α become phosphorylated upon binding of PDGF ligand(s) [28], likely contributing to the strong signal observed in our experiments (Fig. 1 A–B).

Interestingly, the considerably lower magnitude of PDGFR α phosphorylation induced by bone marrow - as compared to that induced by PDGF ligand(s) - did not translate to a significantly lower activation of the downstream Akt pathway. In fact, remarkably close levels of Akt phosphorylation were observed after exposing PC3-ML cells to either PDGF or bone marrow (Fig. 1B, **bottom**) and as evidenced by a time-dependent kinetic (Fig. 1C). In addition, we had previously demonstrated that the majority of this observed Akt activation is due solely to PDGFR α signaling [11]. This suggests that the activation of PI3K, which is functionally upstream of, and mainly responsible for, Akt phosphorylation, must be almost equivalent in these two conditions. Thus, we speculate that the majority of PDGFR α phosphorylation caused by bone marrow corresponds to Tyr-731 and Tyr-742 residues, which specifically bind and activate PI3K [24]. This would explain the lower magnitude of receptor phosphorylation as compared to stimulation by PDGF ligands. However, the phosphorylation of only select tyrosine residues could hardly be justified in the event that bone marrow induces PDGFR α dimerization. In fact, whereas dimers could be observed upon exposure of PC3-ML cells to PDGF-AA, human bone marrow consistently lacked the ability to induce dimerization of PDGFR α in these cells (Fig. 2A–B).

This initial evidence of an unorthodox mechanism used by bone marrow to initiate PDGFR α signaling was further confirmed by a second set of experiments in which dimerization was blocked using a monoclonal antibody directed against the extracellular portion of the receptor. The humanized antibody IMC-3G3 blocks the ligand-binding domain of PDGFR α [11], [29], thereby inhibiting receptor dimerization following treatment with PDGF-AA (Fig.3A). By blocking ligand-induced dimerization, IMC-3G3 also prevented PDGFR α trans-

phosphorylation (Fig.3B), which normally occurs by juxtaposition of intracellular kinase domains between receptor monomers [27] [30]. However, no differences in PDGFR α phosphorylation were observed when cells were exposed to bone marrow alone or in the presence of IMC-3G3 (Fig.3B). This result provides compelling evidence that dimerization is not a pre-requisite for the activation of PDGFR α by the soluble fraction of human bone marrow in PC3-ML prostate cancer cells. If this was indeed the case, an active kinase must still phosphorylate the tyrosine residues responsible for recruitment of PI3K to the receptor, as this step should precede downstream activation of Akt by PDGFR α exposed to bone marrow. One likely possibility was the hetero-dimerization of PDGFR α with other tyrosine-kinase receptors. However, this event could be excluded by the absence of any dimer formation following treatment of cells with bone marrow and subsequent cell-surface receptor crosslinking (Fig.2).

Thus, we hypothesize that PDGFR α is activated without recruitment of its ligand-binding domain and consequent dimerization, possibly by a soluble tyrosine-kinase that phosphorylates the monomeric form of the receptor. In fact, this idea is strongly supported by a recent study of proliferative vitreoretinopathy showing that activated Src family kinases (SFKs) phosphorylate PDGFR α in mouse embryo fibroblasts exposed to rabbit vitreous humor, the clear viscous fluid that occupies the space between the retina and lens of vertebrates' ocular bulb [31].

In these cells, growth factors outside of the PDGF family and present in the vitreous can activate their specific receptor(s), thereby increasing the levels of intracellular reactive oxygen species (ROS). This event led to the direct activation of SFKs, which then mediated the phosphorylation of PDGFR α [19]. We have previously shown that human bone marrow activates downstream Akt despite containing negligible levels of PDGF ligands (measured at 150pg/ml by ELISA [11]), and also induces evident PDGFR α phosphorylation (Fig. 4A). Thus, if bone marrow were engaging PDGFR α in prostate cancer cells with a mechanism analogous to vitreous humor in mouse embryo fibroblasts, this would similarly require an increase in intracellular ROS. In this case, either anti-oxidants or inhibitors of SFKs should then block the activation of PDGFR α . To test this possibility, we treated PC3-ML cells with either 5mM hydrogen peroxide alone or bone marrow in the presence of the anti-oxidant N-Acetylcysteine (NAC, 10mM). The first condition – adopted to induce intracellular ROS production – was unable to induce PDGFR α phosphorylation. Analogously, NAC did not prevent the activation of the receptor and downstream PI3K/Akt signaling caused by bone marrow (data not shown).

We could also exclude the involvement of SFKs in the activation and signaling of PDGFR α induced by bone marrow by using PP2, a specific inhibitor of this family of kinases [32], [33]. In PC3-ML cells, PP2 did not prevent Akt phosphorylation by bone marrow (Fig. 4B), whereas it completely blocked stimulation of this pathway by PDGF-AA. This finding is in agreement with a described role of SFKs in coordinating ligand-induced recruitment of signaling pathways by tyrosine-kinase receptors, by acting upstream of PI3K [34] [35].

Taken together, these results lead us to conclude that human bone marrow activates PDGFR α on prostate cancer cells in a manner that is distinct from the factors found in vitreous humor, supporting the idea that there may be multiple mechanisms whereby this receptor can be activated without involvement of its canonical PDGF ligands.

It is widely recognized that the activity of the kinase domain in tyrosine kinase receptors is significantly augmented upon dimerization and trans-phosphorylation [30]. Because we observed a lack of PDGFR α dimerization upon exposure of prostate cancer cells to human bone marrow, one would predict that the kinase domain is neither necessary nor responsible for the phosphorylation of monomeric PDGFR α . To effectively investigate this idea, we used two different prostate cancer cell lines that show low levels of this receptor (PC3-N) or

completely fail to express it (DU-145) [12] and engineered them to stably express a kinase-inactive PDGFR α mutant (R627)[36]. Surprisingly, both R627-expressing cell types failed to show receptor phosphorylation upon bone marrow exposure, in contrast to when the same cell types over-express the wild-type form of PDGFR α (Fig. 4C). Thus, these results implicate the kinase domain in the phosphorylation and signaling of monomeric PDGFR α induced by bone marrow. This observation suggests the possibility of a receptor autophosphorylation event, independent of ligand-induced dimerization, and most likely affecting the tyrosine residues responsible for PI3K binding and activation. The identification of the mechanism and signaling mediators responsible for this event are the focus of an ongoing investigation in our laboratory.

In previous animal studies we have shown that PDGFR α can confer bone-metastatic potential to prostate cancer cells [13]. Intriguingly, the role exerted by this receptor in the metastatic process may require its indirect activation – likely through the activity of yet unidentified factor. To further investigate this peculiarity of PDGFR α signaling, we stably transfected cancer cells with a truncated receptor mutant ($\alpha\Delta X$) that lacks the extracellular ligand-binding domain (see Materials and Methods for details) and is therefore unable to bind or be activated by proper PDGF ligand(s) or additional molecules that could activate the receptor in a spurious fashion [22].

A first set of experiments was conducted using DU-145 prostate cancer cells, which normally do not express PDGFR α [12] and would therefore not interfere by providing additional signaling through its wild-type full form. The $\alpha\Delta X$ expressed in these cells (Fig. 5A) was clearly insensitive to PDGF-AA, as expected due to its lack of binding capability and shown by the absence of any receptor phosphorylation (Fig. 5B, **top**). However, the exposure of DU-145($\alpha\Delta X$) cells to human bone marrow aspirates induced strong phosphorylation of the truncated receptor, conclusively demonstrating its ligand-independent activation (Fig. 5B, **top**). This phosphorylation involved the Tyr-742 residue (Fig. 5B, **bottom**), which on PDGFR α specifically corresponds to the PI3K binding site through its SH-2 domain [30] [24], unequivocally linking the soluble fraction of human bone marrow to the downstream activation of the Akt signaling pathway in prostate cancer cells. This event could be observed in cells either constitutively expressing PDGFR α (Fig.1 and refs. [11] [13]) or engineered to express the exogenous form of this receptor (Fig.5C).

A second series of experiments aimed to ascertain whether the $\alpha\Delta X$ receptor could reproduce the enhanced capacity of skeletal metastases from prostate cancer cells, as we had previously shown for its full-length form [13]. A confirmatory result would convincingly demonstrate that PDGFR α could induce a pro-metastatic phenotype, with pronounced bone-tropism, through a ligand-independent transactivation caused by the acellular fraction of bone marrow. PC3-N cells were originally selected from the parental PC3 cell line for their lack of invasiveness *in vitro* [21]. We have previously shown that PC3-N cells express lower levels of PDGFR α and respond weakly to human bone marrow as compared to their bone-metastatic counterpart PC3-ML cells [12] [13]. Most importantly, PC3-N cells disseminate to the bone when inoculated in the blood circulation of SCID mice, but fail to grow into macroscopic skeletal metastases unless they are engineered to over-express full-length PDGFR α [13]. When PC3-N cells were stably transduced with a lentiviral vector expressing PDGFR($\alpha\Delta X$) (Fig. 5A) and exposed to bone marrow, Akt was phosphorylated to the same extent observed in either PC3-ML cells (Fig.6A) or PC3-N cells expressing full-length PDGFR α treated in the same fashion.

In order to test their bone-metastatic potential, PC3-N($\alpha\Delta X$) cells were then inoculated via an intracardiac route into SCID mice and the skeletal metastases observed at 4-week post-inoculation were compared to those detected in mice receiving the highly bone-metastatic PC3-ML cells. When the bone tumors in these two groups of mice were compared, no significant

differences in size were observed and the location and bone-destructive properties induced by the $\alpha\Delta X$ and full-length PDGFR α were nearly identical (Fig.6B,C). These results demonstrate that PDGFR α can both increase the responsiveness of human prostate cancer cells to acellular bone marrow *in vitro* and promote their progression in the bone microenvironment in the absence of any involvement of its ligand-binding domain.

Recognizing that PDGFR α could contribute to dissemination and metastatic progression of prostate adenocarcinoma independently of direct ligand stimulation has significant translational implications. It could be inferred that anti-cancer therapeutics that are designed to block PDGF ligand binding to PDGFR α would not prevent the activation of downstream signaling pathways in cells that have spread to the bone marrow. In contrast, therapeutic approaches that induce internalization of PDGFR α may provide a better option to inhibit downstream signaling elicited by this receptor in disseminated prostate cancer cells when exposed to the bone marrow microenvironment.

Acknowledgments

The authors wish to thank Dr. Olimpia Meucci (Drexel College of Medicine) for helpful discussion, Dr. Gregg Johannes and Mr. Jeff Thomas (Department of Pathology, Drexel College of Medicine) for help with the PDGFR α expressing vector, Dr. Nick Loizos (ImClone Systems Inc., NY) for providing the IMC-3G3 antibody. The cDNA for full-length human PDGFR α was a kind gift of Dr. Carl-Henrik Heldin (Ludwig Institute for Cancer Research, Uppsala, Sweden).

GRANT SUPPORT

This work was funded by the W.W. Smith Charitable Trust and Department of Defense Prostate Cancer Program grant PC080987 (AF) and by The National Institutes of Health EY012509 (AK).

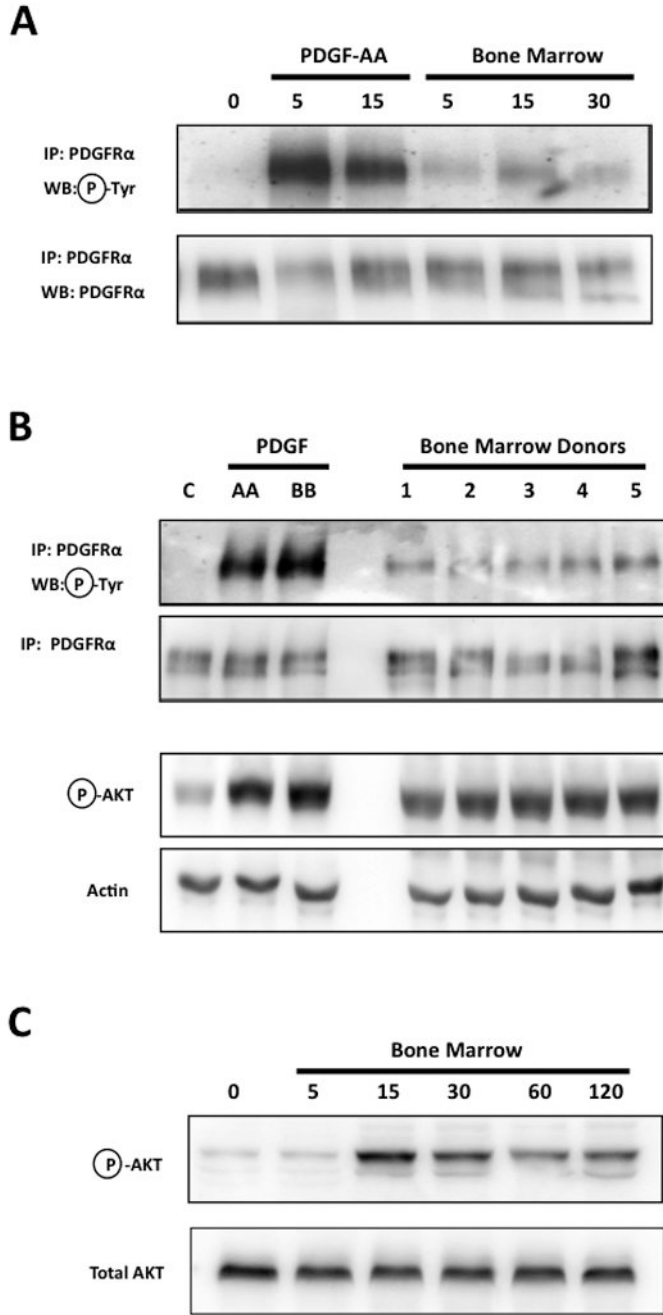

FIGURE 1. Human bone marrow induce phosphorylation of PDGFR α and activation of downstream Akt pathway in prostate cancer cells

The exposure of PC3-ML prostate cancer cells to acellular human bone marrow induces phosphorylation of PDGFR α , although of a lower magnitude compared to that produced by the proper ligand PDGF-AA (30ng/ml) (A); this effect was consistently reproduced by all human samples tested (B, top); despite producing a lower extent of PDGFR α phosphorylation than PDGF-AA, bone marrow activated the downstream signaling kinase Akt to an extent almost equivalent to that of the growth factor (B, bottom) and in a time-dependent fashion (C).

FIGURE 2. Recruitment of PDGFR α by human bone marrow occurs in the absence of receptor dimerization

Phosphorylation of PDGFR α by PDGF-AA was preceded by receptor dimerization, observed as soon as 1 minute after exposure of cells to the ligand. However, bone marrow did not induce PDGFR α dimerization even in cells that were stimulated for up to 30 minutes.

FIGURE 3. Bone marrow-mediated activation of PDGFR α occurs upon blockade of ligand-induced receptor dimerization

Blockade of the ligand binding domain of PDGFR α using the monoclonal antibody IMC-3G3 (20 μ g/ml) prevents receptor dimerization from occurring in response to PDGF-AA ligand (A); As expected, blockade of receptor dimerization prevented receptor phosphorylation in cells exposed to PDGF-AA. However, bone marrow was able to activate PDGFR α despite blockade of PDGFR α dimerization (B).

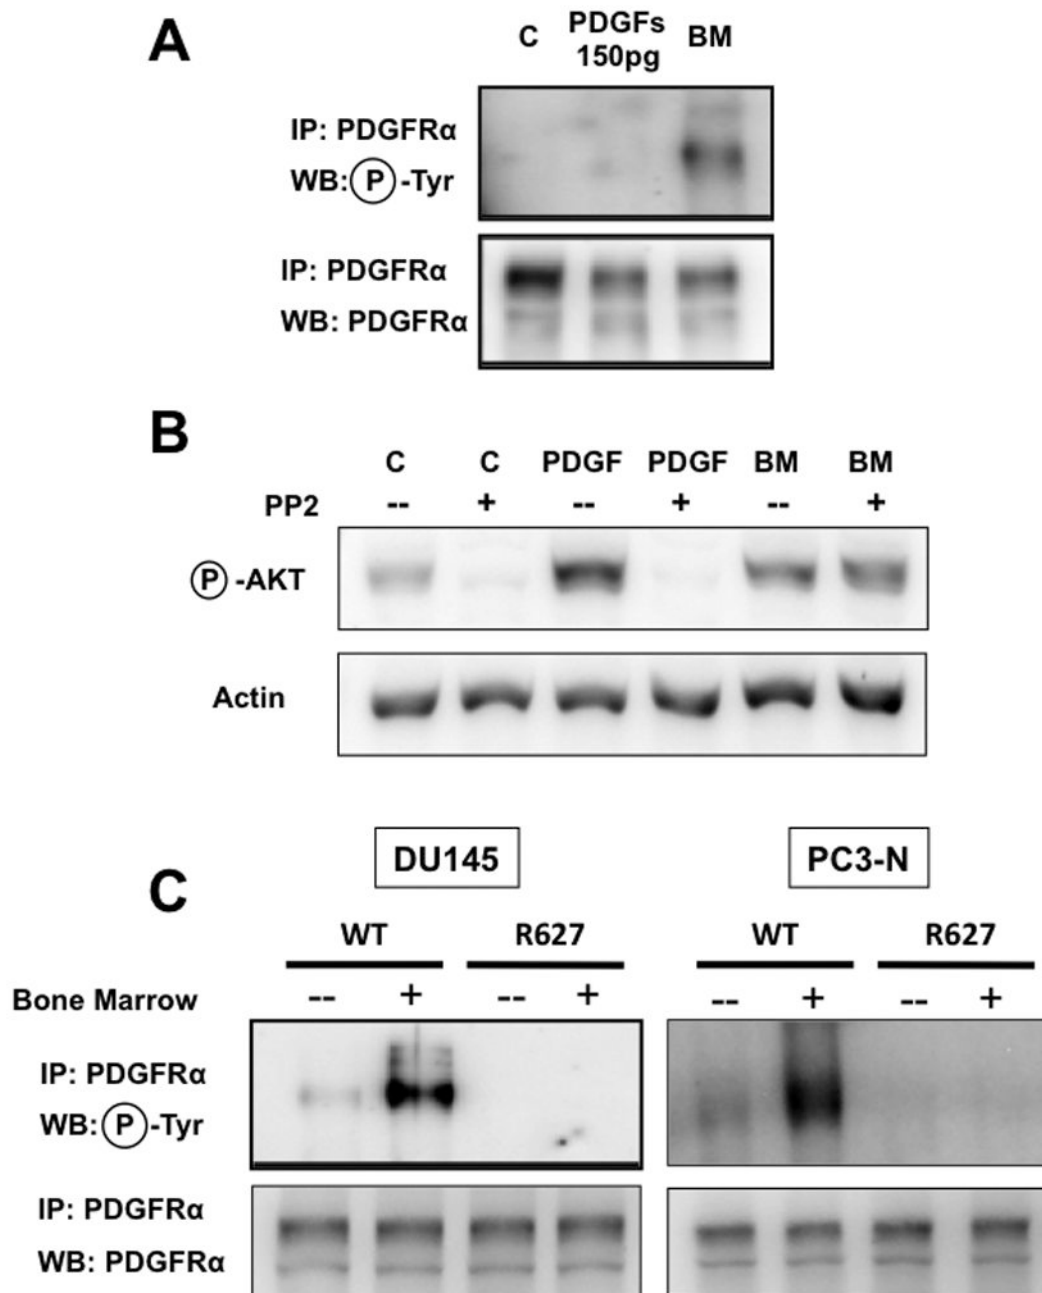

FIGURE 4. PDGF-independent but receptor kinase-dependent phosphorylation of PDGFR α induced by human bone marrow

Exposure of PC3-ML cells to the same concentrations of PDGF ligands detected in human bone marrow fails to achieve receptor phosphorylation (A) or downstream Akt signaling [11]. Signaling through PDGFR α in PC3-ML cells exposed to PDGF ligands depends on the activation of SFKs and was blocked with PP2, an inhibitor of this family of kinases. In contrast, bone marrow-induced signaling through PDGFR α was insensitive to PP2; (B); The R627 kinase-dead mutant of PDGFR α was over-expressed in both DU-145 cells (C, left) and PC3-N (C, right) and demonstrates that bone marrow-mediated activation of PDGFR α requires the receptor kinase-domain for its phosphorylation..

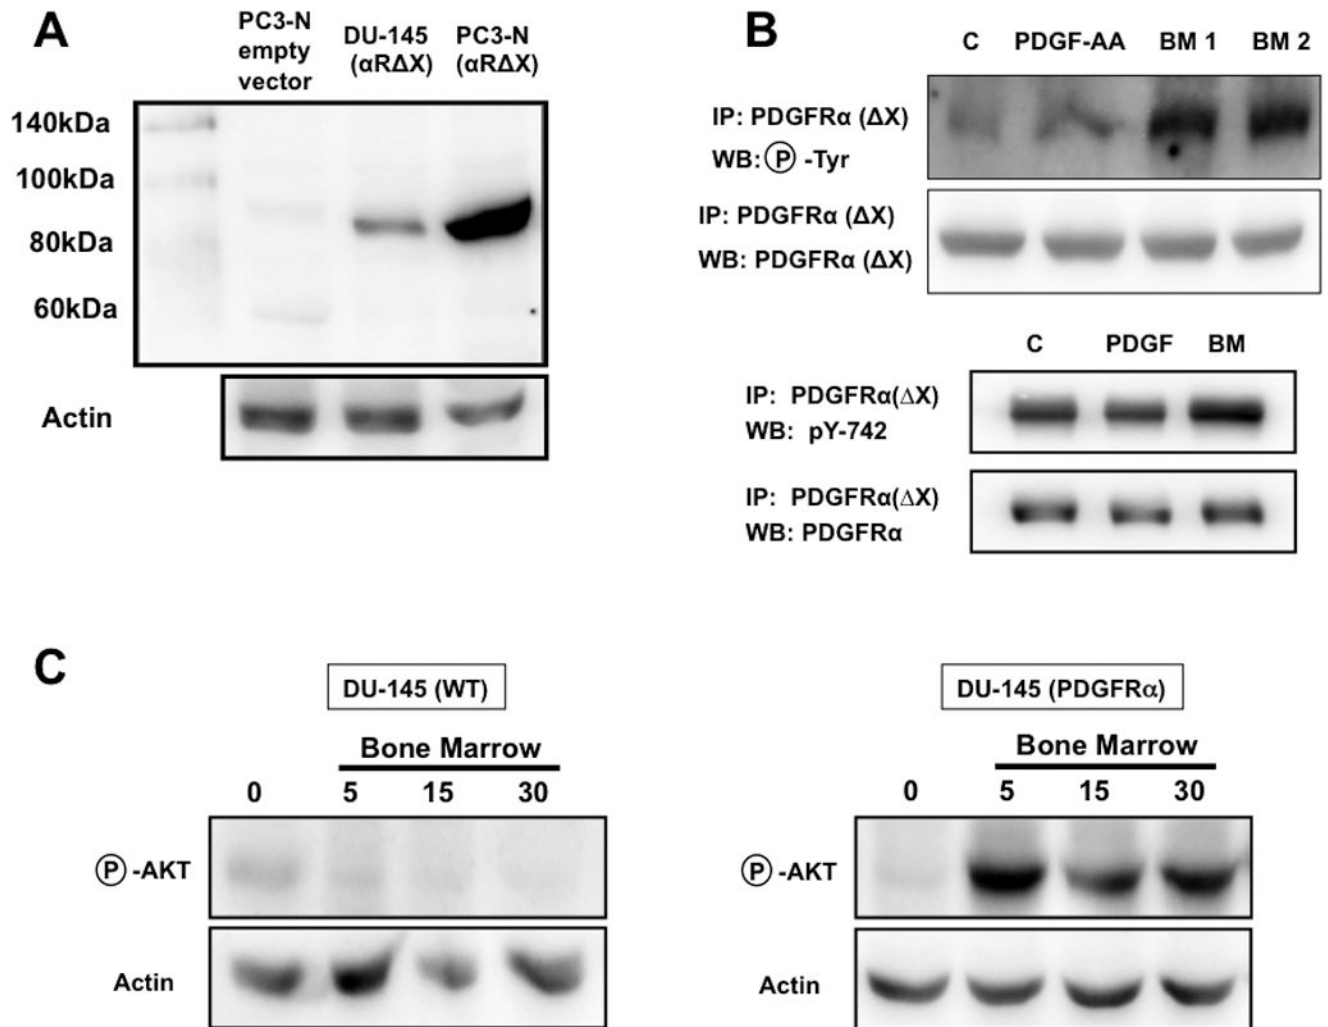

FIGURE 5. PDGFR α activation by human bone marrow is independent of the extracellular ligand-binding domain

A truncated PDGFR α missing the extracellular binding domain ($\alpha\Delta X$) was stably expressed in DU-145 cells, which normally lack PDGFR α expression (A) [12]. As expected, this mutated PDGFR α could not be phosphorylated in cells exposed to PDGF-AA; however, two different samples of human bone marrow elicited a strong receptor phosphorylation (B, top), which involved the Tyr-742 residue, a specific binding site for PI3K (B, bottom); the exposure of wild-type DU-145 cells to bone marrow did not produce an appreciable activation of the PI3K/Akt pathway, which was conferred by the stable expression of PDGFR α , (C).

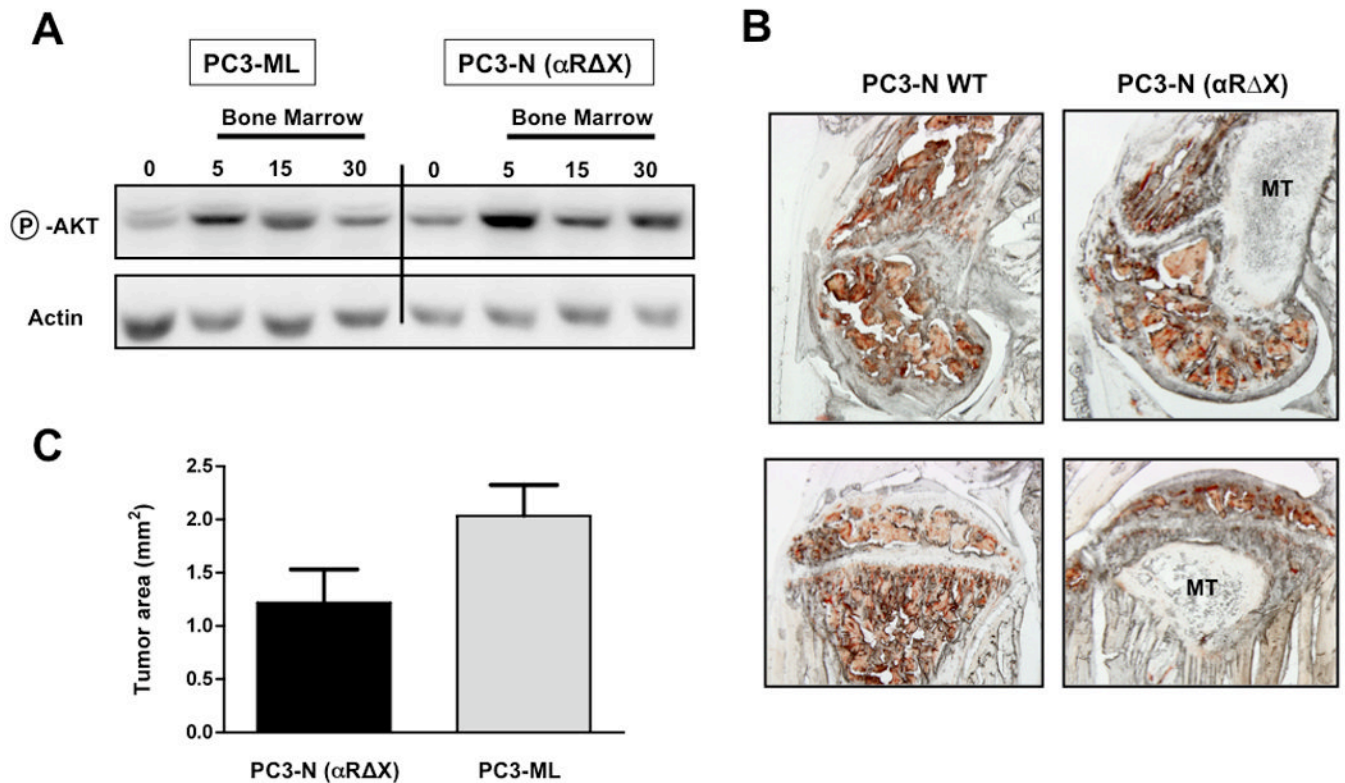

FIGURE 6. PDGFR $\alpha(\Delta X)$ induces a bone metastatic phenotype that is indistinguishable from cells expressing full-length PDGFR α

Expression of PDGFR $\alpha(\Delta x)$ in non-bone-metastatic PC3-N cells results in an increased activation of downstream Akt upon exposure to human bone marrow, to an extent comparable to that observed in bone-metastatic PC3-ML cells (**A**); PC3-N($\alpha\Delta x$) were able to successfully form skeletal lesions four weeks after their intracardiac inoculation in SCID mice (**B**; **top is femur, bottom is tibia**); Importantly, the size of metastases produced by PC3-N($\alpha\Delta x$) cells did not differ significantly from lesions formed by the metastatic PC3-ML cells, which express substantially higher levels of endogenous, full-length PDGFR α (**C**); (**MT** = metastatic tumor). Seven mice were inoculated with PC3-N($\alpha\Delta x$) cells in two different experiments and presented 13 skeletal tumors in total. Eight mice were inoculated with PC3-ML-(empty vector) cells in two different experiments and presented 22 skeletal tumors in total.
