Childhood trauma is associated with hypothalamic–pituitary–adrenal (HPA) axis dysregulation and is a known risk factor for suicidal behavior. In this study we sought to determine whether the impact of childhood trauma on suicide risk might be modified by *FKBP5*, an HPA-axis regulating gene. Sixteen *FKBP5* haplotype-tagging single nucleotide polymorphisms (SNPs) were genotyped in a sample of African Americans: 398 treatment-seeking patients with substance dependence (90% men; 120 suicide attempters) and 432 nonsubstance-dependent individuals (40% men; 21 suicide attempters). In all, 474 participants (112 suicide attempters) also completed the Childhood Trauma Questionnaire (CTQ). Primary haplotype analyses were conducted with the four SNPs implicated in earlier studies: rs3800373, rs9296158, rs1360780, and rs9470080. We found that childhood trauma was associated with suicide attempt ($P < 0.0001$). Although there was no main effect of the two major yin yang haplotypes in the four SNP haplotype blocks, there was a haplotype influence on suicide risk ($p = 0.006$) only in individuals exposed to high levels of childhood trauma. In this group, 51% with two copies of the risk haplotype, 36% with one copy, and 20% with no copies had attempted suicide. The total logistic regression model accounted for 13% of the variance in attempted suicide. Analyses of the 16 SNPs showed significant main effects on suicide attempt of rs3777747, rs4713902, and rs9470080 and interactive effects of rs3800373, rs9296158, and rs1360780 with CTQ score on suicide attempt. These data suggest that childhood trauma and variants of the *FKBP5* gene may interact to increase the risk for attempting suicide.

INTRODUCTION

Suicide is the fifth leading cause of years of potential life lost before age 75 years and the eleventh leading cause of death in the United States (Castle *et al*, 2004). Data from family, twin, adoption, and molecular genetic studies show that there is a genetic component to suicidal behavior (reviewed in Bondy *et al*, 2006). Exposure to childhood trauma is also recognized as an independent risk factor for suicidal behavior. Childhood trauma is common: a general population survey revealed that 31% of men and 21% of women reported a history of childhood physical abuse whereas childhood sexual abuse was reported by 13% of women and 4% of men (Holmes and Slap, 1998; MaMillan *et al*, 1997). Results from the Epidemiologic Catchment Area (ECA)

study and the US National Comorbidity Survey have shown a strong association between childhood sexual abuse and suicidal behavior (Davidson *et al*, 1996; Molnar *et al*, 2001). Similarly, an Australian community study of twins found that a history of childhood trauma significantly increased the risk of a suicide attempt (Nelson *et al*, 2002). Moreover, data from the US National Comorbidity Survey Replication indicate that exposure to childhood physical abuse, sexual abuse, or witnessing domestic violence accounts for 16 and 50% of suicidal ideation and attempts, respectively, among women and 21 and 33% of ideation and attempts among men (Afifi *et al*, 2008). Clinical studies have similarly reported that childhood trauma is associated with suicide attempts in patients with various psychiatric disorders (Brodsky and Stanley, 2007; Roy, 2001a, 2001b; Sarchiapone *et al*, 2007).

Childhood trauma has also been shown to impact stress reactivity in adulthood by altering hypothalamic–pituitary–adrenal (HPA) axis function (De Bellis *et al*, 1994; Heim *et al*, 2004; Nemeroff, 2004; Roy, 2002a). Similarly, preclinical studies in both primates and rodents show that early life trauma impacts HPA axis function in the offspring

(Meaney, 2001; Sánchez *et al*, 2005; Weaver *et al*, 2005). Moreover, HPA axis dysregulation occurs in suicidal individuals. For example, changes on the dexamethasone suppression test, in 24 h urinary free cortisol outputs, salivary cortisol, cerebrospinal fluid levels of corticotrophin-releasing hormone (CRH), and CRH binding sites in frontal cortex have been reported in individuals exhibiting suicidal behavior (Arato *et al*, 1989; Bunney and Fawcett, 1965; Bunney *et al*, 1969; Coryell and Schlessler, 2001; Lindqvist *et al*, 2008; Nemeroff *et al*, 1988; Pfennig *et al*, 2005; Roy *et al*, 1986; Roy, 1992). Furthermore, decreased expression of the glucocorticoid receptor has been detected after postmortem of hippocampus from suicide victims exposed to childhood trauma (McGowan *et al*, 2009).

The mechanism of HPA axis dysregulation includes dysregulation of the hypothalamic peptides CRH and arginine vasopressin (AVP) leading to increased release of plasma ACTH and cortisol. This may be coupled with glucocorticoid receptor insensitivity that results in impairment of the negative feedback loop. Glucocorticoid receptor activation and ligand binding are moderated by a large molecular complex that includes FKBP5, a co-chaperone of hsp90. Upon ligand binding the glucocorticoid receptor dissociates from the chaperone complex and migrates to the nucleus where it initiates transcription in the target genes, *CRH* and *AVP*. Binder *et al* (2004) genotyped single nucleotide polymorphisms (SNPs) in the glucocorticoid receptor, the target genes, and five co-chaperones in the regulatory complex and detected a relationship between *FKBP5* and depression phenotypes. *FKBP5* SNPs have been associated with the response to antidepressants, the recurrence of depressive episodes (Binder *et al*, 2004), suicide attempts in bipolar patients (Willour *et al*, 2009), and the incomplete normalization of stress-elicited cortisol secretion (Ising *et al*, 2008). Moreover, Binder *et al* reported that in an African-American sample, four SNPs (rs3800373, rs9296158, rs1360780, and rs9470080) interacted with childhood trauma in predicting symptoms of posttraumatic stress disorder (PTSD), a disorder associated with both a raised risk of attempting suicide and HPA axis dysregulation (Binder *et al*, 2008; Wilcox *et al*, 2009). Therefore, it may be that *FKBP5* may moderate the sensitization by childhood trauma of the stress-responsive HPA pathway.

We administered the Childhood Trauma Questionnaire (CTQ) to a large group of African-American participants who had also been interviewed about the history of suicide attempts. Data from the ECA study found a 2.3% lifetime prevalence of attempted suicide among African Americans and showed that African Americans were as likely to attempt suicide as were other racial-ethnic groups (Moscicki *et al*, 1998). The majority of our African-American suicide attempters were substance-dependent patients, a psychiatric diagnosis associated with childhood trauma and with a raised risk of suicidal behavior (Arnou, 2004; Harris and Barraclough, 1997; Hyman *et al*, 2006; Johnsson and Fridell 1997; Kosten and Rounsaville 1988; Nelson *et al*, 2006; Roy, 2001a, 2001b, 2002b, 2003; Roy and Janal, 2007). Because suicidal behavior is associated with childhood trauma and HPA axis dysregulation, we decided to test the hypothesis that the interaction between childhood trauma and the *FKBP5* gene might increase the

risk for attempting suicide, at least in substance-dependent individuals in whom suicidality is frequently seen. Our primary haplotype analyses were conducted with the four previously implicated *FKBP5* SNPs (rs3800373, rs9296158, rs1360780, and rs9470080) but we also performed secondary analyses to determine whether denser SNP coverage of *FKBP5* (11 SNP haplotypes) would yield more information.

PARTICIPANTS AND METHODS

Participants

The sample consisted of two subsamples of African-American participants recruited from the same geographic area that were pooled for this study. The first subsample consisted of 706 African-American patients (634 men, 72 women) recruited from the Substance Abuse Treatment Program (SATP) at the Department of Veteran Affairs New Jersey Health Care System (VANJHCS), East Orange Campus. Nearly all were inpatients on a 21-day residential treatment ward, however, a few were recruited from the SATP outpatient clinic or from the methadone clinic. Criteria for inclusion in the study were that patients were ≥ 18 years of age, met DSM-IV criteria for alcohol, cocaine, or opiate dependence, self-identified as African American, and were abstinent. Exclusion criteria included mental retardation, dementia, and acute psychosis. Patients were interviewed by a psychiatrist (AR) with a semi-structured interview that included both the substance abuse section of the Structured Clinical Interview for DSM-IV (SCID) (Spitzer *et al*, 1995) to determine lifetime substance dependence diagnoses, and questions about whether the patient had ever attempted suicide. A suicide attempt was defined as a self-destructive act with some intent to end one's life that was not self-mutilatory in nature. The information from the patient about suicide attempts was supplemented by collateral information from mental health program staff, medical records, the program internist and physician's assistant, and, where possible, from treating mental health professionals. The definition of suicide attempt was implemented by a psychiatrist (AR) after interviewing the patient with a standard series of clinical questions and reviewing all of the collateral information. Their mean (SD) age was 45.2 (7.9) years.

The second subsample consists of 759 African-American men ($n=307$) and women ($n=452$) recruited from churches and a blood bank in Newark, NJ, (46%) and from a consecutive series of insulin-dependent diabetic outpatients seen at an ophthalmology clinic (54%) at the University of Medicine and Dentistry, New Jersey Medical School (UMDNJ), Newark, NJ. These participants had a semi-structured psychiatric interview conducted by either a physician or a research worker (reviewed by AR) that included a standard series of questions about lifetime suicidal behavior and substance abuse/dependence. Their mean (SD) age was 34.3 (10.1) years. These individuals were initially recruited as potential controls for genetic studies in substance dependence.

After a full description of the study was provided, all participants gave written informed consent to the study that was approved by the institutional review boards of the VANJHCS and UMDNJ.

Childhood Trauma Questionnaire

The CTQ (28-item version) was completed by 538 patients (92% men) with substance dependence; 166 (90% men) had attempted suicide. The CTQ was completed by 342 nonsubstance-dependent participants (42% men), 32 (28% men) of whom had attempted suicide (see Figure 1).

The CTQ yields scores for five traumas experienced in childhood: physical abuse, physical neglect, emotional abuse, emotional neglect, and sexual abuse, as well as a total score. Reliability and validity of the CTQ have been shown, including in drug abusers and African-American populations (Bernstein *et al*, 1997, 1994, 2003; Bernstein and Fink, 1998; Scher *et al*, 2001; Thombs *et al*, 2007). Some of the patients' CTQ data have been previously reported (Roy, 2001a, 2001b, 2002b, 2003). CTQ scores for each of the five traumas range from 5 to 25. The total CTQ score ranges from 25 to 125. The CTQ was used as a continuous measure in all logistic regression analyses.

A dichotomous total CTQ score was derived for use in secondary analyses to illustrate the direction of interaction effects on suicide attempt. A total CTQ score ≥ 1 SD above the mean CTQ score of nonsubstance-dependent/no suicide attempt participants (36.49 (11.67), ie, ≥ 48) was designated 'high level of childhood trauma' ($N = 290$); lower total CTQ scores (< 48) were designated 'low level of childhood trauma' ($N = 590$).

Genotyping

Genomic DNA was isolated from blood of 830 participants using standard protocols. Sixteen haplotype-tagging SNPs spanning *FKBP5* were selected; rs numbers for the 16 SNPs, the bases for alleles 1–2, together with the allele 2 frequencies, are shown in Table 1. Alleles 1 and 2 of each SNP are located on opposite DNA strands. All SNPs were genotyped using a TaqMan Assay-on-Demand (Applied Biosystems, Foster City, CA). Genotyping was performed according to the manufacturer's protocol and genotype was determined at end point using an ABI 7900HT Sequence Detection System. Genotyping accuracy was determined empirically by duplicate genotyping of 25% of the samples selected randomly. The error rate was < 0.005 , and the completion rate was > 0.95 . All SNPs were in Hardy–Weinberg equilibrium ($p > 0.14$) with the exception of

rs9470067 ($p = 0.001$), which was subsequently excluded from all analyses.

Summary of Data Set

The data set is summarized in Figure 1. Both genotype and CTQ data were available for 474 individuals: 112 suicide attempters (224 chromosomes for haplotype analyses) and 362 nonsuicide attempters (724 chromosomes for haplotype analyses). Missing DNA and CTQ data were random and showed no selection bias. Supporting evidence for this can be seen in Figure 1: the sex ratio was the same in the total

Table 1 Description of *FKBP5* SNPs

FKBP5 SNPs	Location		Base variation	freq
	chr 6	Gene	Alleles 1–2	Allele 2

SNPs in bold were included in the 4 SNP haplotype analyses.

^aRs9470067 genotypes were not in Hardy–Weinberg equilibrium and this SNP was therefore excluded from analyses.

^bThese 4 SNPs were not included in the 11 SNP haplotype analyses since they were not in LD with the other SNPs.

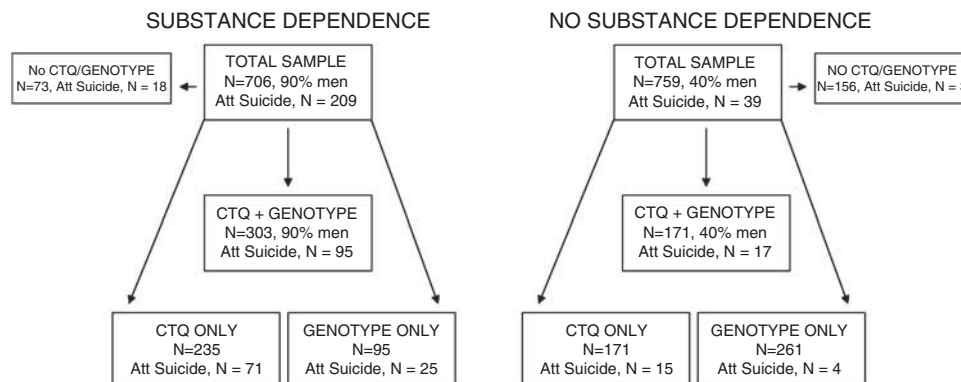

Figure 1 Summary of data set.

group of substance-dependent individuals and the subgroup with both CTQ and genotype data (both 90% men); likewise for the nonsubstance-dependent individuals (both groups had 40% men). Moreover, the proportion of suicide attempters was the same in all four subgroups of substance-dependent individuals shown in Figure 1 ($p = 0.61$).

Assessment of Population Stratification Using Ancestry Informative Markers

The samples were genotyped for 186 ancestry informative markers (AIMs) (Hodgkinson *et al*, 2008). The same AIMs were also genotyped in 1051 individuals from the 51 worldwide populations represented in the HGDP-CEPH Human Genome Diversity Cell Line Panel (<http://www.cephb.fr/HGDP-CEPH-Panel>). Structure 2.2 (<http://pritch.bsd.uchicago.edu/software.html>) was run simultaneously using the AIMs genotypes from our sample and the 51 CEPH populations to identify population substructure and compute individual ethnic factor scores. This ancestry assessment identifies seven ethnic factors that have been previously described (Stephens and Donnelly, 2003). In this sample of African Americans, the mean African factor score was 0.77 (median = 0.81) and the mean European factor score was 0.09 (median value = 0.04). Both a Mid East factor and an Asian factor had an average score of 0.06 (median 0.04).

Statistical Analyses

The primary analyses in this study were haplotype analyses conducted with the four SNPs: rs3800373, rs9296158, rs1360780, and rs9470080 that span 130 kb across *FKBP5*, are in strong linkage disequilibrium (LD) (Figure 2), and have consistently featured significant results in earlier publications (Binder *et al*, 2004, 2008; Ising *et al*, 2008; Willour *et al*, 2009). Secondary analyses were performed to elucidate the results of the primary analyses: (1) to determine whether denser SNP coverage (11 SNP haplotypes)

would yield more information, (2) analyses to illustrate the direction of interaction effects on suicide attempt, and (3) individual SNP analyses to determine whether any of the SNPs provided the signals for the haplotype analyses. Therefore the p -values for the secondary analyses were not adjusted for multiple comparisons. Nevertheless it should be noted that the whole model results for the secondary haplotype analysis ($p < 0.0001$) and the secondary six nonindependent SNP analyses (all $p < 0.0001$) were all highly significant.

Logistic regression analyses were undertaken using JMP 7 software. In the primary analysis, the yin yang haplotypes 2122 and 1211 were included as dependent variables in the model (Table 2) and in secondary analyses, the 11 SNP haplotypes H2 and H5 were included as dependent variables (Table 3). Backward stepwise regression was performed with variables being eliminated from the model in an iterative process. The continuous CTQ score and, ethnic factor scores, and the dichotomous variables: substance dependence diagnosis, age, and sex were included as covariates in the final model if they had significant effects. The interaction term was included in the final model when significant. Logistic regression models with nominal variables yielded likelihood ratio (L-R) χ^2 results.

Logistic regression results for four SNPs (rs9470065, rs4713899, rs7771722, and rs4713902) were unstable due to the low numbers of the 22 homozygotes, therefore analyses were performed on the combined 22 and 12 genotypes.

Haplotype frequencies were estimated using a Bayesian approach implemented with PHASE (Stephens and Donnelly, 2003). Haploview version 2.04 software (Whitehead Institute for Biomedical Research, USA) was used to produce LD matrices. Because rare and uncommon haplotypes are subject to estimation errors because of increased sampling variance, all analyses were conducted with haplotypes $\geq 5\%$ frequency.

Although the mean (SD) age of substance-dependent patients (45.2 (7.9)) was higher than nonsubstance-dependent participants (34.3 (10.1), $F = 211$, $p < 0.0001$) there was no correlation between age and CTQ score in either patients

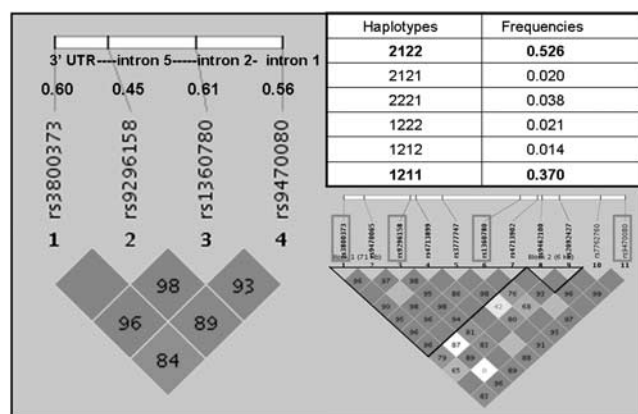

Figure 2 FKBP5 11 single nucleotide polymorphism (SNP) haplotype block structure and four SNP haplotype block and haplotypes. The numbers in the squares refer to pair-wise linkage disequilibrium (LD) measured as D' . Haplotype blocks were defined using a setting of average pair-wise D' within-block of ≥ 0.80 . The left panel shows the haplotype block structure for the four SNPs highlighted in the right panel; the four SNP haplotypes are listed and the yin yang haplotypes are indicated in bold.

Table 2 The Influence of the Primary Four SNP Yin Yang Haplotypes and Childhood Trauma on Attempted Suicide

Parameters	L-R tests χ^2	p -value
FKBP5 yin yang haplotypes: 2122, 1211	2.63	0.11
European ethnic factor score	7.59	0.006
Substance Dependence Diagnosis	31.42	<0.0001
Total CTQ score	27.63	<0.0001
G \times E	4.53	0.006

Whole model test: $\chi^2 = 111$; $df = 5$; $p < 0.0001$, $r^2 = 0.13$.

The effect likelihood ratio tests (L-R) are shown (1 df for each test).

The yin yang haplotypes account for 90% of total haplotype diversity (see Figure 2).

$N = 749$. Since these are haplotype analyses the N represents the number of chromosomes (2 per individual).

The total Childhood Trauma Questionnaire (CTQ) score is a continuous measure.

G \times E indicates the interaction between yin yang haplotypes and total CTQ score.

Table 3 The Influence of Two II SNP Haplotypes, H2 and H5, and Childhood Trauma on Attempted Suicide

Parameters	L-R tests χ^2	p-value
II SNP haplotypes H2, H5	1.38	0.239
European ethnic factor score	5.20	0.023
Substance Dependence Diagnosis	17.24	<0.0001
Total CTQ score	6.83	0.009
G \times E	6.89	0.009

Whole model test: $\chi^2 = 43$; $df = 5$; $p < 0.0001$, $r^2 = 0.19$.

The effect likelihood ratio tests (L-R) are shown (1 df for each test).

$N = 230$. As these are haplotype analyses, the N represents the number of chromosomes (2 per individual). Only carriers of haplotypes H2 (freq = 17%) and H5 (freq = 9%) were included in these analyses. Haplotype H2: 11212111211; haplotype H5: 21111221112

The total childhood trauma questionnaire (CTQ) score is a continuous measure. G \times E indicates the interaction between haplotypes H2, H5, and total CTQ score.

($r = 0.07$, $p = 0.211$) or nondependent individuals ($r = 0.09$, $p = 0.276$). Inclusion of age as a covariate had no effect on outcomes.

There were no sex differences in CTQ scores within the categories: nonsubstance-dependent/no suicide attempt, substance-dependent/no suicide attempt, nonsubstance-dependent + suicide attempt, substance-dependent + suicide attempt. Therefore both sexes were included together in the analyses.

RESULTS

Substance abuse was associated with significantly higher total CTQ scores ($F(1,879) = 100$, $p < 0.0001$). However, individuals who had attempted suicide had higher CTQ scores irrespective of whether they were substance dependent—mean (SD) CTQ scores in: nonsubstance-dependent/no suicide attempt = 36.5 (11.7) ($n = 310$); substance-dependent/no suicide attempt = 46.6 (15.2) ($n = 372$); nonsubstance-dependent + suicide attempt = 53.0 (18.3) ($n = 32$); substance-dependent + suicide attempt = 53.7 (19.5) ($n = 166$), $F(3,876) = 54.3$, $p < 0.0001$.

In this sample of African Americans, European admixture significantly influenced the risk of suicide attempt (Tables 2 and 3).

Four SNP Haplotype Analyses

The primary analyses were conducted with the four SNPs (rs3800373, rs9296158, rs1360780, and rs9470080) that have been implicated in earlier studies and which were the subject of our hypothesis. Figure 2 shows that these four SNPs that span *FKBP5* are in strong LD. Within this haplotype block there are six haplotypes with $\geq 1\%$ frequency that account for 99% of the haplotype diversity (Figure 2). There are two major yin yang haplotypes, 2122 and 1211, that account for 90% of the haplotype diversity. For simplicity, analyses were performed with these two yin yang haplotypes.

Logistic regression analyses were performed to determine the effects of the yin yang haplotypes and childhood trauma

Figure 3 The interaction of *FKBP5* yin yang diplotypes with high levels of childhood trauma predicts suicide attempts. High level of childhood trauma = total Childhood Trauma Questionnaire (CTQ) score ≥ 1 SD (≥ 48) above mean of nonsubstance-dependent/no suicide attempt participants. Low level of childhood trauma = total CTQ score < 48 . $N = 427$; $\chi^2 = 8.5$, $df = 2$, $p < 0.014$.

(the continuous total CTQ score) on suicide attempt and the results are presented in Table 2. Childhood trauma had a significant effect on suicide attempt but there was no main effect of the yin yang haplotypes. However the interaction between the yin yang haplotypes and CTQ score significantly influenced the risk of attempted suicide. The total model shown in Table 2 was significant ($\chi^2 = 111$, $df = 5$, $p < 0.0001$) and contributed to 13% of the variance in attempted suicide.

Secondary Analyses

Interaction Between CTQ Score and Four SNP Diplotypes

To illustrate the direction of the interaction effect on suicide attempt, we used the previously described dichotomous CTQ high/low variable (high level of childhood trauma designated as CTQ total score ≥ 1 SD above the mean score of nonsubstance-dependent/no suicide attempt participants; lower CTQ scores were designated low level of childhood trauma). Figure 3 shows the individuals who had experienced a high level of childhood trauma, 51% of those with two copies of the 2122 haplotype had attempted suicide compared with 36% of those with one copy of 2122 and 20% of those with no copies of the risk haplotype ($\chi^2 = 8.5$, $df = 2$, $p = 0.014$). In contrast, haplotype 2122 conferred no risk to the individuals who had been exposed to low levels of childhood trauma. Similar results were found if the same diplotype analysis was performed only in the substance-dependent participants ($N = 274$): 56% of those with two copies of the 2122 haplotype had attempted suicide compared with 39% of those with one copy of 2122 and 23% of those with no copies of the risk haplotype ($\chi^2 = 7.0$, $df = 2$, $p = 0.031$) whereas genotype had no effect on individuals who had been exposed to low levels of childhood trauma (26–30% suicide attempters).

Eleven SNP Haplotype Analyses

Further secondary analyses were performed to determine whether denser SNP coverage would yield more information about haplotype–diplotypes associations. There is strong LD across the whole gene within which we had genotyped 16 SNPs (Table 1), however 4 low-frequency SNPs clustered in the middle of the haplotype block (rs7762668, rs9462099, rs9380524, and rs7771722) showed poor LD and were eliminated from the haplotype analyses. Moreover, as rs9470067 genotypes were not in Hardy–Weinberg equilibrium this SNP was also excluded from the analyses.

The resulting 11 SNP haplotype analyses indicated one haplotype block across the gene (Figure 2). There were 14 haplotypes with ≥1% frequency that accounted for 95% of haplotype diversity and 8 haplotypes with ≥5% frequency that accounted for 85% of haplotype diversity. For simplicity, and as rare and uncommon haplotypes are subject to estimation errors because of increased sampling variance, analyses were performed with the haplotypes with ≥5% frequency in the total sample: H1, 11%; H2, 17%; H3, 9%; H4, 18%; H5, 9%; H6, 7%; H7, 6%; and H8, 8%. Haplotypes derive from two cladistic groupings: H1–H3 and H4–H8 (Figure 4).

Haplotype H5 was more abundant in those individuals who attempted suicide whereas haplotype H2 was more abundant in individuals who had not attempted suicide (Figure 4). Moreover, 60% of individuals with the H5/H5 diplotype ($N=5$) had attempted suicide compared with 20% with the H2/H5 diplotype ($N=20$) and 10% with the H2/H2 diplotype ($N=30$). However, the logistic regression analysis (Table 3) revealed no main effect of H2 or H5 haplotype on suicide attempt (Table 3). Instead, a $G \times E$ interaction was apparent. The total model shown in Table 3 was significant ($\chi^2 = 43$, $df = 5$, $p < 0.0001$) and contributed to 19% of the variance in attempted suicide.

Interaction Between CTQ Score and 11 SNP Haplotypes

To illustrate the direction of the interaction effect on suicide attempt, we used the previously described CTQ high/low levels of childhood trauma variable. Diplotype analyses

											Haplotype Frequency		
											Att Suicide	None	
1	1	2	1	2	1	1	1	1	1	1	H1	0.12	0.12
1	1	2	1	2	1	1	1	2	1	1	H2	0.15	0.22 ↓
1	1	2	2	2	1	1	1	1	1	1	H3	0.09	0.10
2	1	1	1	1	2	1	1	1	1	2	H4	0.24	0.21

Figure 4 Frequencies of FKBP5 haplotypes in individuals who have attempted suicide compared with nonsuicide attempters. Total number of haplotypes = 1312. Cladistic grouping of haplotypes (H1–H3 and H4–H8) with frequencies ≥0.05 in total sample. Increased frequency of haplotype H5 and decreased frequency of haplotype H2 in suicide attempters. SNPs extend left to right from rs3800373 to rs9470080 (see Table 1). For each SNP, alleles 1 and 2 are located on opposite DNA strands.

were not possible because, as can be deduced from Figure 4, the frequencies of the 11 SNP diplotypes were too low. Figure 5 shows the individuals in the total group who had experienced a high level of childhood trauma, 62% of those with the H5 haplotype had attempted suicide compared with 25% of those with the H2 haplotype ($\chi^2 = 11.2$, $df = 1$, $p = 0.0008$). In contrast, haplotype H5 conferred no risk to the individuals who had been exposed to low levels of childhood trauma.

Individual SNP Analyses

Secondary analyses were performed with the individual SNPs to determine whether any of the SNPs provided the signals for the findings of the haplotype analyses. Results for the SNPs that were associated with an effect on suicide attempt are summarized in Table 4. When all significant covariates were included in the logistic regression analyses, the following three SNPs showed significant associations with attempted suicide: rs3777747 located in intron 5 (allele 1 frequency increased in attempted suicide: 0.45 vs 0.38); rs4713902 located in intron 1 (allele 2 frequency increased in suicide attempters: 0.14 vs 0.08); and rs9470080 located in intron 1 (allele 1 frequency decreased in attempted suicide: 0.38 vs 0.45). Three SNPs showed a $G \times E$ interaction: rs3800373, rs9296158, and 1360780 (Table 4). Results with all other SNPs were negative.

From Figure 4 and Table 1 it can be deduced that haplotypes H2 and H5 differ in the four SNPs included in the primary haplotype analyses and they also differ in SNPs rs3777747, rs4713902 (unique to H5), and rs2092447 (unique to H2). rs3777747 had a main effect on suicide attempt but its variation is common to several haplotypes. rs2092447 is unique to H2 but showed no association with

Figure 5 Interaction between FKBP5 haplotypes and childhood trauma; influence on suicide attempt. Haplotype H2 (11212111211), freq = 17%; haplotype H5 (21111221112), freq = 9%. High level of childhood trauma = total Childhood Trauma Questionnaire (CTQ) score ≥1 SD (≥48) above mean of nonsubstance-dependent/no suicide attempt participants. Low level of childhood trauma = total CTQ score <48. $N = 235$; $\chi^2 = 11.2$, $df = 1$, $p = 0.0008$.

Table 4 The Influence of Selected *FKBP5* SNPs and Childhood Trauma on Attempted Suicide

SNPs	Gene effect		Substance dependence		Childhood trauma effect		G × E interaction		Whole	Model	
	L-R χ^2	P	L-R χ^2	P	L-R χ^2	P	L-R χ^2	P	P	df	Var
Rs3800373			21.6	<0.0001	7.3	0.007	9.0	0.011	<0.0001	6	0.12
Rs9296158			18.8	<0.0001	11.1	0.0009	7.2	0.028	<0.0001	6	0.12
Rs3777747	7.9	0.019	17.9	<0.0001	21.5	<0.0001	—	—	<0.0001	4	0.11
Rs1360780			18.5	<0.0001	8.8	0.003	7.9	0.020	<0.0001	6	0.11
Rs4713902	5.1	0.023	19.5	<0.0001	17.9	<0.0001	—	—	<0.0001	3	0.11
Rs9470080	7.2	0.027	19.2	<0.0001	21.3	<0.0001	—	—	<0.0001	4	0.11

Var, variance explained by total model; df, degrees of freedom.

Results are for effect likelihood ratio (L-R) tests and are given for $p < 0.05$.

The childhood trauma effect derives from the childhood trauma questionnaire (CTQ) score, a continuous measure.

df for rs4713902 is 3 as the 11 and 12 genotypes were combined to increase power.

All other SNPs showed no significant main or interactive effects on attempted suicide.

attempted suicide. In contrast, rs4713902 is unique to H5 and showed a significant association with attempted suicide. This suggests that rs4713902 is initiating the 11 SNP haplotypes' association with attempted suicide.

FKBP5 SNP Variation and Substance Dependence

Logistic regression analyses were performed to determine whether there was any association between any of the SNPs listed in Table 4 (that showed a main or interactive effect on suicide attempt) and substance dependence. The continuous CTQ score and the dichotomous suicide attempt variable (yes or no) were included as covariates as they had significant effects on substance dependence. There were no main gene effects nor was there an interactive effect between *FKBP5* SNPs and the continuous CTQ score on substance dependence.

There were no interactive effects between substance dependence, CTQ scores and *FKBP5* SNPs on suicide attempt.

Bioinformatics SNP analysis. A bioinformatics search was performed to look at the six SNPs that had either a main or G × E effect on suicide attempt. The search was for potential function such as protein effect by nonsynonymous variants, regulatory effects such as changes in transcription factor binding sites, microRNA sites, or microRNA targets, nearby splice sites or effects on exonic splicing enhancers (ESEs). The only finding was that rs3800373 C > A causes the loss of the ESE SC35. Although there are some alternative splicing isoforms for *FKBP5*, rs3800373 is not close to these alternatively spliced exons so it is not known whether this ESE has any importance in this context.

DISCUSSION

This study has shown that individuals who attempted suicide had experienced significantly greater childhood trauma than individuals who had never attempted suicide. This was the case in both the total group and the substance-dependent group and is in accord with previous reports

showing that childhood trauma is a risk factor predisposing individuals to attempt suicide when stressed (reviewed in Brodsky and Stanley, 2007). The novel finding from this study comes from the results suggesting that interaction between childhood trauma and the stress-related gene *FKBP5* may have a role in suicidal behavior.

In testing our primary hypothesis of interaction with childhood trauma we examined *FKBP5* haplotypes derived from the four SNPs that had been implicated in earlier studies (Binder *et al*, 2004, 2008; Ising *et al*, 2008; Willour *et al*, 2009). These four SNPs are in strong LD with each other and also the other seven SNPs that were tested. Because studies have not yet shown which (if any) of the linked SNPs in the haplotype block is functional, it was more appropriate that the primary focus of our study was haplotype analyses. There was no direct effect of the two major yin yang (2122 and 1211) haplotypes on suicidal behavior. However, the interaction between *FKBP5* haplotypes and childhood trauma significantly increased the risk of attempting suicide. Among subjects who had experienced high childhood adversity, 51% of those with two copies of the 2122 haplotype had attempted suicide compared with 36% of those with one copy and only 20% of those with no copies. In contrast, there was no gene effect in individuals who had been exposed to little or no childhood trauma. The total logistic regression model accounted for 13% of the variance in attempting suicide.

Similarly, in a more comprehensive secondary haplotype analysis with 11 SNPs spanning *FKBP5* we also detected a significant haplotype–childhood trauma interaction associated with a raised risk of attempting suicide. The total model resulting from this more refined analysis now accounted for 19% of the variance for attempting suicide. The 11 SNPs were all in strong LD, however, individual SNP analyses revealed a gene × childhood trauma interactions for rs3800373, rs9296158, and rs1360780 (Table 4). Three SNPs had main effects on suicide attempts: rs9470080, rs3777747, and rs4713902. The latter is of interest as it is unique to the 11 SNP haplotype that was associated with suicide attempt. However, the results of this analysis should be interpreted with caution until replicated due to the small sample size.

FKBP5 is known to be an inhibitor of glucocorticoid sensitivity therefore elevated levels of FKBP5 might result in the impairment of the HPA axis negative feedback loop.

The SNPs rs3800373, rs9296158, rs1360780, and rs9470080 are in strong LD and their frequencies are in approximate allelic identity in African Americans (0.39–0.45), suggesting that they may have been subjected to selective pressure. There is some evidence that one or other of these SNPs, or another linked SNP, are functional. Binder *et al* (2004) found that the minor homozygotes of rs1360780 and rs3800373 were associated with FKBP5 levels in lymphocytes that were twice as high as those with the other two genotypes, however there was no difference in mRNA levels or in plasma cortisol levels. The minor homozygotes of rs1360780 and rs3800373 were associated with a stronger induction of *FKBP5* mRNA by cortisol. Further studies are clearly warranted to determine the possible effects of *FKBP5* genetic variation on the HPA axis. In our study we found that the major alleles of these four SNPs, together with the minor allele of rs4713902, the SNP that was promoting the 11 SNP haplotype association, were associated with suicide attempt. Moreover, a bioinformatics search revealed that rs3800373 C>A causes the loss of the ESE SC35. Although it is not known whether this ESE has any relevance *in vivo*, nevertheless in our study the rs3800373 A allele was associated with risk for suicide attempt.

As can be deduced from Table 1 and Figure 3, we found that the more abundant alleles of the four primary SNPs (rs3800373, rs9296158, rs1360780, and rs9470080) were risk factors for suicide attempt in individuals exposed to high childhood adversity. In contrast, Binder *et al* (2008) using the child abuse section of the Traumatic Events Inventory found that the less abundant variants of these four SNPs were significantly associated with greater PTSD severity in the small group of individuals (approximately 47) exposed to two types of child abuse but not in the larger group exposed to one type of abuse. Although Binder *et al* (2008) used the CTQ total score in secondary analyses, no results were reported for CTQ interactive effects in the primary analyses with these four SNPs. Because different CTQs were used to detect effects on different outcomes, it is premature to comment at this time on the different direction of *FKBP5* SNP associations in our study and that by Binder *et al* (2008). However, it is tempting to speculate that these differences may be due to contrasting HPA axis sensitivities in PTSD and addiction. Results from studies in PTSD implicate a sensitization of the HPA axis to exposure to stressors (Heim and Nemeroff, 2009; Binder, 2009). In contrast, alcohol and drug dependence are associated with a blunted HPA axis response to stress (Richardson *et al*, 2008). The addicted participants in this study had such severe substance dependence that they were in an inpatient treatment program and therefore it is likely that their HPA axis responsivity was compromised. Clearly, replication studies in other populations with addiction are needed.

Suicide is generally considered to be a multidetermined act with distal and proximal risk factors. In the stress-diathesis risk factor model of suicidal behavior, both childhood trauma and genetic factors are distal suicide risk factors. They are thought to have their effect by predisposing an individual to an increased risk of attempting suicide when he/she experiences more proximal risk factors such

as recent life stress. The fact that a gene implicated in the HPA axis stress-reactivity pathway may be involved in suicidal behavior is of interest given that stress often precipitates suicide attempts. For example, Paykel *et al* (1975) first showed that those who attempted suicide reported four times as many life events in the 6 months before the attempt than controls. The authors' conclusion that there is strong and immediate relationship between suicide attempts and recent life stress has been replicated in different countries and age groups as well as in completed suicides (Beatrais *et al*, 1997; Crane *et al*, 2007; Heikkinen *et al*, 2007; Osvath *et al*, 2004). The results of the present study suggest that distal genetic and developmental risk factors may themselves interact to raise the risk of an individual attempting suicide when stressed. In fact in an earlier study we similarly showed that the stress-related serotonin transporter promoter polymorphism (5-HTTLPR) interacted with childhood trauma to predict suicidal behavior in these same substance-dependent patients (Roy *et al*, 2007). In this study it was the distal risk factors of childhood trauma and the *FKBP5* gene that together influenced suicide attempt.

Is there a possible explanation in terms of specific etiologic pathways by which the interaction of *FKBP5* and childhood trauma found in the present study might increase the risk of an individual attempting suicide? As *FKBP5* impacts glucocorticoid sensitivity, one might speculate that one mechanism underlying this interaction might be the epigenetic effects of childhood trauma. In this regard it is noteworthy that a recent postmortem study has reported a significant effect of childhood abuse on the epigenetic regulation of glucocorticoid receptors in suicide victims (McGowan *et al*, 2009). Such a mechanism might also explain why Binder *et al* (2008) found a G × E effect on PTSD symptoms with childhood trauma but not trauma exposure in adulthood.

The strengths of this study include the fact that we studied an African-American sample similar to that of Binder *et al* (2008), and that we corrected for population stratification in this admixed population using ethnic factor scores derived from 186 AIMS. It turned out that correction for population stratification was necessary as European admixture significantly influenced the risk of suicide attempt. There are a few limitations to our study. The childhood trauma data were derived from a self-report questionnaire. Nevertheless, the CTQ has been shown to have high reliability and validity (Bernstein *et al*, 1997, 1994; Bernstein and Fink, 1998; Scher *et al*, 2001; Thombs *et al*, 2007). Studies have shown that the retrospective reporting of childhood trauma is valid (Bifulco *et al*, 1997; Goodman *et al*, 1999) and is not influenced by psychiatric state at the time of report (Fergusson *et al*, 2000). In this regard it is noteworthy that all the patients were abstinent at the time of study. Most patients were interviewed in the last week of a 3-week stay in a locked substance abuse residential program. Other limitations are that the CTQ does not include an exhaustive list of potentially traumatic events that are commonly experienced in youth and that adult exposure to potentially traumatic events was not assessed. Because men predominated in the sample, it was not possible to determine potential sex differences. Moreover, the nature of each suicide attempt was not

systematically recorded. As the complete SCID was not administered, data about possible comorbid disorders such as PTSD and depression were not available. Finally, the sample size decreased to 474 (112 suicide attempters) when examining gene \times environment interactions although this sample size is comparable to that for the significant findings in Binder *et al* (2008). Our results should therefore be interpreted with caution until replicated by others.

In conclusion, this study reports that significant interaction between childhood trauma and the HPA axis gene *FKBP5* appears to raise the risk of attempting suicide. However, as only up to 19% of the variance in risk for a suicide attempt was accounted for, and as the sample was African American and the suicide attempts were largely confined to the substance-dependent patients, it is not known whether the results of our study can be extrapolated to other groups and nonsubstance-dependent patients. Therefore, the generalizability of the results is an issue and further studies are indicated in relation to suicidal behavior in other diagnostic and ethnic groups.
