Organelle localization is often crucial to properly modulate cellular functions and signalling cascades. For example, the distribution of organelles in axons is crucial for their function and is dysregulated in several diseases. Similarly, relative positioning of two or more organelles is also important to perform certain specialized processes. Perhaps, the best-known form of interorganellar organization is that between endoplasmic reticulum (ER) and mitochondria. Close communication between these two compartments has been observed for a long time. Recent evidence suggests that this is the basis for a bidirectional communication regulating a number of physiological processes ranging from mitochondrial energy and lipid metabolism to Ca^{2+} signalling and cell death. The recent discovery of some of the molecular mediators of the tethering already allowed to extend the function of this paradigmatic spatial organization to previously unexpected functions, and will foster future research to explore it in cellular signalling cascades as well as in disease.

Introduction

Compartmentalization is one of the key features of cellular signalling. The requirement for spatial and temporal limitation of amplifying second messengers stems from their pleiotropic nature. One single messenger, like Ca^{2+}, can control cell proliferation or death: the outcome is determined by the strength, the localization, the duration and the pattern of the signal. Organelles are key participants in the amplification of signalling cascades, either because they regulate the production or the release of crucial second messengers, or

because they are strategically located in the cytoplasm at the sites of signal propagation. One particular aspect that is gaining further consideration is the impact of relative organelle positioning on organellar and cellular function (Figures 1–3).

Like localization, relative position of organelles in the cytoplasm is not random. Often their reciprocal position is precisely organized in order to allow the exchange of different components: this is the case of the endoplasmic reticulum (ER)-Golgi and Golgi stack relationships or of the nucleus-vacuole tethering in yeast. This organization has precise consequences on integrated signalling cascades, as well as on the function of the individual organelles. The interorganellar organization, which is perhaps best characterized from a functional point of view, is that between ER and mitochondria: we have already learned a great deal on its function in Ca^{2+} signalling, cell metabolism and death.

Here, we will review our current understanding of the molecular basis and of the functional consequence of the specialized relative spatial organization of mitochondria and ER in cellular signalling cascades. Before going into the details of the functional consequences of mitochondria–ER connection, we should consider that the relative juxtaposition of these two very dynamic organelles is likely to be influenced by their morphology. We will therefore briefly describe the key-known regulators of mitochondrial and ER shape, for some of which a function in ER–mitochondria tethering has been demonstrated.
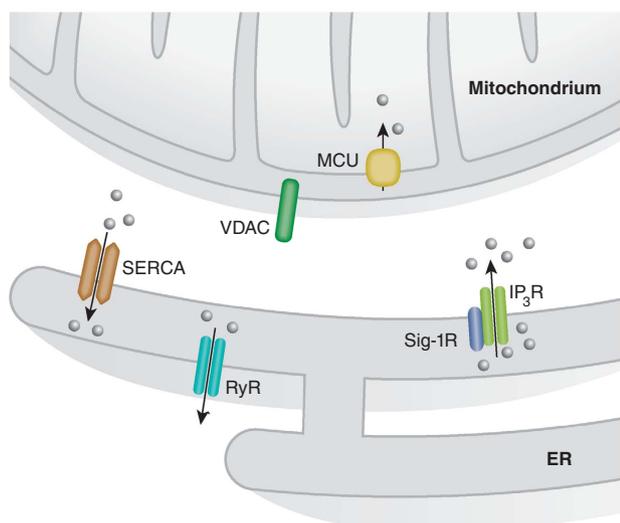

Mitochondrial shape

Early studies by George Palade and Fritjof Sjostrand revealed that mitochondria possess two membranes, an outer mitochondrial membrane (OMM) and a highly convoluted inner membrane (IMM), folded into a series of ridges called cristae (Palade, 1952; Sjostrand, 1953). More recent electron tomography (ET) studies extended these earlier observations, showing that cristae are enlarged cisternae or sacs, with narrow, tubular connections to the peripheral surface of the inner boundary membrane. These observations implicate the existence of three compartments in mitochondria, formed by the matrix, the intermembrane space and the interior of the cristae (Perkins *et al*, 1997; Frey and Mannella, 2000; Scorrano and Korsmeyer, 2003; Frezza *et al*, 2006).

Mitochondrial shape in living cells is very heterogeneous and can range from small spheres to interconnected tubules (Bereiter-Hahn and Voth, 1994). Mitochondria of rat cardiac muscle and diaphragm skeletal muscle appear as isolated ellipses or tubules in embryonic stages but then reorganize into reticular networks in the adult (Bakeeva *et al*, 1981). The dynamics of the mitochondrial network is well depicted by
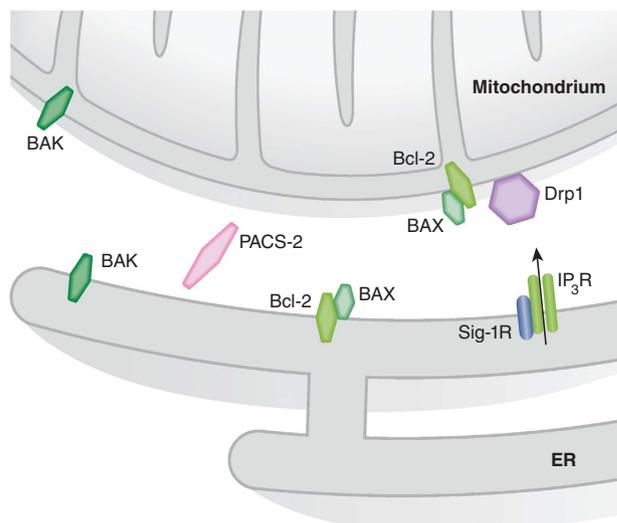

Figure 1 Local Ca^{2+} signalling at the ER–mitochondria interface. The proteins involved in Ca^{2+} signalling between ER and mitochondria are shown. Ca^{2+} release from the ER occurs mainly through IP$_3$R and RyR enriched at the regions of the ER in close contact with mitochondria. These receptors account for the formation of microdomains of high Ca^{2+} concentration that are needed to activate the transport of the ion into the mitochondrial matrix through the MCU. Finally, the recently identified Sig-1R is able to modulate the activity of the IP$_3$R and thus Ca^{2+} transmission from the ER to mitochondria.

Figure 2 Apoptotic signalling at the ER–mitochondria interface. Cross-talk between ER and mitochondria has a major function in the decision whether the cell should live or die. Bcl-2 family members can control apoptosis by controlling indirectly the amount of ER-releasable Ca^{2+} that can reach mitochondria. Drp1 has a dual function in controlling apoptosis. On one side, recruitment of Drp1 to mitochondria upon sustained Ca^{2+} release from the ER can protect from cell death by fragmenting the mitochondrial network and impeding the propagation of the fatal Ca^{2+} wave. On the other hand, mobilization of Drp1 to mitochondria can also trigger mitochondrial cristae remodelling, facilitating cytochrome c mobilization and subsequent apoptosis. Also, the recently identified Sig-1R has a bivalent function in apoptosis. Sig-1R promotes Ca^{2+} transmission to mitochondria through the IP$_3$R thus maintaining mitochondrial metabolism in conditions of ER Ca^{2+} depletion. However, excessive Ca^{2+} transfer to mitochondria risks to expose this organelle to Ca^{2+} overload and subsequent dysfunction. In this regard, the truncated version of SERCA-1 S1T, expressed upon ER stress, promotes Ca^{2+} transfer to mitochondria leading to Ca^{2+} overload.

the continuous movement of mitochondria. Occasionally, two mitochondrial units encounter each other and eventually fuse (Bereiter-Hahn and Voth, 1994). On the other hand, mitochondrial tubules can undergo fission and give rise to two or more mitochondrial units. It is important to note that mitochondrial fusion and fission are complicated processes, being mitochondria bound by two membranes, thus, any mechanism of fusion and fission has to take into account the coordinate fusion–fission of four lipid bilayers.

The first mediator of mitochondrial fusion identified was the *Drosophila melanogaster* Fuzzy onions 1 protein (Fzo1p), a large transmembrane guanosine triphosphatase required for the formation of the large mitochondrial derivative during spermatogenesis (Hales and Fuller, 1997). In mammals, two Fzo1p homologues, Mitofusin (Mfn)1 and Mfn2 are widely expressed in many tissues (Rojo *et al*, 2002; Santel *et al*, 2003; Eura *et al*, 2003). Mfn1 and Mfn2 display high (81%) homology, similar topologies and both reside in the OMM (Rojo *et al*, 2002; Chen *et al*, 2003; Santel *et al*, 2003). IMM fusion is mediated by another GTPase, Opa1. During mitochondrial fusion, Mfn1 and Mfn2 are believed to dock two juxtaposed mitochondria through their coiled-coil domains (Koshiba *et al*, 2004). Mfn1 has a higher GTPase activity than Mfn2, although its affinity for GTP is lower (Ishihara *et al*, 2004). In agreement with this, Mfn1 exhibits a higher capacity in inducing fusion (Ishihara *et al*, 2004) and participates in Opa1-mediated mitochondrial fusion, as opposed to Mfn2 (Cipolat *et al*, 2004).

The two proteins Fis1 and dynamin-related protein 1 (Drp1) are required for mitochondrial fission in mammals. Drp1 exists largely in a cytosolic pool, but a fraction is found at spots on mitochondria at sites of constriction (Labrousse *et al*, 1999; Smirnova *et al*, 2001). Fis1, on the other hand, is

evenly distributed on the surface of the OMM (James *et al*, 2003) and is thought to recruit Drp1 on punctuate structures on mitochondria during mitochondrial fission in yeast (Yoon *et al*, 2003). In mammalian cells, as opposed to yeast, the mechanism of Drp1 translocation to mitochondria seems to be independent of the presence of Fis1 (Lee *et al*, 2004; Wasiak *et al*, 2007) and is regulated by post-translational modification, like phosphorylation at several different Serine residues (Taguchi *et al*, 2007; Cereghetti *et al*, 2008). Once on mitochondria, Drp1 is then stabilized by sumoylation (Harder *et al*, 2004; Braschi *et al*, 2009; Zunino *et al*, 2009).

Several other players besides these 'core'-shaping proteins have been shown to participate in the regulation of mitochondrial morphology. Further details can be found in recent and comprehensive reviews (Zorzano *et al*, 2010).

ER shape

The ER is a continuous membrane-bound compartment present in all eukaryotic cells occupying >10% of the total cell volume (Baumann and Walz, 2001; Voeltz *et al*, 2002). Despite the continuity of the ER network, morphologically defined compartments can be distinguished: the nuclear envelope and the peripheral ER comprising the ribosome-bound rough ER and the ribosome-free smooth ER (Baumann and Walz, 2001; Voeltz *et al*, 2002; Goetz and Nabi, 2006).
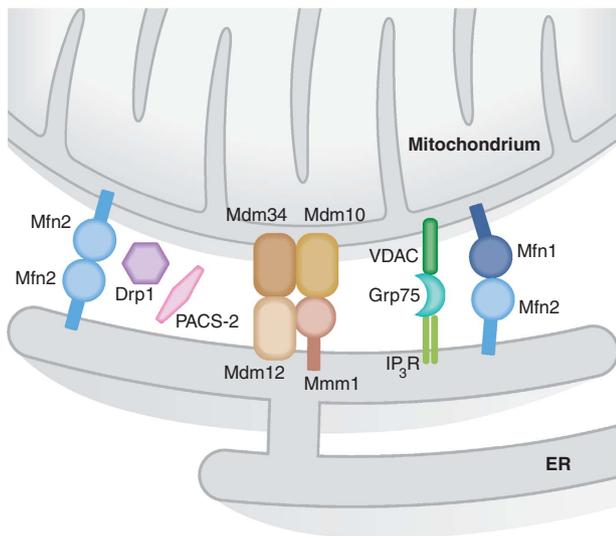

Figure 3 Tethers between ER and mitochondria. The molecular bridges that regulate the close contacts between ER and mitochondria are shown. PACS-2 and Drp1 indirectly controls the distance between the two organelles by impinging on mitochondrial morphology and distribution. A more direct function in linking ER and mitochondria has been suggested for the complex composed by the IP$_3$R on the ER, the cytosolic chaperone Grp75 and the mitochondrial anion channel VDAC. Further, ERMES, a multimeric complex formed by the mitochondrial proteins Mdm34 and Mdm10 and Mmm1 and Mdm12 on the ER appears to regulate ER–mitochondria tethering in yeast. Importantly, the dynamin-related GTPase Mfn2 on the ER forms homo–heterodimers with Mfn1 or Mfn2 on mitochondria to keep the tight contacts between the two organelles.

Although the nuclear envelope separates the cytoplasm from the nuclear lumen in interphase cells (Baumann and Walz, 2001), the peripheral ER is evenly distributed throughout the whole cellular volume. In general, the peripheral ER consists of sheet-like cisternae and a polygonal array of tubules connected by three-way junctions, the thickness of the sheets and the diameter of the tubules varies typically between 60–100 nm (Voeltz and Prinz, 2007), indicating that an active mechanism maintains this shape. In fact, interaction between the ER and microtubule (MT)-binding proteins seems to have a function in shaping the ER in mammalian cells. The interaction through motor proteins could permit the extension along stationary MT. In the case of non-motor proteins, this interaction would mediate the movement of the ER attached to motile or polymerizing MT (Vedrenne and Hauri, 2006), as it has been suggested for cytoskeleton-linking membrane protein 63 kDa (CLIMP63), VAP-B/Nir3 couple and p22 (Klopfenstein et al, 1998; Andrade et al, 2004; Amarilio et al, 2005).

CLIMP63 is an integral ER protein localized exclusively on the peripheral ER. Anchoring of the ER to MT by CLIMP63 seems to be required for maintaining the spatial distribution of the ER network (Klopfenstein et al, 1998). Regarding p22, this myristoylated EF-hand containing protein, binds MT in a Ca^{2+}-dependent manner, providing a link between ER morphology and Ca^{2+} (Andrade et al, 2004). Moreover, in vitro studies show that branching ER tubules can be created in a system containing solely giant unilamellar lipid vesicles, MT and MT motor proteins (Koster et al, 2003; Leduc et al, 2004). Despite this evidence, the function of MT in regulating ER morphology remains controversial. In fact, ER tubules can be

generated in vitro from oocyte-derived light microsomes and this occurs in the absence of MT (Dreier and Rapoport, 2000). This in vitro ER tubulation assay was used to identify two classes of proteins required for the shaping of the ER: the reticulons and DP1/Yop1 (Voeltz et al, 2006). These integral ER proteins are enriched in ER tubules and excluded from sheets and nuclear envelope. It is thought that they adopt a hairpin topology on the cytoplasmic leaflet of the ER membrane, occupying more space in the outer than in the inner leaflet and causing the ER membrane to curve and tubulate, forming the typical ER tubules (Voeltz et al, 2006). More recently, a different class of proteins, the dynamin-related membrane GTPases atlastins, has been shown to also control morphology of the ER by promoting the branching of the tubules (Hu et al, 2009; Orso et al, 2009). On the other hand, Snapp et al (2003) have suggested that ER shape results from the weak interaction between cytosolic domains of ER integral proteins during formation of stacked ER cisternae within cells.

Turning back to the function of Ca^{2+} in regulating ER morphology, increases in concentration of this ion are known to cause ER fragmentation (Subramanian and Meyer, 1997; Ribeiro et al, 2000; Terasaki et al, 2001). This can occur through the action of the EF-hand containing protein p22 (Andrade et al, 2004), as mentioned above, or through Drp1 (Pitts et al, 1999). However, how the different regulators of ER shape cooperate to generate the branched and tubular network remains an open question.

The ER/mitochondria liaison: an historical overview

The first proposal of the existence of a close contact between the membrane of the ER and mitochondrial outer membrane (OMM) dates back to the 1960s by several independent groups (Ruby et al, 1969). Subcellular fractionation studies identified ER membranes co-purifying with mitochondrial fractions (Lewis and Tata, 1973). Electron microscopy (EM) observations suggested even a continuity between OMM and ER membrane, establishing a direct communication between the cisternal space of the ER and the mitochondrial inter-membrane space (Ruby et al, 1969; Franke and Kartenbeck, 1971; Morre et al, 1971). Modern EM techniques reveal that mitochondria are surrounded by tubules of the ER that lie preferentially within 200 nm of distance (Wang et al, 2000), whereas wide-field digital 3D deconvolution microscopy indicates that as much as 20% of the mitochondrial surface is in direct contact with the ER (Rizzuto et al, 1998). Finally, ET and high-resolution three-dimensional ET shows the existence of physical linkers between the two organelles. The size of these bridges appears to vary between 10 and 25 nm in length (Perkins et al, 1997; Marsh et al, 2001; Csordas et al, 2006). The specific ER region that interacts with mitochondria has been christened mitochondria-associated membrane (MAM) by Jean Vance when she identified for the first time an important function for the intimate relationship between the two compartments in the exchange of phospholipids (Vance, 1990). The functional importance of the contact sites is further substantiated by a 'quasi-synaptic' mechanism transmission of Ca^{2+} between the two organelles (Rizzuto et al, 1993, 1998; Csordas et al, 1999) and by the crucial

function of this process during apoptosis (Szalai et al, 1999; Scorrano et al, 2003).

How ER and mitochondria collaborate to produce lipids

The physiological function of the close apposition between ER and mitochondria started to become evident when its function in phospholipid synthesis was discovered. Lipids are poorly soluble in water and most of them are predicted not to move efficiently across the hydrophilic cytosol by diffusion (Daum and Vance, 1997). Thus, a mechanism that exchanges phospholipids between membranes of different organelles must exist. For many years, this was thought to be performed by phospholipid exchange proteins (Voelker, 2005). Alternatively, interorganellar lipid transfer could be mediated by vesicles. In the latter model, a vesicle buds from the donor membrane, crosses the cytosol and fuses with the acceptor membrane where it delivers the lipid cargo. However, a more recent hypothesis indicates that the most likely mechanism of interorganellar lipid transfer involves the direct contact between the donor and the acceptor membrane eliminating the need of the energetically unfavourable transfer of lipids through the hydrophilic cytosol (Voelker, 2003). In agreement with his view, phosphatidylserine (PtdSer) synthase-1 and -2, the enzymes involved in the synthesis of PtdSer, and PtdSer are enriched in MAMs as opposed to the bulk ER. On the other hand, PtdSer decarboxylase, the enzyme that catalyses the conversion of PtdSer to phosphatidylethanolamine (PtdEtn), is associated to the external leaflet of the inner mitochondrial membrane. PtdEtn, synthesized in mitochondria, can shuttle back to the MAMs, where it is further processed into phosphatidylcholine by PtdEtn methyltransferase (Cui et al, 1993). Altogether, this suggests the exchange of phospholipids and existence of a close physical interaction between the ER and mitochondria (Vance, 1990; Stone and Vance, 2000). In addition to the function in phospholipid homeostasis, MAMs have been implicated in the metabolism of cholesterol and its metabolites. First, the ER is the main site of synthesis and storage of cholesterol and several enzymes involved in the metabolism of cholesterol derivatives, such as diacylglycerol acyltransferase and acyl-coenzymeA:cholesterol acyltransferase, are highly enriched in MAMs (Rusinol et al, 1994). However, cytochrome P450scc, the enzyme required for conversion of cholesterol to pregnenolone is localized exclusively on mitochondria (Thomson, 2003). Although it has not been clarified yet how cholesterol is imported into the mitochondria, one possibility is that this occurs at contact sites with the ER. Finally, MAMs might also be implicated in the metabolism and trafficking of sphingolipids (Hayashi et al, 2009). Upon exposure to a fluorescently labelled analogue of ceramide, sphingolipids are trafficked through the ER to mitochondria (Lipsky and Pagano, 1983). Further, MAMs and mitochondria participate together in the metabolism of ceramide, a metabolite of sphingolipids with assigned functions in cell cycle, differentiation and apoptosis (Bionda et al, 2004).

Altogether, strong evidence supports the idea that the interface between ER and mitochondria has a major function in controlling the metabolism of different classes of lipids. In agreement with this view, studies in yeast indicate that disrupting the close contact sites between the two organelles affects the exchange of phospholipids (Kornmann et al, 2009).

The protein liaison: dual targeting to mitochondria and ER

Most of the proteins are specifically targeted to a single organelle, yet in some cases the same transcript can be found on different compartments, like ER and mitochondria. Most of the proteins that are delivered to two different organelles result either from two different genes, two mRNAs deriving from the same gene or two translation initiations on the same mRNA; in each case, the translation product differs by the presence or absence of distinct targeting signals (Danpure, 1995). More recent discoveries show that additionally the same translation product can be sent to two different compartments.

To target a protein to an organelle, the transcript has to be both 'recognized' and imported into the specific compartment; implying that dual targeting results either from promiscuity or competition of the targeting signal (Karniely and Pines, 2005). The targeting of proteins with accessible (either one ambiguous or two different) targeting signals depends on the relative affinity of the receptors. Dual targeting is also achieved if during translation, a subpopulation of proteins suffers a post-translational modification that renders the targeting sequence inaccessible as it happens for mammalian NADH cytochrome b5 reductase, which is double targeted to both mitochondria and ER because of the presence of a myristoylation site on the N-terminus of the protein. In the absence of myristoylation, the protein is recognized by the signal recognition particle (SRP) and is targeted to the ER. However, myristoylation on a glycine residue on the N-terminal of the transcript diminishes the affinity of the protein for the SRP and the nascent chain remains attached to free ribosomes, becoming available for post-translational targeting to the OMM (Colombo et al, 2005). Several members of the cytochrome P450 family are also dually localized on mitochondria and ER. As for NADH cytochrome b5 reductase, the targeting signal of cytochrome P450 2B1 to the ER can be 'masked' by a post-translational modification, phosphorylation (Anandatheerthavarada et al, 1999). In the case of cytochrome P450 1A1, alternative targeting is achieved by endoproteolytic cleavage that removes the ER targeting sequence (Addya et al, 1997).

Several members of the B-cell leukaemia-2 (Bcl-2) family similarly are localized both on ER and on mitochondria, such as Bcl-2 (Annis et al, 2001) itself, Bax and Bak (Gajkowska et al, 2001; Nutt et al, 2002). However, very little is known on how Bcl-2 family proteins reach the two different organelles.

Finally, it is important to note that alternative localization of proteins either on ER and mitochondria may have different functions (in the case of Bcl-2 family proteins, differently localized proteins regulate apoptosis through different mechanisms). Preferential targeting of proteins to either one compartment or the other can be regulated by the enzymatic activity (such as phosphorylation, myristoylation,…) of the cell, as exemplified for cytochrome p450 2b1.

The Ca^{2+} liaison

The ER is the main Ca^{2+} store of the mammalian cell, although it has been known for a long time that mitochondria

as well are able to accumulate Ca^{2+}. In response to cytosolic Ca^{2+} transients not exceeding concentrations of 1–$3\,\mu M$, mitochondrial Ca^{2+} concentrations rise almost simultaneously to values above $10\,\mu M$ (Rizzuto and Pozzan, 2006). This is unexpected considering the low affinity to Ca^{2+} of the mitochondrial Ca^{2+} uniporter (Rizzuto et al, 1993, 1998). Moreover, Ca^{2+} released by the ER into the cytosol in response to inositol-1,4,5-triphosphate (IP_3) is transferred to mitochondria much more efficiently than Ca^{2+} elevations induced by leakage of Ca^{2+} from this organelle (Rizzuto et al, 1993; Hajnoczky et al, 1995). These observations led to the proposal by Rizzuto and Pozzan of the existence of close contact points between ER and mitochondria, enriched in IP_3 and Ryanodine receptors. Upon cell stimulation, the release of high concentrations of Ca^{2+} at contact sites between the two organelles leads to the formation of microdomains of high Ca^{2+} concentration that are crucial for efficient Ca^{2+} uptake by mitochondria (Figure 1) (Rizzuto et al, 1993, 1998).

Ca^{2+} transmission from the ER to mitochondria, and thus contact between the two organelles, has a crucial function in regulating mitochondrial metabolism. Mitochondrial Ca^{2+} levels regulate the activity of several enzymes of the tricarboxylic acid and of the electron transport chain, such as α-ketoglutarate, isocitrate dehydrogenases and pyruvate dehydrogenase (Bernardi, 1999). In addition to enzymes involved in mitochondrial metabolism, Ca^{2+} also controls the phosphorylation status and thus the activity of mitochondrial metabolite transporters, manganese superoxide dismutase and other enzymes (Hayashi et al, 2009).

Paradoxically, excessive Ca^{2+} can also be detrimental for mitochondria. Indeed, the entry of Ca^{2+} into the mitochondrial matrix is an energetically expensive process, associated with a transient depolarization of the IMM and therefore with a transiently lower driving force for ATP synthase (Duchen, 2000). Finally, exaggerated accumulation of Ca^{2+} in mitochondria can lead to overload and impairment of mitochondrial function because of opening of the permeability transition pore, an inner mitochondrial membrane channel that allows the diffusion of ions and other small molecules along their gradients, ultimately leading to dissipation of the mitochondrial potential and in certain cases to cell death (Bernardi, 1999; Hajnoczky et al, 2006).

If one considers the dual function of Ca^{2+} ions as mediators of life and death, then a tight control over the distance between ER and mitochondria would be required to regulate vital mitochondrial functions. However, little is known on how physiological stimuli control the distance between ER and mitochondria and therefore Ca^{2+} transfer between the two organelles. In an attempt to gain further insight into this mechanism, a pioneer work shows that the chaperone Sigma-1 receptor (Sig-1R) could have a function in controlling the sustained Ca^{2+} signalling at the ER–mitochondria interface upon ER Ca^{2+} depletion (Hayashi and Su, 2007). In basal conditions, Sig-1R forms a complex with the ER chaperone immunoglobulin heavy-chain binding protein (in B lymphocytes) (BIP). As soon as ER Ca^{2+} stores are depleted or the Sig-1R is activated by binding to its ligands, the receptor dissociates from BIP and modulates the activity of the IP3R, leading to prolonged Ca^{2+} signalling into mitochondria (Figure 1), a mechanism that could impact dramatically on Ca^{2+}-dependent mitochondrial functions as well

as on interorganellar Ca^{2+} signalling and cell survival. It is tempting to speculate that different physiological processes might use specialized 'molecular tools' to regulate communication between ER and mitochondria according to cellular needs.

How does the Ca^{2+} liaison lead to death?

If one considers that Ca^{2+} homeostasis participates actively in different forms of cell death and that mitochondria are main effectors during this process, it is not surprising that the cross-talk between ER and mitochondria contributes in several circumstances to take the decision whether the cell should live or die. The first indication was given by the demonstration that IP_3-induced Ca^{2+} mobilization from the ER to mitochondria has a function in apoptosis (Szalai et al, 1999). Interestingly, the anti-apoptotic protein Bcl-2 decreases the steady-state Ca^{2+} content of the ER, resulting in a reduced amount of agonist-releasable Ca^{2+} and in a diminution of cytosolic and mitochondrial Ca^{2+} response (Pinton et al, 2000, 2001). Thus, by diminishing ER Ca^{2+} levels, Bcl-2 is able to protect from Ca^{2+}-dependent apoptotic stimuli (Pinton et al, 2001). Moreover, knocking out the pro-apoptotics Bax and Bak leads to a dramatic reduction of the steady-state Ca^{2+} concentration in the ER, rendering the knock-out cells more resistant to apoptosis (Figure 2) (Scorrano et al, 2003). Again, the amount of Ca^{2+} that can be released into the cytosol (and thus the amount of Ca^{2+} that reaches mitochondria) rather than effective ER Ca^{2+} concentration is relevant for the transmission of the cell death signal to mitochondria.

As mentioned above, phospho-acidic cluster protein (PACS)-2 is also involved in the regulation of apoptosis. In response to apoptotic stimuli, PACS-2 induces Bid translocation to mitochondria initiating the apoptotic cascade (Simmen et al, 2005).

Interestingly, during apoptosis, the mitochondria-shaping protein Drp1 is recruited to mitochondria where it protects from Ca^{2+}-dependent death by inducing fragmentation of the mitochondrial network and consequently by blocking the transmission of potentially fatal Ca^{2+} waves along this organelle (Szabadkai et al, 2004). However, contrasting evidence indicates that cell death activation by death receptors leads to the cleavage of BAP31 by caspases-8 and its translocation to mitochondria. Translocation of BAP31 accompanied by ER Ca^{2+} release mediates mitochondrial fragmentation and recruitment of Drp1 to mitochondria. Finally, Drp1 on mitochondria may lead to mitochondrial cristae remodelling and contribute to the apoptotic response (Breckenridge et al, 2003; Germain et al, 2005). Despite the inconsistency of the above-mentioned data, both observations imply that certain paradigms of apoptosis are regulated by the cross-talk between mitochondria and ER (Figure 2).

A more indirect but still very interesting approach to elucidate how distance between ER and mitochondria regulates cell function was taken by Hajnoczky and colleagues. The use of synthetic linkers or limited proteolyses, which either increase or decrease artificially the distance between ER and mitochondria, demonstrates that altering the distance between the two organelles leads inevitably to cell dysfunction. In fact, decreasing the space between ER and mitochondria leads to mitochondrial Ca^{2+} overload. On the

other hand, an increase in the distance between the two compartments puts at risk the Ca^{2+}-dependent regulation of mitochondrial metabolism by removing Ca^{2+} transmission between them (Csordas et al, 2006) and consequently cell viability. In extreme cases, both conditions can trigger cell death, further substantiating the view that the distance between the two organelles needs to be tightly regulated. On one side, the Sig-1R is able to sense Ca^{2+} concentrations in the ER and control the amount of releasable Ca^{2+} that can be tunnelled to mitochondria in order to maintain mitochondrial metabolism and protect the cell from energy depletion (Hayashi and Su, 2007). On the other hand, enhanced Ca^{2+} transmission from the ER to mitochondria during ER stress might also have a function in the onset of apoptosis. For instance, a truncated version of the Sarcoendoplasmic reticulum Ca^{2+}-ATPase 1 (S1T) expressed upon ER stress appears to increase ER Ca^{2+} leak and promote Ca^{2+} transfer to mitochondria. The subsequent mitochondrial Ca^{2+} overload promotes apoptosis (Chami et al, 2008). In a similar manner, gangliosides can also have a function in linking ER stress to mitochondrial apoptosis (Sano et al, 2009). GM1-ganglioside accumulation at MAMs can influence the activity of the IP_3R by directly interacting with the channel. This binding promotes an increased Ca^{2+} release from the ER. Ca^{2+} is then tunnelled to the mitochondria promoting Ca^{2+} overload and activating the mitochondrial apopototic cascade (Sano et al, 2009). Finally, ER and mitochondria participate together in the metabolism of ceramides. As it has been proposed that ceramides are able to initiate the apoptotic pathway by forming channels in the OMM (Siskind, 2005), it is tempting to speculate that MAMs are at the cross-road also for the action of ceramide during apoptosis.

Structural basis for ER–mitochondrial tethering

Although over the last 20 years substantial evidence accumulated on the cellular importance of communication between ER and mitochondria, the field has gained little insight onto the structural basis for tethering between the two organelles. One crucial question is how the intimate liaison is maintained despite considering the continuous movement and reorganization of both organelles in the cell. However, live imaging studies support that also the tethering regions are continuously formed and disrupted in a dynamic process (Rizzuto et al, 1998). It is therefore not surprising that both the mitochondria-shaping protein Drp1 (Pitts et al, 1999) and PACS-2 (Simmen et al, 2005) can have a function in regulating contacts between ER and mitochondria. PACS-2, mainly localized at the ER, regulates juxtaposition of the two compartments through BAP31-dependent fission and perinuclear clustering of mitochondria (Simmen et al, 2005). In the same way, Drp1 could alter tethering by causing fragmentation of mitochondria (Figure 3) (Pitts et al, 1999; Szabadkai et al, 2004). Interestingly, ionomycin-induced increases in cytosolic Ca^{2+} also seem to disrupt vicinity between ER and mitochondria by an unknown mechanism involving autocrine motility factor receptor (Wang et al, 2000; Goetz et al, 2007). However, the function of these proteins appear to be indirect, resulting from alterations in mitochondrial morphology and distribution in the cell. In other words, they do not take direct part in the bridges of

proteinaceous origin directly linking ER to mitochondria whose existence has been shown in EM of ER–mitochondria contact sites (Perkins et al, 1997; Marsh et al, 2001; Csordas et al, 2006). The nature of these bridges remained largely elusive. One hypothesis is that the IP_3R on the ER and the voltage-dependent anion channel (VDAC)1 on the OMM are physically coupled through the chaperone glucose-regulated protein 75 kDa (GRP75) (Figure 3) (Szabadkai et al, 2006). Albeit IP_3R might regulate contact points between the two organelles, recent work by the group of Hajnoczky demonstrates that an IP_3R-independent tether exists (Csordas et al, 2006).

The first direct ER–mitochondria tether to be discovered was Mfn2 (de Brito and Scorrano, 2008). This mitochondria-shaping protein localizes not only on mitochondria, as previously believed, but it is also highly enriched in the MAM fraction and retrieved, albeit to a lower extent, at the ER. Expression of Mfn2 exclusively on the ER or on mitochondria indicates that Mfn2 needs to be localized on the ER to maintain the shape and continuity of this organelle. These surprising results suggest that Mfn2 has a crucial function on the ER–mitochondria interface. The use of advanced imaging techniques and a novel in vitro interaction assay demonstrated that Mfn2 is required on the ER to maintain the close contact points between the two organelles (Figure 3). Moreover, Mfn2 on the ER forms large complexes comprising Mfn2 or Mfn1 on mitochondria that could represent the bridges identified in EM experiments. In other words, while mitochondrial Mfn2 regulates shape of this organelle, ER-associated Mfn2 is required for ER morphology and its tethering to mitochondria (de Brito and Scorrano, 2008). The finding that Mfn2 participates in forming a structural linker between ER and mitochondrial, constituted a valuable genetic tool to demonstrate the functional consequence of the altered ER–mitochondria distance on mitochondrial Ca^{2+} uptake (Rizzuto et al, 1993, 1998). For the first time, using a loss of function model, the increased distance between ER and mitochondria was unequivocally linked to reduced uptake of Ca^{2+} by mitochondria during physiological IP_3-mediated Ca^{2+} signalling. This constituted the first experimental proof of the 'Ca^{2+} microdomain' theory proposed by Pozzan and coworkers in the nineties (Rizzuto et al, 1993, 1998). More recently, the microdomain theory has been reconfirmed in the laboratory of Tullio Pozzan by taking advantage of the use of recombinant Ca^{2+} sensors (Giacomello et al, 2010).

A completely different approach, based on synthetic biology, was used to screen for the nature of the tethers in yeast. A synthetic linker that inserts in both the OMM and in the membrane of the ER was used to rescue a library of mutagenized yeast cells, thereby identifying the mutations whose viability is rescued by the synthetic bridge. This elegant approach revealed that Mdm12, an OMM protein, is required for maintenance of the contact points between the two organelles in yeast. Further, Mdm12 is part of a tethering complex, the 'ER–mitochondria encounter complex' (ERMES), which consists of outer mitochondrial and ER membrane proteins and appears essential to keep the contact points between the two organelles in yeast (Figure 3) (Kornmann et al, 2009). Even tough this study provides a first exciting glance for the identification of the tethering complex, it needs to be extended to mammalian cells to

identify meaningful tethering components. Indeed, yeast is not the best experimental system as the only crucial ER–mitochondria process that is conserved is phospholipid biosynthesis. On the other hand, ER is not the main Ca^{2+} store in *Saccharomyces cerevisiae*, and yeast mitochondria do not posses the Ca^{2+} uniporter. Therefore, the existence of specialized tethers for phospholipid transfer is likely and confirmed by the lack of conservation in higher eukaryotes of the components of the ERMES complex. It is worth mentioning that synthetic linkers have already been applied successfully in mammalian cells (Csordas *et al*, 2006; Komatsu *et al*, 2010). In particular, a chemically inducible dimerization probe where one of the dimerization partners was targeted to the OMM while the other localized to the ER membrane allows efficient tethering upon addition of the chemical dimerizer (Komatsu *et al*, 2010). This strategy would be particularly interesting to screen for novel components of the mammalian tethering complex and to dynamically study the function of the tethering, avoiding the problems arising from the stable expression of tethers that reduce the distance in a permanent manner.

A more obvious regulator of juxtaposition between ER and mitochondria is the cytoskeletal network (Soltys and Gupta, 1992). In fact, both ER and mitochondria bind to MTs and actin filaments (Sturmer *et al*, 1995; Ebneth *et al*, 1998), implicating that the cytoskeleton could provide a scaffold that stabilizes the contact points between the compartments. As a matter of fact, a recently identified protein, trichoplein/mitostatin, which binds to keratins and other intermediate filaments, is highly enriched in MAMs, and negatively regulates the juxtaposition between mitochondria and ER in an Mfn2-dependent manner (Cerqua, Anesti, Baffa, Dimmer and Scorrano, unpublished data). These result open the possibility that intermediate filaments participate in the tethering. In addition, mitostatin is an oncosuppressor, deleted in a variety of solid tumours (Vecchione *et al*,

2009), placing the ER–mitochondria interface also in the stage of neoplastic transformation.

Concluding remarks

We are only at the beginning of our understanding of the details of how ER and mitochondria interact. Several indirect mechanisms such as binding to the cytoskeletal scaffold or alterations in organelle morphology and positioning probably have a function. However, more direct regulators of this interaction are emerging, and it remains to be elucidated how these tethers function. Another open question is how are these tethers regulated in response to diverse cellular cues; is increased distance between ER and mitochondria privileged in response to intense Ca^{2+} release from the ER? Does the need for phospholipid synthesis encourage a more intimate contact between the two compartments? These are all open questions that need to be addressed in the future.

In conclusion, current evidence supports the view that the multiple aspects of interorganellar signalling between ER and mitochondria, as well as the functions of these organelles, are regulated by their relative spatial organization. The importance of the spatial organization is confirmed by the evidence that its impairment severely affects this balance and can initiate cell death.
