**Abstract** For the resection of anteriorly located meningiomas, various approaches have been used. Posterior approach is less invasive and demanding; however, it has been associated with increased risk of spinal cord injury. We evaluated ten consecutive patients that underwent surgery for spinal meningiomas. All patients were preoperative assessed by neurological examination, computed tomography and magnetic resonance imaging. All tumors were ventrally located and removed via a posterior approach. Transcranial motor-evoked potentials (TcMEPs), somatosensory-evoked potential (SSEP) and free running electromyography (EMG) were monitored intraoperative. Postoperative all patients had regular follow-up examinations. There were four males and six females. The mean age was 68.2 years (range 39–82 years). In nine out of ten cases, the tumor was located in the thoracic spine. A case of a lumbar meningioma was recorded. The most common presenting symptom was motor and sensory deficits and unsteady gait, whereas no patient presented with paraplegia. All meningiomas were operated using a microsurgical technique via a posterior approach. During the operation, free running EMG monitoring prompted a surgical alert in case of irritation, whereas TcMEP and SSEP amplitudes remained unchanged. Histopathology revealed the presence of typical (World Health Organisation grade I) meningiomas. The mean Ki-67/MIB-1 index was 2.75% (range 0.5–7). None of our patients sustained a transient or permanent motor deficit. After a mean follow-up period of

26 months (range 56–16 months), no tumor recurrence and no instability were found. Posterior approach for anteriorly located meningiomas is a safe procedure with the use of intraoperative monitoring, less invasive and well-tolerated especially in older patients. Complete tumor excision can be performed with satisfactory results.

**Keywords** Meningiomas · Spine · Posterior approach · Intraoperative monitoring

### Introduction

Spinal meningiomas constitute approximately 25% of all spinal tumors and are the second most common tumors after the nerve sheath. There is a female predominance and nearly 80% occur in the thoracic spine [1, 2]. The majority are benign and classically found in an intradural extramedullary location. Spinal meningiomas are usually localized lateral to the spinal cord, whereas in 15–27% of cases are located anterior to the spinal cord and constitute a surgical challenge [3]. Herewith, we report on ten cases of anteriorly located spinal meningiomas that were totally excised via a posterior approach with the use of intraoperative monitoring.

### Materials and methods

We evaluated ten consecutive patients that underwent surgery for spinal meningiomas between January 2005 and January 2009. All patients were preoperative assessed by neurological examination, computed tomography (CT) and magnetic resonance imaging (MRI) of the spine. All tumors were ventrally located and removed via a posterior approach. Transcranial motor-evoked potentials (TcMEPs),

somatosensory-evoked potentials (SSEPs) and free running electromyography (EMG) were monitored intraoperative by an experienced neurophysiologist (DK). Postoperative all patients had regular follow-up examinations.

## Operative technique

The patient is positioned prone. After careful preoperative planning, a midline skin incision is performed extending two levels above and below the extent of the lesion. The paraspinal, intrinsic dorsal and deep transversospinal muscles are separated subperiosteally on either side. Depending on tumor size, we performed a monosegmental or multisegmental laminectomy above and below the extent of the tumor. A partial facetectomy ( $\sim 30\%$ ) is performed in order to increase the viewing angle. Pedicles removal was not performed in any case. The dura was opened in the midline and fixed to the sides. Dentate ligament section is usually required to facilitate spinal cord handling. The spinal cord is usually displaced dorsally and rotated by the tumor. Tumor removal begins laterally where the tumor attaches to the dura, in order to minimize thermal injury to the spinal cord. The meningioma shrinks and then is debulked in order to create more space. After tumor removal and careful hemostasis, the dura is coagulated in all cases and primarily closed in a watertight manner.

## Technique for TcMEP, SSEP and EMG

Multipulse transcranial electrical stimulations were generated with an XLTEK stimulator. The electrodes were placed to C1/C2 position of the International 10-20 system. Stimulus intensity was gradually increased from 0 to 200 mA and the duration from 0.2 to 0.5 ms. The first recording was stored as baseline and was compared to the postoperative value. Regarding interpretation of the TcMEP, we used the total loss of amplitude as suggestive of damage. Free running EMG monitoring was performed during operation. The EMG electrodes were placed to the muscles (Netter's dermatomes) according to the thoracic and lumbar segment operated on, in order to record the corresponding nerve roots. Concerning meningiomas in the thoracic region, the electrodes were placed apart from the corresponding muscles (i.e. intercostals, forceps) to the muscles of the lumbar section.

Stimulation of SSEP was performed with electrical pulses of 300-s duration and a maximum intensity of 35 mA at a frequency of 4.7 Hz. Stimulating electrodes were placed over each tibial nerve and the evoked potentials were recorded from the popliteal fossa (right and left),

C5S (cervical 5) or C2S, CP3 (central parietal) and CP4, CPz and FPz (frontal parietal), according to the International 10-20 system. Significant SSEP changes were defined as more than 50% reduction or over 10% delay from baseline values.

## Anesthesia

Anesthesia was maintained with continuous propofol infusion (20 ml/h). No muscle relaxants were used after induction and intubation. Invasive blood pressure, ECG, end-tidal carbon dioxide concentration, pulse oximetry and temperature were monitored.

## Results

Patient's data are summarized in Table 1. There were four males and six females. The mean age was 68.2 years (range 39–82 years). In nine out of ten cases, the tumor was located in the thoracic spine. A single case of a lumbar meningioma was recorded. All meningiomas were intradural and ventrally located to the spinal cord. The most common presenting symptom was motor and sensory deficits and unsteady gait, whereas no patient presented with paraplegia. All meningiomas were operated using a microsurgical technique via a posterior approach (Figs. 1, 2). During the operation, free running EMG monitoring prompted a surgical alert in case of irritation of the lumbar section recordings. In these cases, we ran TcMEP in order to identify changes in the amplitude. In all cases, no change of TcMEP was recorded suggesting no neurological deterioration (Fig. 3). SSEP was also unchanged. Histopathology revealed the presence of typical (World Health Organization grade I) meningiomas. Five meningiomas were psammomatous type, 3 transitional and 2 meningotheiomatous. The mean Ki-67/MIB-1 index, which is a proliferation index of the tumor, was 2.75% (range 0.5–7). None of our patients sustained a transient or permanent motor deficit. Postoperative all patients had marked neurological improvement. After a mean follow-up period of 26 months (range 56–16 months), no tumor recurrence was noted on MRI evaluation and no instability.

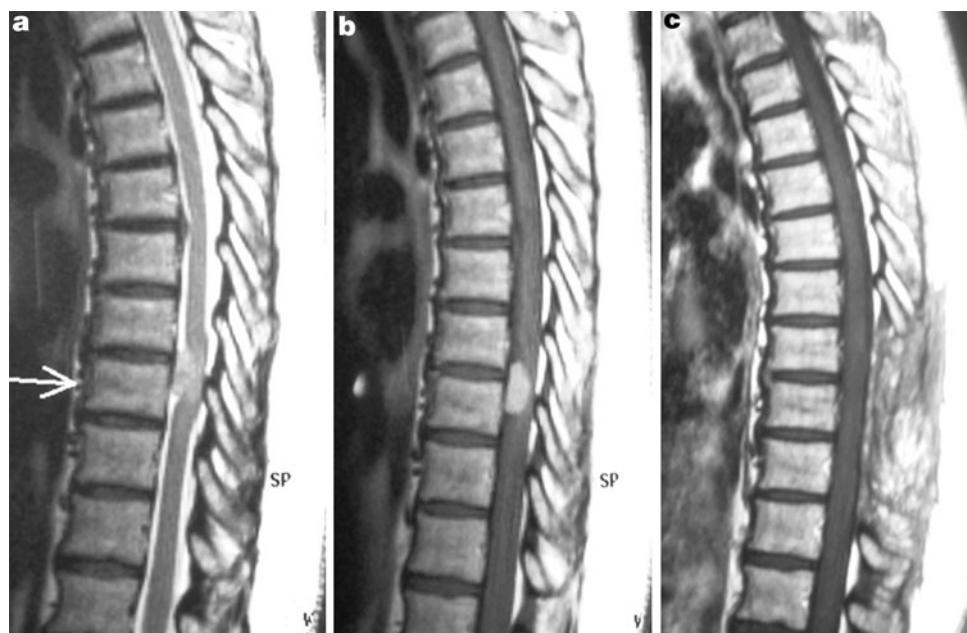

## Discussion

Spinal intradural extramedullary tumors account for 2/3 of all intraspinal neoplasms and are mainly represented by meningiomas and schwannomas, with the former accounting for approximately 25% of all primary intraspinal tumors [1]. Spinal meningiomas occur less

**Table 1** Summary of patient's data

	Age/sex	Location	Symptoms	Grade	Histology	MIB-1 (%)
1	60/F	Thoracic	Radicular pain, sensory symptoms	I	Psammomatous	1
2	80/M	Thoracic	Unsteady gait, sphincter disturbances	I	Meningotheliomatous	4
3	56/F	Thoracic	Motor deficits	I	Psammomatous	2
4	70/M	Thoracic	Motor deficits, radicular pain	I	Transitional	1
5	63/F	Lumbar	Motor deficits	I	Psammomatous	0.5
6	39/F	Thoracic	Radicular pain	I	Transitional	7
7	57/F	Thoracic	Motor deficits	I	Psammomatous	7
8	79/M	Thoracic	Unsteady gait, motor deficits	I	Meningotheliomatous	1
9	73/F	Thoracic	Radicular pain	I	Psammomatous	<0.5
10	85/M	Thoracic	Motor deficits	I	Transitional	4

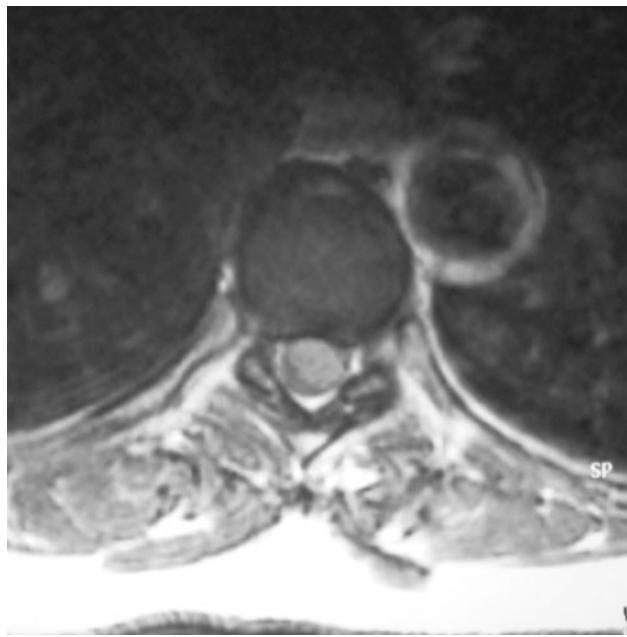

**Fig. 1** Illustrative case of patient no. 3, a 56-year-old female with an anterior located thoracic meningioma at T7–T8 level. The tumor displayed intermediate signal intensity on sagittal T2-weighted MRI (a), marked enhancement after intravenous contrast administration (b). c Gadolinium-enhanced T1-weighted MRI 1 year later without evidence of tumor recurrence

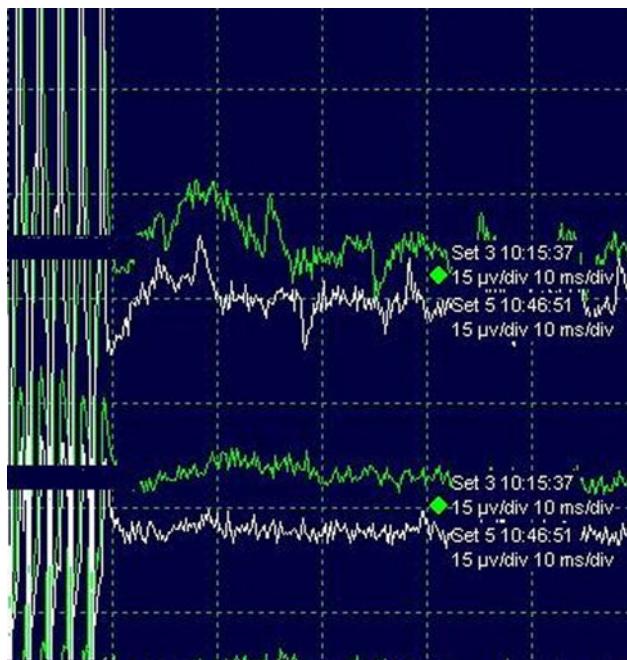

frequently than intracranial ones and account for approximately 7.5–12.7% of all meningiomas [2]. They are usually affecting middle-aged women and arise in the thoracic spine. Meningiomas also occur in the cervical and lumbar regions, albeit less frequently. Cohen-Gadol et al. [3] reported that patients younger than 50 years of age had more frequently meningiomas located in the cervical spine. Multiple tumors can occur only rarely. In the majority of cases, they are intradural like in our series. Epidural meningiomas account for only 3.5–7.0% of all spinal meningiomas and occur more commonly in children than in adults [4, 5].

Symptomatology depends on tumor location and usually involves motor and sensory deficits, local or radicular pain, sphincter disturbances and paraplegia. Histopathologically spinal meningiomas are usually benign. Meningotheliomatous and psammomatous types are the most common,

similar to our series. Ki-67 index has been found as an independent predictor of both tumor recurrence and overall survival in intracranial meningiomas [6]. Nevertheless, the value of Ki-67 index in spinal meningiomas has not been yet fully elucidated. Roser et al. compared spinal and intracranial meningiomas and reported that the proliferation rates of intracranial meningiomas were significant higher. The mean Ki-67 index was 2.48%. Likewise, in our series, the mean Ki-67 index was 2.75% [7]. Nevertheless, further studies are needed to determine the Ki-67 role in predicting spinal meningiomas behavior. On MRI examination, spinal meningiomas have on T1-weighted images signal intensity similar to that of the spinal cord that does not substantial increased on T2-weighted images. Contrast enhancement is immediate and homogeneous. Lack of foraminal extension favors a diagnosis of meningioma over a diagnosis of schwannoma or neurofibroma [5].

**Fig. 3** Patient no. 3: Compared TcMEP values before (green wave) and after removal of a thoracic meningioma, revealing no significant amplitude change

Complete surgical excision is the treatment of choice. After total removal, significant neurological improvement is usually observed, whereas tumor recurrence rate has been reported to be 1.3–14% [2, 8]. Recently, radiosurgery has also been utilized for the treatment of intradural spinal

tumors. Gerszten et al. [9] reported radiographic control of mainly recurrent meningiomas with radiosurgery; however, more studies are needed with longer follow-up periods. Advanced age does not seem to contraindicate surgery, even in patients with severe preoperative neurological deficits the quality of life can be improved in most cases [10]. For ventrally located spinal meningiomas, the trans-thoracic approach has been used. This approach provides direct access to the ventral surface of the spinal cord, enables dural manipulation and no spinal cord traction [11–13]. Nevertheless, a posterior approach is an alternative and offers fewer potential complications, eliminates the necessity of vertebrectomy, is less invasive and technically more easy [14–17]. The greatest disadvantage of this approach is the limited exposure, insufficient space to expose the disease and the need for spinal cord manipulation. If the operative field is narrow, scarification of one or more nerve roots has been suggested for widening the field to prevent spinal cord damage [8]. A postero-lateral approach has also been used with good results [12, 14]. Gambardella et al. [12] reported radical excision of ten ventral thoracic meningiomas via a postero-lateral approach.

Damage of the spinal cord and incomplete resection of anterior spinal lesions via a midline posterior laminectomy has been reported [2, 14, 18, 19]. In our series, we managed to safely excise all tumors by the use of TcMEP and continuous EMG. Intraoperative monitoring has been increasingly used as a method to prevent neurological injury during spine surgery. SSEPs and/or TcMEP have been applied for preventing motor deficits in spine surgery. Although SSEPs are easily recordable without adjusting the anesthetic regimen, there are reports of false negative results in up to 25% [15, 19, 20]. TcMEPs have been used as an alternative with favorable results [21]. TcMEPs evaluate the pyramidal motor pathways and in combination with continuous EMG monitoring give an immediate and conclusive feedback of motor tract integrity. Furthermore, we found that TcMEPs may hold an additional prognostic role for predicting patient's postoperative improvement [22]. Nevertheless, the choice and management of the anesthetic agents may impair the diagnosis of intraoperative spinal cord injury [23]. TcMEPs are significantly affected by the use of halogenated agents and nitrous oxide as well as the level of neuromuscular blockade because these agents affect the neural synaptic and axonal functional activities [23, 24]. At an alveolar concentration (MAC) of 1.0 or higher, TcMEPs are often unobtainable. For that reason, a close working relationship of the monitoring team, the anesthesiologist, and the surgeon is key to the successful conduct and interpretation of TcMEP. In our series, TcMEP and EMG prompted alert in case of imminent surgical damage.

Although the present study had a limited follow-up period of 26 months, the posterior approach with the use of intraoperative monitoring for anteriorly located meningiomas seemed to be a safe procedure, less invasive and well-tolerated especially in older patients. Complete tumor excision can be performed with satisfactory results.
