Abstract

Recent years have witnessed a renewed interest in using oscillatory brain electrical activity to understand the neural bases of cognition and emotion. Electrical signals originating from pericranial muscles represent a profound threat to the validity of such research. Recently, McMenamin et al (2010) examined whether independent component analysis (ICA) provides a sensitive and specific means of correcting electromyogenic (EMG) artifacts. This report sparked the accompanying commentary (Olbrich, Jödicke, Sander, Himmerich & Hegerl, *in press*), and here we revisit the question of how EMG can alter inferences drawn from the EEG and what can be done to minimize its pernicious effects. Accordingly, we briefly summarize salient features of the EMG problem and review recent research investigating the utility of ICA for correcting EMG and other artifacts. We then directly address the key concerns articulated by Olbrich and provide a critique of their efforts at validating ICA. We conclude by identifying key areas for future methodological work and offer some practical recommendations for intelligently addressing EMG artifact.

Recent years have witnessed a renewed interest in using neural oscillations to understand the substrates of mental function and dysfunction (Uhlhaas & Singer, 2010). Electrical activity generated by the pericranial musculature, electromyogenic (EMG) artifact, is one of the most profound threats to the validity of such studies. The danger is intrinsic to the cardinal features of EMG, particularly its high amplitude, broad spectral and anatomical distributions, and sensitivity to psychologically interesting processes. Consequently, even subtle EMG artifact can generate spurious effects and can mask or otherwise alter genuine ones across virtually the entire spectrum of the electroencephalogram (EEG).

A number of tools for EMG correction have been developed, however, the pace of algorithm development and dissemination has outstripped work to rigorously assess the sensitivity and

specificity of such tools. Collectively, these issues motivated several recent methodological publications by our group (McMenamin et al., 2010; McMenamin, Shackman, Maxwell, Greischar, & Davidson, 2009; Shackman, 2010; Shackman, McMenamin, Maxwell, Greischar, & Davidson, *in press*; Shackman et al., 2009). In particular, in McMenamin et al. (2010), we examined the validity of the extended Infomax independent component analysis (ICA) algorithm (Jung et al., 2000a,b; Onton, Westerfield, Townsend, & Makeig, 2006).

It was this report that sparked the accompanying commentary by Olbrich (Olbrich, Jödicke, Sander, Himmerich & Hegerl, 2010). Our response is organized as follows. We begin by briefly summarizing the EMG problem and then outline recent research, including our own, assessing the utility of ICA for correcting artifacts. Next, we directly address the key concerns articulated by Olbrich and critique their efforts at validating ICA. We conclude by identifying key areas for future methodological work and offer some practical recommendations for dealing with EMG artifact.

Nature of the EMG Problem

The difficulty encountered when addressing EMG artifact can be attributed to three key factors: a) its spatial and spectral distribution, b) its exquisite sensitivity to a variety of psychologically interesting processes, and c) its lack of stereotypy. The EMG signal has remarkable spatial extent and spectral breadth. Although the EMG power spectrum peaks at relatively high frequencies (~100Hz), it is sufficiently broad to overlap with all EEG frequencies of interest. Goncharova, McFarland, Vaughan, and Wolpaw (2003) report reliable myogenic effects as low as 2 Hz. They also demonstrated that EMG can be detected anywhere on the scalp due to volume conduction of activity generated by muscles across the head, face and neck. Comparably widespread effects were observed by McMenamin (Figure 1).

These problems are further complicated by the fact that EMG is sensitive to a variety of experimental manipulations. Facial EMG, in particular, is sensitive to numerous cognitive and affective processes, including cognitive load (Cohen et al., 1992; Waterink & van Boxtel, 1994), facial mimicry (Dimberg et al., 2000), vocalization (Brooker & Donald, 1980), and induced emotional states (Borden et al., 1991; Coan and Allen, 2001; Bradley et al., 2001). Such effects are not limited to the face: activity generated by the muscles of the neck, for instance, has been shown to closely track performance motivation (Roesch & Olson, 2007). A consequence of such effects is that changes in neurogenic and myogenic activity are often confounded, allowing muscle activity to masquerade as EEG or fundamentally alter the magnitude or topography of genuine neurogenic effects. Indeed, McMenamin showed that when changes in neurogenic and myogenic activity negatively covaried, alpha-blocking associated with eye-opening was attenuated at locations across the scalp and source-space, including posterior locations far removed from peak myogenic activity. These effects did not reflect an artificially extreme degree of EMG contamination. In fact, the statistical effect-size for the alpha-blocking contrast was three times larger than the myogenic contrast. Together, these observations underscore that even low-intensity myogenic activity represents a serious risk to validity.

Lastly, EMG exhibits a poorly stereotyped response, making removal difficult. EMG arises from the activity of spatially distributed, functionally independent muscle groups, with distinct topographic and spectral signatures. For instance, *frontalis* activity peaks around 25 Hz, whereas *temporalis* has a lower peak (~20 Hz) and broad plateau around 40–80 Hz (Goncharova et al., 2003). The spectral composition of myogenic activity can vary with contraction intensity (Goncharova et al., 2003) and fatigue (Chung et al., 2002). This is compounded by the fact that the relative contributions of each muscle can vary substantially across elicitors and individuals (Tassinary et al., 2007). Consistent with this, McMenamin

demonstrated that even carefully instructed myogenic activity is characterized by marked individual differences (Table 1). Across participants ($n = 17$), anywhere from 3% to 67% of the 64 independent components that were extracted were classified as 'pure' myogenic activity. Likewise, myogenic components accounted for as little as 1.5% and as much as 78.5% of the variance in EEG activity (see Figures 6–7 in McMenamin). Given such individual differences in the spectral and topographic profile of myogenic activity, canonical spatial or spectral filters or templates of the kind that have been fruitfully applied to the correction of ocular artifact (e.g., Viola et al., 2009) probably are not suitable for correcting typical EMG artifacts.

Validating the use of Infomax ICA for EMG Correction

The Infomax ICA algorithm has rapidly become one of the most prominent techniques for removing EMG and other contaminants from the EEG. Conceptually, ICA-based correction entails three steps. First, ICA is used to perform an unsupervised decomposition of the EEG into temporally independent components (Onton et al., 2006; Onton & Makeig, 2006). Next, components are classified, and those categorized as artifact are discarded (for a detailed classification protocol, see the Supplement to McMenamin). Classification is typically performed manually, although algorithmic techniques have been developed (Shackman et al., 2009). Finally, the 'artifact-free' time-series is reconstructed from the remaining components. ICA's ability to reconstruct the time-series is a key advantage over artifact correction techniques that cannot do so, such as those based on the general linear model (McMenamin et al., 2009). Although ICA shows great promise for correcting EMG and other artifacts (e.g., Jung et al., 2000a,b), attempts to assess its validity have been limited (reviewed in McMenamin and in Shackman et al., 2009). Moreover, few studies have gauged the impact of ICA-based EMG correction on source modeling ('localization'), an increasingly popular technique for maximizing the anatomical information yielded by the EEG (Pizzagalli, 2007).

Accordingly, McMenamin quantitatively assessed the sensitivity and specificity of ICA on the scalp and in the cerebral source-space using a dataset in which neurogenic and myogenic activity were independently manipulated. Critically, this design allowed us to examine ICA-based EMG correction under conditions in which neurogenic and myogenic activity covaried, as they do in many experimental settings. The degree to which artifact correction produced spurious effects in the absence of artifact was also assessed. Finally, given earlier work suggesting the importance of varying the procedures for discarding non-myogenic artifacts (Shackman et al., 2009), McMenamin tested whether varying these procedures affected the quality of EMG correction[1]. Importantly, our validation analyses made use of both mean *difference* and mean *equivalence* tests (Seaman & Serlin, 1998)—the latter are essential for rigorously demonstrating the sensitivity and specificity of a particular correction technique.

Results revealed that some, but not all, of the correction procedures exhibited adequate sensitivity and specificity on the scalp (see also Shackman et al., 2010). The most sensitive and specific procedure was among the strictest of the nine examined, entailing the rejection of any component showing evidence of EMG, in addition to those reflecting gross or ocular artifacts, noise, or unclassifiable low-variance signals. None of the procedures consistently showed excellent performance on the scalp. That is, a modest number of 'worst-case' electrodes

---

[1]Nine procedures for filtering classified components were examined by McMenamin, reflecting the factorial crossing of procedures for discarding myogenic vs. non-myogenic artifacts (see Table 1 and the Supplement to McMenamin). Three procedures for discarding myogenic components were assessed: *Minimal-EMG*: Myogenic components; *Intermediate-EMG*: Myogenic and Myogenic > Neurogenic ('Myogenic-Dominant' heterogeneous) components; *Maximal-EMG*: Myogenic, Myogenic > Neurogenic, and Neurogenic > Myogenic ('Neurogenic-Dominant' heterogeneous) components. Three procedures for discarding non-neurogenic/non-myogenic (NNNM) components were assessed: *Minimal-NNNM*: Gross or Ocular components; *Intermediate-NNNM*: Gross, Ocular or Noise components; *Maximal-NNNM*: Gross, Ocular, Noise or Low Variance components. Application of the different filtering procedures led to marked differences in the percentage of scalp variance that was discarded (range: 26%–73%; see McMenamin, Figures 6–7).

evinced under- or over-correction. This residual error on the scalp resulted in poor sensitivity and specificity in the cerebral source-space. This conclusion was not entirely unexpected, given other work highlighting the potential limitations of Infomax ICA (Crespo-Garcia et al., 2008; Fitzgibbon et al., 2007; Wallstrom et al., 2004; Romero et al., 2008; Castellanos & Makarov, 2006; Debener et al., 2008; Hyvärinen, Ramkumar, Parkkonen & Hari, 2010; Klemm, Haueisen & Ivanova, 2009; Lindsen & Bhattacharya, 2010; Vanderperren et al, 2010).

Rebuttal of Olbrich

We next address the three key concerns articulated by Olbrich. Although they raise several conceptually and methodologically important points, none of their specific concerns fundamentally change the implications of our research.

Too Few Components?

Olbrich suggests that the inadequate performance of ICA-based EMG correction reported by McMenamin might reflect the procedures used for extracting independent components, rather than an intrinsic limitation of the Infomax ICA algorithm. In particular, they expressed concern that an insufficient number of components may have been extracted to adequately separate neurogenic and myogenic sources. There are two reasons for rejecting this possibility. First, as noted by McMenamin (their footnote 5), preliminary visual inspection of the 128 components extracted from the native electrode array indicated over-fitting, evidenced by the fission of artifactual signals across components (e.g., ocular and cardiac artifacts loaded onto an excessive number of components; see also Viola et al., 2009). Based on these exploratory analyses, we ultimately elected to use principal components analysis (PCA) to extract 64 components for validation testing. Qualitatively, reducing the number of components attenuated the amount of 'splitting' or 'leakage' of artifacts across multiple components. Second, using information theoretic procedures, McMenamin demonstrated that extracting 64 components always exceeded the Bayesian estimate of the minimum number required to describe the data (Table 1), providing quantitative evidence against underfitting.

Olbrich also suggested that it might have been more appropriate to compute ICA separately for each condition (i.e., quadrupling the number of components available for separating sources). There are several potential problems with this suggestion, aside from the strong possibility of overfitting the data. First, everything else being equal, reducing the amount of data used to decompose the EEG will tend to degrade the quality of the source separation (Makeig & Onton, *in press*). Put simply, given fewer exemplars of a particular artifact, ICA will be less able to cleanly separate it from other sources. A second problem with this suggestion is that generating separate ICA-based artifact filters for each condition has the potential to confound errors introduced by artifact correction with differences in neurogenic activity. Artificial correlations between condition and correction errors, like correlations between condition and EMG artifact, pose a direct threat to inferential validity. Fortunately, it is easy to eliminate this artificial threat simply by performing component extraction and classification on the complete dataset for each participant (i.e., all conditions considered simultaneously).

Classification Biases?

Olbrich suggested that our results might reflect problems with component classification, rather than a failing of Infomax ICA. But this concern appears to be entirely theoretical. To our knowledge, a reasonably well-validated algorithm for classifying components simply does not exist. Instead, prior work to develop classification algorithms has largely relied on simple heuristics (e.g., EMG components display more activity >40Hz than <20Hz) or training datasets that were pre-classified by 'expert' raters (e.g., Mammone & Morabito, 2008). By contrast, we provided a detailed classification protocol that relied on a comprehensive

inspection of each component, including its time-series, spectra, and topography (see the Supplement to McMenamin). This classification protocol proved highly reliable across *two* independent human raters (αs = .93–.98). Notably, we also systematically examined the influence of 9 different procedures for rejecting myogenic and non-myogenic artifacts (see Footnote 1). Systematic biases in the classification or rejection of components cannot explain the *combination* of low sensitivity and low specificity in the source-space. Had we been too strict, rejecting all but the most prototypical neurogenic components, we would expect to find excellent sensitivity and poor specificity. Conversely, had we been too liberal, rejecting only the most egregious artifacts, we would expect to find the reverse pattern. The bottom line is that systematic procedural biases cannot readily account for our results, whereas a failure to cleanly separate myogenic and neurogenic sources does.

Confounding Myogenic and Neurogenic Activity?

Finally, Olbrich raise the possibility that our results may reflect the fact that one of our simplifying assumptions, namely that neurogenic activity is consistent across periods of muscle tensing and quiescence, is wrong. The key contrast for testing the sensitivity of ICA-correction technique in McMenamin was comparing the eyes-open, tense condition (OT) after EMG-correction to the uncorrected eyes-open, relaxed condition (OR). Significant differences in this contrast were interpreted as the presence of residual myogenic artifact—an interpretation that hinges on the assumption there is no systematic variation in neurogenic signals during the tensing of facial muscles. Olbrich et al (2010) cite several ways in which this assumption may fail, and we agree that basic neurophysiology dictates that there will be greater neuronal activity in regions innervating the pericranial musculature during the Tense condition. Empirically, however, the observed effects in the Corrected OT-OR contrast are far more consistent with residual artifact.

In particular, McMenamin did not observe effects in the lateral precentral gyrus for the OT-OR contrast (Figure 1), so these regions were not incorporated into the 'myogenic' region of interest (ROI) that was relied on for testing the sensitivity of ICA-based EMG correction. Primary motor regions were also not incorporated into the 'neurogenic' ROI that were used to test specificity. Thus, neither validation test was likely to have been confounded by differences in *neurogenic* activity associated with the tensing manipulation[2].

A further argument against Olbrich's interpretation stems from the remarkable similarity between the topography of the corrected and uncorrected myogenic contrasts (OT vs. OR; Figures 1–2 in McMenamin). The distribution of the myogenic contrast is nearly identical before and after ICA-based correction. This implies one of two possibilities. Either ICA-based correction failed to wholly correct the artifact, leaving a substantial residual, or it unmasked a neurogenic signal that was temporally and spatially coincident with EMG. The frontal topography renders the latter suggestion implausible. Collectively, these observations indicate that neural activity associated with muscle tensing had little effect on our conclusions.

[2]Similar logic allows us to rule out a significant contribution from between-condition differences in gross arousal—as one might expect if muscle tensing was associated with greater arousal or cognitive workload than quiescence. Olbrich and colleagues (2009) recently used source modeling to show that such differences are associated with altered alpha-band (8–12 Hz) cortical current density in posterior regions of the cingulate, occipital, and temporal cortices. None of these regions contributed to the ROI we used to evaluate the sensitivity of ICA-based artifact correction (i.e., attenuation of myogenic activity). Such regions *did* overlap with the ROI used for evaluating specificity (i.e., the preservation of neurogenic activity; see Figure 9 in McMenamin), but differences in alpha-band activity associated with tensing could not have influenced the primary test of specificity, which examined the impact of ICA-based correction on the neurogenic contrast (eyes-open/muscles-relaxed vs. eyes-closed/muscles-relaxed) in the absence of EMG artifact.

Critique of Olbrich's Simulation

Quantitatively validating any EMG correction tool requires data in which the presence and absence of EMG is definitive or can be reasonably assumed. McMenamin generated such a dataset by instructing participants to tense or relax facial muscles. An alternative approach is to build a synthetic dataset in which the experimenter mathematically 'injects' artifact into otherwise artifact-free data. Simple simulations can provide proof-of-principle, but may not be very informative about real-world performance given the substantial variability that is a hallmark of the pericranial EMG (see above and Table 1) and some other kinds of artifact (e.g., Gwin, Gramann, Makeig & Ferris, 2010). A related concern is that the assumptions underlying simple generative models (e.g., the degree of temporal and spatial correlation with neurogenic signals) probably do not characterize real EMG contamination, leading to low external validity (Grouiller et al., 2007;Hoffmann and Falkenstein, 2009). Of course, it is possible to create more complex simulations that can yield a more detailed understanding of the conditions under which a particular correction algorithm is valid (e.g., Delorme, Sejnowski & Makeig, 2007;Fitzgibbon et al., 2007).

But the simulation conducted by Olbrich was not of this kind. Instead, they simulated EMG contamination by superimposing EMG from a single extracranial muscle on the artifact-free EEG at three adjacent channels. The magnitude, spectral characteristics, and topography of simulated artifact was held constant across participants ($n = 10$). No attempt was made to examine conditions in which neurogenic and myogenic signals covaried. It is not clear what protocol was used for classifying components or even whether rater(s) were blind to the simulation protocol. Analyses were restricted to testing the null, a significant limitation that could have been circumvented using the sorts of equivalence tests employed by McMenamin. This concern is magnified by the strict threshold used for examining mean differences. Given these limitations, it is unlikely that the conclusions drawn by Olbrich from this simulation will accurately predict the real-world performance of ICA-based EMG correction.

Future Challenges

Several factors could plausibly account for the inability of Infomax ICA to fully separate myogenic from neurogenic sources. Testing these hypotheses represents a profitable avenue for future research. First, inadequate separation might reflect the extraction of too many components. Consistent with this possibility, Bayesian estimates of 'model order,' the minimum number of components necessary to describe each participant's EEG, indicated a moderate degree of overfitting that varied substantially across individuals (Table 1). Overfitting could explain poor source separation (Naeem et al., 2009;Ryali et al., 2009). This possibility could be more systematically investigated using information theoretic approaches (Beckmann and Smith, 2004;Calhoun et al., 2001;Li et al., 2007;Moraux and Iannetti, 2009), deflationary approaches (http://www.cis.hut.fi/projects/ica/fastica;Mantini et al., 2008), or stepwise ICA (Hesse and James, 2004) to objectively identify the optimal model order for each participant. Doing so might also facilitate the development of criteria for discarding problematic participants (e.g., those with an unusual number of components).

Second, source modeling was not incorporated into the component classification protocol. Classification was instead based on the visual inspection of time-series, power spectrum, and topography. While this is a conventional approach, it is possible that inspection of component dipoles would have facilitated more accurate classifications, particularly in the case of 'mixed' components (e.g., Myogenic dominant). This possibility could be evaluated by modeling dipoles for each independent component[3]. Those characterized by dipoles at the edge or outside

---

[3]This could be readily accomplished using the *dipfit2* or *besafit* plug-ins for EEGLAB (http://sccn.ucsd.edu/eeglab/).

of the brain could, in combination with other criteria, then be classified as artifactual (myogenic or otherwise; Onton and Makeig, 2006,2009; Milne et al., 2009) and the impact on sensitivity and specificity assessed.

Third, inadequate separation might reflect EMG violating key assumptions of the Infomax algorithm (Bell and Sejnowski, 1995; James and Hesse, 2005; Makeig & Onton, *in press*). The lengthy blocks of neurogenic and myogenic activation in the present study—and in many studies of emotion (e.g., Coan and Allen, 2001; Davidson et al., 1990; Shackman et al., 2006)—may not adequately satisfy the assumption that component activation is non-Gaussian. Furthermore, if neurogenic and myogenic activity are too closely coupled in the time-domain they would violate the assumption that sources are mutually temporally independent (but cf. Ohla et al., 2009). Future studies should test whether second-order separation algorithms, which do not make such assumptions, yield better separation (Joyce et al., 2004; Romero et al., 2008; Tang et al., 2005). It might also prove fruitful to investigate signal-space projection methods (Nolte and Curio, 1999; Tesche et al., 1995; Uusitalo and Ilmoniemi, 1997) or source separation in the frequency-domain (Anemuller et al., 2003; Hyvärinen et al., 2010; Lee et al., 2008), which may improve the separation of sources with overlapping spectra.

A fourth promising direction is to validate correction techniques using data obtained in the presence and absence of neuromuscular blockade (Whitham et al. 2008, 2007). Doing so would avoid the assumptions necessitated by simulated, scripted, and ad hoc datasets (Shackman et al., 2009).

Recommendations and Conclusions

Although ICA cannot be viewed as a panacea for EMG contamination, careful application is a useful means of rejecting the most dubious results on the scalp. Nevertheless, in cases where myogenic activity is plausible, we cannot recommend the use of source modeling techniques for hypothesis testing. Likewise, the results of McMenamin and others indicate that findings in the upper frequency bands (i.e., beta, gamma) should be interpreted with extreme caution, particularly when they occur in the vicinity of scalp muscles. At minimum, scalp topography plots should be presented (Shackman, 2010; Shackman et al., *in press*). We recommend that investigators adequately describe the procedures used for classifying and filtering artifactual components and, where relevant, quantitatively assess inter-rater reliability.

There is increasing interest in using scalp-recorded and source-localized EEG to answer fundamental questions about how the mind arises from and interacts with the brain (Makeig et al. 2004; Pizzagalli 2007). The development and careful validation of novel tools for separating myogenic from neurogenic signals will have substantial benefits for this endeavor.

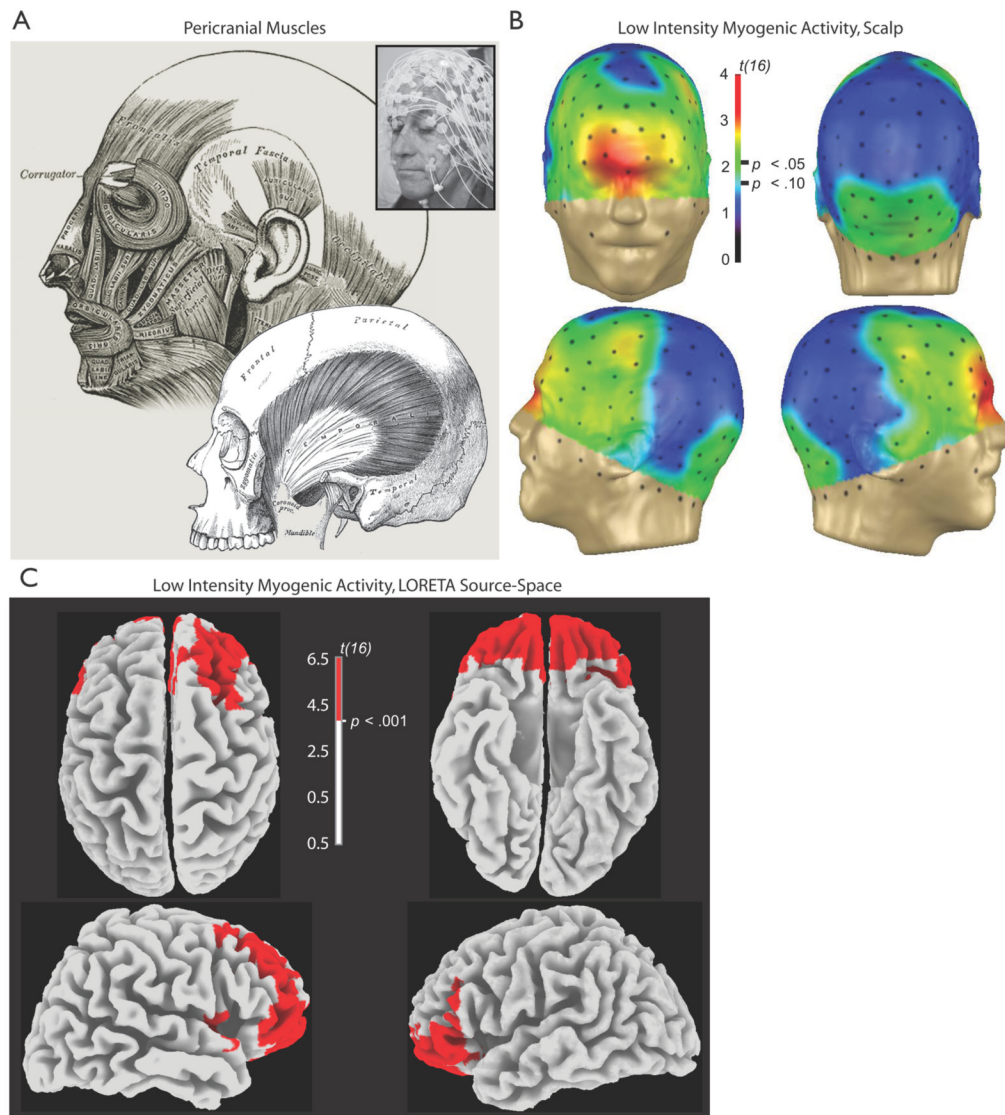

Figure 1. Myogenic activity
A. *Cranial muscles.* Nearly all cephalic electrodes lie atop or adjacent to muscle, making EMG artifact a concern for the entire head—*not* just anterior electrodes. Key generators of myogenic artifact include the *corrugator* along the brow, *orbicularis oculi* around the eyes, *frontalis* above the brow, *masseter* on the jaw, the peri-auricular muscles surrounding the ear, and *occipitalis* at the base of the skull. Lower engraving depicts *temporalis*. Inset shows the 128-channel EEG array. Engravings adapted from *Gray's Anatomy* (Gray, 1918/2000). **B.** *Low intensity myogenic activity on the scalp.* Spline-interpolated topographic plots of the thresholded myogenic contrast (Tense minus Relaxed, Eyes Open; n = 17). One-third of the 128-channel array reached threshold (p = .05) and one-half showed trends (p = .10). C. *Low intensity myogenic activity increased activity in large regions of the cerebral source-space.* Images depict the thresholded myogenic contrast. Note the absence of suprathreshold voxels in primary motor cortex (M1; precentral gyrus). Data were modeled using LORETA, as detailed in McMenamin. Additional images are presented in the Supplement to McMenamin.

Table 1

Individual Differences in Independent Component Classification: Frequencies

Subject	Unclassifiable Noise	Myo > Neuro	Neurogenic	Myogenic	Low Variance	Ocular	Neuro > Myo	Gross	Sum (Est. Model Order)
1	6	29	2	8	7	8	3	1	64 (51)
2	11	18	8	4	15	5	1	2	64 (37)
3	12	20	5	5	7	13	2	0	64 (41)
4	4	23	11	3	10	9	3	1	64 (38)
5	8	8	10	17	13	7	1	0	64 (29)
6	16	4	11	8	18	4	3	0	64 (35)
7	22	1	12	2	19	5	0	3	64 (39)
8	22	8	11	4	5	10	1	3	64 (41)
9	14	9	8	8	13	9	2	1	64 (23)
10	3	8	2	37	4	6	3	1	64 (33)
11	14	3	8	21	3	13	2	0	64 (41)
12	15	5	12	15	7	5	3	2	64 (53)
13	16	18	6	10	6	2	4	2	64 (47)
14	13	7	14	7	10	10	2	1	64 (37)
15	3	10	0	43	0	7	0	1	64 (40)
16	1	12	8	10	8	22	2	1	64 (40)
17	10	11	5	21	8	7	1	1	64 (43)
Median	12	9	8	8	8	7	2	1	64 (40)
Min-Max	1–22	1–29	0–14	2–43	0–19	2–22	0–4	0–3	64–64 (23–53)

Notes: Preliminary inspection of the ICA results indicated that low-variance components were dominated by noise, making them difficult to reliably classify and leading raters to devote an undue amount of time to their consideration. Accordingly, components accounting for <0.2% of scalp variance were categorized as *Low Variance*, excepting cases where unambiguous classification was possible. Using the protocol detailed in the Supplement to McMenamin, remaining components were classified as *Neurogenic*, *Myogenic*, a combination of the two (*Neuro > Myo* or *Myo > Neuro*), or artifact (*Gross or Ocular*). Components that met the minimum variance criterion, but proved impossible to unambiguously classify were considered *Noise*. Classifications were made by two raters based on inspection of component time-series, power spectra, topography, and where necessary the raw time-series. Interrater reliability was excellent, α=0.98 (see the Supplement to McMenamin). Final classification was by consensus. Post hoc analyses used a Bayesian model order estimation procedure (Beckmann & Smith, 2002, 2004; Rajan & Rayner, 1997) to estimate the minimum number of components, *Model Order*, necessary to adequately describe our data. Results indicated that the 64-component extraction used by McMenamin was sufficient to avoid underfitting, but moderately overfit most participants.
