Comparison of outpatient health care utilization among returning women and men Veterans from Afghanistan and Iraq

Mona Duggal*¹, Joseph L Goulet^{1,3}, Julie Womack³, Kirsha Gordon³, Kristin Mattocks³, Sally G Haskell^{1,3}, Amy C Justice^{1,3} and Cynthia A Brandt^{2,3}

Abstract

Background: The number of women serving in the United States military increased during Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF), leading to a subsequent surge in new women Veterans seeking health care services from the Veterans Administration (VA). The objective of this study was to examine gender differences among OEF/OIF Veterans in utilization of VA outpatient health care services.

Methods: Our retrospective cohort consisted of 1,620 OEF/OIF Veterans (240 women and 1380 men) who enrolled for outpatient healthcare at a single VA facility. We collected demographic data and information on military service and VA utilization from VA electronic medical records. To assess gender differences we used two models: use versus nonuse of services (logistic regression) and intensity of use among users (negative binomial regression).

Results: In our sample, women were more likely to be younger, single, and non-white than men. Women were more likely to utilize outpatient care services (odds ratio [OR] = 1.47, 95% confidence interval [CI]: 1.09, 1.98), but once care was initiated, frequency of visits over time (intensity) did not differ by gender (incident rate ratio [IRR] = 1.07; 95% CI: 0.90, 1.27).

Conclusion: Recently discharged OEF/OIF women Veterans were more likely to seek VA health care than men Veterans. But the intensity of use was similar between women and men VA care users. As more women use VA health care, prospective studies exploring gender differences in types of services utilized, health outcomes, and factors associated with satisfaction will be required.

Background

Of the over 900,000 service members who have returned from active duty during Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF), 102,000 (11%) are women [1,2]. Women currently constitute a higher proportion of military service members than at any other time in United States history [2]. Compared with Veterans of prior conflicts, OEF/OIF Veterans are seeking Veterans Administration (VA) medical services in greater numbers [3]. The current demand for VA medical services has far exceeded what had been anticipated [4]. An influx of OEF/OIF women Veterans will likely create

increased demand for VA health care services beyond the levels usually associated with the VA.

Gender differences in health care use are a combination of interacting economic, social, psychological and biological factors. Although, men aged more than ≥ 59 years have higher health care utilization than women of the same age, younger women report higher use of health care services than men during their child bearing years [5,6]. These differences may be associated with reproductive biology, gender-specific conditions and higher morbidity rates in women in this age group [5,7-10]. Approximately 85% of OEF/OIF women Veterans are under 40 years [11]. In addition, other socio-demographic characteristics such as being single, low income and education levels, and belonging to a minority group have been found to negatively affect health care utiliza-

tion [12-15]. Therefore understanding the effect of gender and other underlying determinants on use of health care services is important in promoting equal access to health care.

OEF/OIF women Veterans' use of VA health services is a relatively new area of research. Few published peer-reviewed studies to date have examined the association between gender and health care service utilization rates among OEF/OIF Veterans. In previous eras of military service, women Veterans were much less likely to use VA services than their male counterparts, with differences between men and women in seeking VA health care services attributed to biases in the provision of care for women Veterans [2,16,17]. Overall, however, more than 40% of men and women OEF/OIF Veterans have enrolled for VA health care services [1,2]. Due to this surge in new women Veterans seeking health care services from the VA, gender differences in utilization of VA outpatient care clinics may determine if there are any gender-related disparities in utilization. Therefore, the objective of this study was to examine gender differences in utilization of outpatient VA health care services among OEF/OIF Veterans at a single VA facility. We hypothesized that among OEF/OIF Veterans, women have higher utilization of outpatient VA health care services than men. Our findings expand upon the current literature on health care services utilization among Veterans by examining gender differences in use and intensity of use of outpatient healthcare services of enrolled OEF/OIF Veterans.

Methods

The institutional review boards at the local Veterans Affairs Medical Center (VAMC) and Yale University approved this study.

Sample

Our initial sample consisted of 1820 OEF/OIF Veterans who enrolled for care at the local VAMC or at one of the six associated community-based outpatient clinics (CBOCS) between September 1, 2002, and October 30, 2006. The OEF/OIF manager at the local facility provided a roster of enrolled OEF/OIF Veterans. However, the addresses of many of these Veterans (as determined by zip codes) were outside the state or were within the vicinity of other VA medical facilities. Since one of the aims of this study was to explore intensity of use of services, we included only Veterans living in zip codes within a 100-mile radius of our facility and its associated CBOCS. By restricting the sample, we also sought to control for the effect of distance on utilization intensity [18,19]. Using this criterion, we excluded 200 Veterans, making our final sample size 1620 Veterans.

Data Sources

Information on socio-demographic characteristics and health care utilization was abstracted from the VA electronic medical record (EMR) system. Military service variables were obtained from the local OEF/OIF roster.

Outcome Variables

Based on our primary objective, we operationalized outpatient healthcare use in a sequential two-step process to outpatient care visit resulting in two related measures. We defined a visit as a face-to-face outpatient encounter on a unique date and location. The outpatient VA services use include basic care (e.g., primary care, mental health) specialty care (e.g. services by clinical specialist such as surgeon, radiologist, cardiologist etc.) and other ancillary care services such as preventive screening, immunization, visits to outpatient pharmacy, counseling sessions for weight, smoking etc, labs and electrocardiograms [20]. The first measure, initiation of care, was defined as having at least one visit to the outpatient care clinic. Only visits after return from OEF/OIF deployment were included. The second measure, intensity of utilization, was described as the number of visits, including the initial visit, among those who used outpatient care during the study period. This approach recognizes differences in the processes affecting initiation of care and rate of health care use [21,22].

Model Covariates

Gender was the primary predictor variable. Additional covariates consisted of socio-demographic and military service related characteristics, including age, race (white, non-white, unknown), marital status (married, single), presence of private health insurance, length of military service (< 3 years vs. ≥ 3 years), service branch (e.g. Army, Marine Corps), and percent service-connected disability (< 30% vs. $\geq 30\%$). Age was included as a continuous variable. Service-connected disability, a known predictor of use of health care services within the VA system, was defined as an injury or illness that either was incurred or aggravated by military service affecting employability or functioning [23,24]. This is based on the proportion of the disability assigned by Veterans Benefits Administration [3,25,26]. Persons with more than 30% service connected disability are entitled to maximum benefits, including Veterans' retirement pay, disability severance pay, separation incentive payments, and increased amounts of VA compensation [25,27]. Therefore, we dichotomized this variable to individuals with $\geq 30\%$ and < 30% service connected disability, including no disability.

Data Analysis

Socio-demographic and military characteristics were compared with utilization status and gender using the

chi-squared test for categorical variables and the t test for continuous measures to determine the association between the independent variables and the outcomes of interest. We also compared differences between female users and non-users and male users and non-users. We utilized logistic regression analysis to compare the odds of initiating outpatient care among women and men and standard negative binomial regression analysis to assess the intensity of utilization. A negative binomial model is preferred over Poisson regression for count data when data are over-dispersed (i.e., the variance is greater than the mean), as in our study [26,28]. Both the logistic and negative binomial models included the same covariates that have been shown to have an impact on both initiation and intensity. To adjust for the varying length of observation time per subject, we incorporated the log of the time variable as an offset in the negative binomial model. We also included interaction terms between gender and other covariates of interest to explore the extent to which significant predictors moderated any between-gender differences identified. A significant interaction ($P < 0.05$) would indicate that the association of gender with the outcome varied at levels of the other variable. All sta-

tistical analyses were performed using Stata/SE 9.2 for Windows (Stata Corporation, College Station, TX, USA).

Results

We identified 240 women and 1380 men OEF/OIF Veterans who met the eligibility criteria for this study. The mean age of the study population was 33 years (Table 1), with approximately 60% each being single, without any outside health insurance, and self identifying as being of white race. Over 60% had served in the military for less than 3 years, with the majority (70%) having served in the Army. During the observation period, 54% (874/1620) of the study population did not have any visits to the local VAMC for outpatient health care. Bivariate analyses showed that users and non-users of medical services did not differ significantly in age ($p = 0.30$), or length ($p = 0.84$) or branch ($p = 0.23$) of service. We observed a significant difference in utilization by gender, in that women were significantly more likely than men to have utilized care [$p = .01$].

Women non users compared to men non users (Table 2) were significantly younger (mean age 29 vs. 33 years, $p < 0.001$) and were more likely to be from the army service

Table 2: Sample Characteristics of Veterans Not Using Care by Gender

branch (75% vs. 68%, $p = 0.04$). There was no significant difference by race ($p = 0.7$), marital status ($p = 0.13$) having private health insurance ($p = 0.6$), a service-connected disability ($p = 0.7$) or length of service ($p = 0.3$).

Among the individuals who utilized VA healthcare (746/1620), more women utilized care than men (53% vs. 45%, $p < 0.01$). Women health care users were more likely than men health care users to be younger (Table 3) (mean age 31 vs. 34 years, $p < 0.001$), single (74% vs. 62%, $p < 0.001$) and non-white (24% vs. 12%, $p < 0.001$). Men and women did not differ in having private health insurance ($p = 0.7$), a service-connected disability ($p = 0.8$) or length of service ($p = 0.2$). Women and men users showed no differences in the mean \pm standard deviation (SD) (9.7 ± 10.6 vs. 9.47 ± 9.79 , $p = 0.8$) and median (6.5 versus 6.0, $p = 0.6$) number of outpatient visits (Table 3). The range of study time was between 0.5 years and 2.3 years for the visits. The average observation time for women and men was similar (0.71 ± 0.61 vs. 0.79 ± 0.63 years, $p = 0.22$). The average number of outpatient visits per person per year, for women and men was 16.3 and 15.4 visits per year, respectively ($p = 0.7$).

Results of initiation of care analysis

Multivariable logistic regression analysis showed that, after adjusting for age, race, marital status, private health

insurance, service-connected disability, length of service and type of service branch, women were more likely to initiate care than men (OR = 1.47; 95% CI: 1.09, 1.98) (Table 4). Other characteristics associated with initiation of care included having a $\geq 30\%$ service connected disability (OR = 2.73; 95% CI: 1.93, 3.85) and having private health insurance (OR = 1.44; 95% CI: 1.15, 1.86). For the logistic regression interaction model, the following interaction terms were included: sex*race, sex*marital status, sex*covered by health insurance, sex* service connected disability. No interaction terms were significant so they were omitted from the final model.

Results of rate of care analysis

In the adjusted negative binomial regression model, the intensity of utilization among health services users was similar for women and men (incident rate ratio (IRR) = 1.07; 95% CI: 0.90, 1.27) (Table 4). The rate did not differ by race (IRR = 0.90; 95% CI: 0.75, 1.09) or by percentage of service-connected disability (IRR = 1.03; 95% CI: 0.88, 1.21). Veterans with longer length of service (≥ 3 years) had significantly higher intensity of use (IRR = 1.14; 95% CI: 1.00-1.30). Veterans with health insurance were less likely than those without insurance to continue utilizing outpatient care at the VA (IRR = 0.77; 95% CI: 0.67, 0.88). The interaction model investigated the interactions

between sex and age, marital status, race, and service branch, but none of these interaction terms was significant and they were omitted.

Discussion

We have demonstrated that returning OEF/OIF women Veterans who were eligible for VA care were more likely than men to initiate use of health care services at VA facilities. However, there was no gender difference in the intensity of use, even after adjusting for socio-demographic and military service variables. Our study has some important strengths and limitations. While, this analysis is reflective of only those Veterans who sought health care at a specific VA facility and may not reflect OEF/OIF Veterans in other VA networks or those using services outside the VA, the results of our study support our hypothesis that OEF/OIF women Veterans were more likely to seek VA care than men Veterans. Although

intensity of use was similar between women and men users of VA care, insufficient power may explain why the intensity of utilization and interaction terms were insignificant. Additionally, because of the small number of women included in our study population, we combined utilization at VA facilities with that at CBOCSs to increase the sample size. This site effect may have altered our findings, as initiation and utilization rates may differ between the VA Medical Center and the CBOCS. Recent studies have shown differences in the overall characteristics of Veterans utilizing CBOCS and VA Medical Centers [25]. A larger representative sample of OEF/OIF Veterans visiting other VA healthcare facilities is therefore required to better explore gender differences in health care utilization. Further analysis on types of services utilized over time and factors influencing satisfaction are required to better inform new policy decisions or recommendations. Finally, despite not having data on

several important variables, such as socioeconomic status, education, and provider characteristics, the main strength of this study is that we had complete information on selected independent predictors of health care utilization variables for both users and non-users, as well as assessing sufficient numbers of women and men to allow for meaningful comparisons [26,28-30].

Our primary finding, that enrolled women OEF/OIF Veterans were more likely than their male counterparts to initiate care in the VA healthcare system, a significant change from earlier conflicts, should be interpreted in the context of continuous efforts by the VA over the past two

decades to provide quality health care to women [30]. It has been estimated that only 14% of women Veterans of the Persian Gulf War (1990-1991) used VA healthcare after returning [18]. In the 1990 s, to meet the needs of this rapidly growing population, the VA adopted new models for delivering gender-specific health care services. This included the creation of separate women's health clinics at tertiary VA facilities, access to one or more female providers, and provision of basic gender-specific services, including pelvic examinations [31,32]. Nevertheless, lack of information about available VA services was cited as one of the most important barriers to

women's use of VA healthcare [33]. In response, the VA implemented outreach and personal assistance initiatives specifically aimed at women [34,35]. Women at our site possibly were aware of a separate women's clinic at the Veterans Administration Medical Center and therefore may have been more likely to initiate care. Although we did not directly assess the impact of these efforts on utilization, our results suggest that these steps could have contributed to the increase we observed in the decision by women OEF/OIF Veterans to initiate health care use. An additional factor contributing to the increased use of health services by women Veterans may have been that, compared with previous conflicts, more OEF/OIF women had been exposed to combat and thus had higher levels of service-connected disability [36]. Our results confirm this finding, as female users had higher levels of service-connected disabilities than male users.

Conversely, however, the higher probability of initiation of care by women did not extend to increased intensity of use. This finding differs from the results of recent studies on gender and VA utilization, which showed higher outpatient health care utilization rates by women who were deployed or worked in non-traditional occupations [36,37]. These divergent results may be due to women using non-VA care for gender specific services that are not provided by the VA. Many VA outpatient clinics and physicians, especially those at the CBOCSs, are unable to provide basic healthcare services for women such as reproductive care, including pregnancy-related care, contraception, and care related to menopause [38]. The availability of health care providers and services plays a major role in decisions to continue utilizing care after enrollment. Since most of the OEF/OIF women Veterans in our study population were less than 40 years of age, they may have utilized outside care for reproductive health-related services, which are often contracted out by the VA healthcare system to local community providers or affiliates. Women in general often use their obstetrics and gynecology provider as their primary care provider. We did not have records of outside visits and therefore could not assess the intensity of health care use outside the VA [2,38,39].

Conclusion

Our results suggest that among recently discharged Veterans women were more likely to seek VA care than men Veterans, indicating the need for comprehensive gender-specific outpatient care services for women within the VA healthcare system. Additional information on the organization, structure, and management of women's health practices, types of services utilized over time, health outcomes, factors influencing satisfaction with health care, and utilization costs is required to improve health care delivery to women at VA facilities. With the increase in

the number of OEF/OIF Veterans using VA health care, understanding gender differences in their utilization of health care services may help VA policy makers provide better care to both women and men.
