Accession no. Y00503

We present the cDNA sequence of human keratin 19 (40kD;(1)) determined from clones isolated from a lambda g11 expression library of human placenta by using specific monoclonal antibodies. The sequence has a full-length open reading frame (initiating ATG and stop codon are underlined). Although keratin 19 is considered characteristic of simple epithelia, the sequence is clearly closer to human keratinocyte keratins (2,3) than to the simple epithelial keratin 18 (4). It is very similar to that of the homologous bovine keratin (5): 73% bases are identical in the 3' untranslated region, and in the coding region there is 86% identity over the head domain and 89.5% over the helical rod domain. In the short tail domain (posns. 1168-1207) this falls to only 64%, even though other keratins maintain over 80% identity with homologous proteins across species boundaries in all three domains. Translation of this sequence shows the tail homology to be even lower at the amino acid level (38%: only 5 out of the 13 amino acids shared). This high divergence between human and bovine sequences over the tail domain suggests that little if any selection pressure has been acting on this region. This indicates that the abnormally short tail of keratin 19 is, like our own, vestigial.
