Abstract

Background—Hepatoerythropoietic porphyria (HEP) is a rare autosomal recessive disorder resulting from the markedly deficient, but not absent, activity of the heme biosynthetic enzyme, uroporphyrinogen decarboxylase (UROD). HEP typically manifests during infancy or early childhood with extreme photosensitivity, skin fragility in sun-exposed areas, hypertrichosis, erythrodontia, and pink urine.

Observations—We describe three siblings, offspring of parents of Puerto Rican and Dominican descent, who presented with excessive scarring on the face and dorsal aspect of the forearms, which initially led to the erroneous suspicion of child abuse. Although these lesions were photodistributed, overt photosensitivity had not been observed, with the exception of a single episode of blistering and onycholysis following intense sun exposure in one affected child. Mild facial hypertrichosis, chronic anemia, polyarticular arthritis, and developmental delay represented additional findings. Biochemical studies of urine, plasma, and erythrocyte porphyrins from the affected siblings established the diagnosis of HEP. Sequencing of the *UROD* gene revealed compound heterozygosity for a novel missense mutation, V166A, and a complex deletion/insertion, 645del1053ins10.

Conclusions—Our report expands the phenotypic and genotypic spectrum of HEP, highlighting mild cutaneous presentations that can occur without obvious photosensitivity and potentially masquerade as child abuse.

Introduction

Hepatoerythropoietic porphyria (HEP), a rare autosomal recessive disorder of heme biosynthesis, results from markedly deficient activity of uroporphyrinogen decarboxylase (UROD) due to mutations in the *UROD* gene.[1-5] HEP is the recessive form of familial porphyria cutanea tarda (PCT), an autosomal dominant condition in which heterozygous *UROD* mutations predispose carriers to clinical manifestations.[1,2] Since the initial description of HEP in 1969,[6] there have been approximately 40 reported cases.[2,7-34] Clinical manifestations usually develop during infancy or early childhood and include extreme photosensitivity, skin fragility (bullae, erosions, and scarring) in sun-exposed areas, hypertrichosis, erythrodontia, and pink-to-red urine. Sclerodermoid skin changes often become evident over time. Compared to PCT, the cutaneous features of HEP typically have earlier onset, increased severity leading to disfigurement, and closer resemblance to those in congenital erythropoietic porphyria (CEP; Günther disease).[4,5] However, extracutaneous findings including hemolytic anemia are more frequent and severe in CEP than HEP.[4,5,30]

Here we describe three siblings with HEP who presented with mild cutaneous findings that led to a child abuse investigation. They also had chronic hemolytic anemia and other extracutaneous manifestations not previously recognized as features of HEP, including arthritis, developmental delay, and neonatal thrombocytopenia. Sequencing the *UROD* gene revealed a novel missense mutation and a complex deletion/insertion in the affected siblings. This kindred highlights the importance of recognizing mild cutaneous presentations of HEP, which may occur without obvious photosensitivity, and extends the phenotypic spectrum of the disease.

Report of a Case

The proband, a 7-year-old girl who was the third child of a Puerto Rican mother and a Dominican father, presented with a 2-month history of blistering, erosions, and scarring on the dorsal aspect of the hands and forearms as well as shedding of her fingernails. These findings developed after intense summer sun exposure. She took no medications and had not previously exhibited photosensitivity, although facial scarring had appeared after minor trauma. The patient had a history of severe neonatal thrombocytopenia requiring a platelet transfusion, chronic hemolytic anemia, and chronic reddish-brown urine. Her growth was normal, but she was developmentally delayed, including a receptive and expressive speech disorder and poor coordination resulting in an abnormal gait; she has been followed by a neurologist and received speech, physical, and occupational therapy since infancy.

Physical examination revealed linear-to-polygonal scars and mottled hyperpigmentation on the face, dorsal aspect of the hands, and extensor forearms. She had mild facial hypertrichosis, brownish teeth, and no evidence of hepatosplenomegaly. Two of the patient's four siblings had similar cutaneous and extracutaneous findings including chronic anemia and developmental delay (Table 1). The children's cutaneous findings are shown in Figure 1. Although both affected siblings were older (11-year-old brother, 10-year-old sister), neither had exhibited photosensitivity. However, multiple round (resembling cigarette burns), linear, and geometric scars in all three affected siblings had led to a year-long child abuse investigation by state authorities, which was initiated by teachers, school nurses, and emergency room physicians. The unaffected siblings (5-year-old brother, 3-year-old sister) had no history of photosensitivity, other skin findings, anemia, or developmental delay. With the exception of photosensitivity, these features had manifested in the affected siblings during the first years of life. The parents were non-consanguineous and unaffected, although the mother tended to sunburn easily.

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

Biochemical studies in the affected siblings were diagnostic of HEP. These included markedly elevated urine porphyrins (predominantly uroporphyrin-I/III and heptacarboxylporphyrins), a plasma porphyrin fluorescence peak at 620 nm, increased erythrocyte zinc protoporphyrin, and decreased erythrocyte UROD activities (Table 2). Sequencing the *UROD* gene in the affected siblings revealed compound heterozygosity for two *UROD* mutant alleles. A previously reported complex deletion/insertion, 645del1053ins10, inherited from their mother predicted truncation of the UROD enzyme's 367 amino acid sequence at residue 198. A novel missense mutation, a T-to-C transition at position 497, inherited from their father predicted a valine-to-alanine substitution at amino acid residue 166 (V166A). The two unaffected siblings were heterozygous for V166A. Neither of the mutations was identified in 100 normal individuals.

HFE genotype analysis revealed heterozygosity for the H63D mutation in the proband and her affected sister, both of whom had elevated serum ferritin levels (see Table 2) and relatively pronounced skin fragility. Vitamin B12, folate, and liver chemistries were normal and viral hepatitis screens were negative in all family members. Brain MRIs in the affected children were normal.

A year after diagnosis, the proband and her older affected sister simultaneously developed pain, swelling, and limited range of motion in the interphalangeal and metacarpophalangeal joints and wrists of both hands; MRI confirmed the presence of synovitis. Mild cutaneous sclerosis and tapering of the fingertips was noted. Rheumatoid factor was negative in both girls and the older sister had antinuclear antibodies (titer 1:320) with a speckled pattern.

Comment

Most patients with HEP develop photosensitive eruptions during infancy or early childhood. Sun-induced erythema and blistering occurred by age 2 years in 75% of reported cases (25/33 patients with data available).[2,6-9,11-16,19-24,26-34] Spontaneous improvement of acute photosensitivity during later childhood, but persistent skin fragility, has been described.[8,11,29,33] Other patients have presented in the second or third decade of life with mild skin fragility or photodistributed annular plaques.[26,28,30,33] Photomutilation can result in considerable morbidity in patients with HEP via impaired function of the hands and facial disfigurement, making photoprotection essential.[4,5] Although helpful in PCT, phlebotomy and antimalarials are generally ineffective in HEP.[5,35]

The primary cutaneous manifestations in our kindred were fragility, scarring, and hyperpigmentation during childhood rather than acute photosensitivity. Round erosions and scars resembled cigarette burns, while linear and geometric lesions suggested forceful use of other instruments. The presence of multiple wounds in different stages of healing, the lack of an explanation for the injuries, and their occurrence in several siblings were additional features suspicious for child abuse.[36] These skin findings had initially led to a long investigation by child protective services that resulted in considerable distress to the family.

Over 40 *UROD* mutations have been described, some occurring in both HEP and familial PCT.[32,34] To date, 15 missense mutations, 2 deletions, and 1 nonsense mutation have been reported in HEP.[3,5,17,18,21,25,26,29,30,32,33,34] Homozygosity for the F46L missense mutation causes relatively mild HEP,[29,30] as may be true of the novel V166A mutation in our family. In contrast, mutations that abolish UROD activity, like the 645del1053ins10 lesion in our family, are only compatible with life when the individual's other *UROD* allele encodes residual enzymatic activity.[5] Of note, 645del1053ins10 was previously described in an Argentinean kindred with PCT.[37] Our three affected siblings had the same *UROD* mutations, but the severity of their clinical manifestations varied, underscoring the role of

NIH-PA Author Manuscript

NIH-PA Author Manuscript

NIH-PA Author Manuscript

environmental and genetic modifiers. Our proband and her most severely affected sibling were heterozygous for the *HFE* H63D mutation and had increased serum ferritin levels, which may have contributed to their clinical presentations. Severe cutaneous findings, a *HFE* H63D mutation, and elevated ferritin levels were recently described in a 2-year-old boy with HEP.[32]

Sclerodactyly, osteolysis and shortening of the phalanges, and progressive joint deformities can occur as components of acral photomutilation in patients with HEP, CEP, and homozygous variegate porphyria.[4,5,10,13,19,35,38] To our knowledge, arthritis has not been previously reported in patients with HEP. Whether our two sisters' painful polyarticular arthritis represents a typical (but heretofore unrecognized) inflammatory precedent of joint deformity in HEP or an idiosyncratic inflammatory process, perhaps triggered by porphyrin deposition together with exposure to ultraviolet light or another environmental insult, remains to be determined.

Anemia was present in >50% of HEP patients for whom hematologic status was reported (15/27),[2,6-16,19-22,26,28,30,32,33] but severe anemia requiring transfusions or administration of epoetin-α has only been observed in a few individuals.[28] The affected children in our family all had chronic anemia and were followed by a hematologist for years prior to diagnosis of HEP, emphasizing the importance of recognizing anemia as a feature of HEP. Thrombocytopenia, often due to secondary hypersplenism, has been described in patients with CEP (including neonates) but not in those with HEP.[39,40,41]

In contrast to the autosomal recessive form of variegate porphyria, which is characterized by developmental delay and seizures,[38] neurologic abnormalities are not typically associated with HEP or CEP.[4,5,39] Nevertheless, developmental delay and seizures have been previously reported in HEP.[22,27] A 4-year-old boy had delayed speech and language skills then presented with focal seizures and acute left hemiparesis.[22] Two young adults, ages 21 and 23 years, with severe HEP developed generalized seizures and had neuroimaging evidence of cerebral cortical atrophy and punctate calcifications in the frontal lobes, presumably related to hypoxic injury as in other porphyrias.[27] These observations, together with our affected siblings' developmental delay, support neurologic assessment of HEP patients in order to better define this possible manifestation.

In summary, this report expands the clinical features of HEP to potentially include arthritis, neonatal thrombocytopenia, and developmental delay. The mutations identified in our kindred add to the *UROD* alleles that can cause HEP. We emphasize the importance of considering HEP in children who present with skin fragility and scarring in sun-exposed sites, even in the absence of acute photosensitivity. Increased awareness of the clinical manifestations of HEP will allow recognition of more affected individuals, delineation of the phenotypic spectrum, and evaluation of future therapies.[42]

Acknowledgments

Funding/Support: This study was supported in part by a grant from the Protect the Future Program of the American Porphyria Foundation to Dr Balwani, a NIH research grant (R37 DK34045) to Dr Desnick, and a Medical Dermatology Career Development Award from the Dermatology Foundation to Dr Schaffer.

Role of the Sponsors: The sponsors had no role in the design and conduct of the study; in the collection, analysis, and interpretation of data; or in the preparation, review, or approval of the manuscript.
