# Abstract

Recent experiments have shown that the congener,  $A\beta_{1-40}$ [D23-K28], in which the side chains of charged residues Asp23 and Lys28 are linked by a lactam bridge, forms amyloid fibrils that are structurally similar to the wild type (WT) AB peptide, but at a rate that is nearly thousand times faster. We used all atom molecular dynamics in explicit water, and two force fields, of the WT dimer, a monomer with the lactam bridge (A $\beta_{10-35}$ -lactam[D23-K28]), the monomer and dimers with harmonically constrained D23-K28 salt bridge (A $\beta_{10-35}$ [D23-K28]), to understand the origin of the enhanced fibril rate formation. The simulations show that the assembly-competent fibril like monomer  $(N^*)$  structure, that is present among the conformations sampled by the *isolated* monomer, with strand conformations in the residues spanning the N and C termini and a bend involving residues  $D^{23}VGSNKG^{29}$ , are populated to a much greater extent in  $A\beta_{10-35}[D23-K28]$ and A $\beta_{10-35}$ -lactam[D23-K28] than in the WT, which has negligible probability of forming N\*. The salt bridge in  $N^*$  of A $\beta_{10-35}$ [D23-K28], whose topology is similar to that found in the fibril, is hydrated. The reduction in the free energy barrier to fibril formation in A $\beta_{10-35}$ [D23-K28] and in  $A\beta_{10-35}$ -lactam[D23-K28], compared to the WT, arises largely due to entropic restriction that enables the bend formation. A decrease in the entropy of the unfolded state and the lesser penalty for conformational rearrangement including the formation of the salt bridge in A $\beta$  peptides with D23-K28 constraint results in a reduction in the kinetic barrier in the  $A\beta_{1-40}$ -lactam[D23-K28] congener compared to the WT. The decrease in the barrier, that is related to the free energy cost of forming a bend, is estimated to be in the range  $(4-7)k_BT$ . Although a number of factors determine the growth of fibrils, the decrease in the free energy barrier, relative to the WT, to N\* formation is a major factor in the rate enhancement in the fibril formation of A $\beta_{1-40}$ [D23-K28] congener. Qualitatively similar results were obtained using simulations of A $\beta_{9-40}$  peptides, and various constructs related to the A $\beta_{10-35}$  systems that were probed using OPLS and CHARMM force fields. We hypothesize that mutations or other constraints that preferentially enhance the population of  $N^*$  species would speed up aggregation rates. Conversely, ligands that lock it in the fibril-like N\* structure would prevent amyloid formation.

## Introduction

Aggregation of A $\beta$  peptides 1·2, which are products of proteolytic cleavage of the Amyloid- $\beta$ precursor protein, is linked to the Alzheimers disease3. Besides the amyloid plaques, whose major protein component is the A $\beta$  peptide, it has been suggested that soluble oligomers can also be neurotoxic4<sup>-6</sup>. These findings make it important to describe, at the molecular level, the cascade of events that drive the largely unstructured monomer to the ordered amyloid fibril formation. It is generally thought that the isolated A $\beta$  monomer is a fluctuating random coil at neutral pH. Segments of the Aß peptide are structured and the large number of heterogeneous conformations can be clustered into several distinct basins7. The structures among the basins can inter convert on a broad range of time scales. The structural plasticity associated with the A $\beta$  monomer finds considerable support in several molecular dynamics simulations7<sup>-11</sup>, and a few NMR experiments12. In contrast, the monomers are ordered in the Aβ amyloid fibril. The Tycko model13<sup>,14</sup> (TM) of the amyloid fibril, which was constructed using a number of solid state NMR derived constraints, shows that roughly the first ten residues are disordered. The ordered monomer has two  $\beta$  strands, that run from residues 10–22 and 30–40, and are connected by a bend comprising of residues 23– 29(DVGSNKG). The strands are arranged in a parallel manner so as to maximize the number of hydrophobic contacts, and is further stabilized by the D23-K28 salt bridge. Such an arrangement is in accord with the generic principle of amyloid self-assembly (PASA) which is formulated by using a combination of experimental and computational studies 14<sup>-</sup> 25. According to PASA, stable higher structures (oligomers, protofilaments, and fibrils) are those that maximize the number of intra and inter peptide interactions as well as the salt bridges.

It follows from PASA, which emphasizes side chain packing in the fibrils, that favorable electrostatic interactions must play a role in the early structural organization of soluble  $A\beta$ oligomers (dimers, trimers etc.) that eventually form amyloid fibrils. Indeed, a comparison of the structures of the monomer in isolation and in the fibril shows that the formation of the D23-K28 salt bridge ensures that the unpaired charges are not buried in the low dielectric interior of the fibril. The monomer structure of A $\beta$  peptides can be organized using a transition disconnectivity graph that represents the sampled conformations as a free energy spectrum7<sup>,</sup>8<sup>,</sup>26. It is likely, that many of the conformations are assembly-competent giving rise to fibrils with somewhat different morphology14. The average assembly-competent structure (N<sup>\*</sup>) of the conformations, in one of the higher free energy basins in the A $\beta_{10-35}$ monomer energy landscape7, is similar to that found in the TM model. We stress that the significance of  $N^*$  is that it is a state that is already present in the monomer, and does not typically require inter-peptide interaction to form. In this sense, the postulate that fibril like  $N^*$  exists already in the spectrum of monomer conformations is similar to population shift mechanism that has been proposed in the context of allosteric transitions27. Thus, an increase in the population of  $N^*$ , with the intact D23-K28 salt bridge and a bend, which in the wild type (WT) can occur by fluctuations or denaturation stress, can lead to oligomer formation that can convert to amyloid fibril.

The physical picture that the conformations that are accessible in the monomer is assembly competent28, raises an important question, namely, given that the spontaneous interaction between D23 and K28 in the isolated monomer is free energetically unfavorable, is it possible that monomers with preformed salt bridges can preferentially populate  $N^*$ , so that ordered fibrils can form more effectively? In a recent study29, Sciarretta *et al.* showed that the aggregation rate in A $\beta_{1-40}$ -lactam[D23-K28], in which the residues D23 and K28 are chemically constrained by a lactam bridge, is nearly 1000 times greater than in the WT. The fibrils of the congener, A $\beta_{1-40}$ -lactam[D23-K28], that are structurally similar to the WT, form without the usual lag phase. Motivated by the experimental findings and building on

earlier studies 7<sup>-10</sup> on the energy landscape of WT A $\beta_{10-35}$ , we have used molecular dynamics (MD) simulations to examine the changes in the conformational fluctuations in the A $\beta$  peptides with a constrained D23-K28 salt bridge.

Previous studies7,30,31 show that spontaneous formation of a stable D23-K28 salt bridge in the A $\beta_{10-35}$  monomer is unlikely because the barrier to desolvation of the charged residues is too steep for favorable salt bridge formation. The free energy landscape revealed7 that the basins, with conformations containing the D23-K28 salt bridge are metastable. As a result, they are not significantly populated at ambient conditions. Therefore, understanding the conformations sampled by A $\beta_{10-35}$ [D23-K28], where the D23-K28 salt bridge is preformed, might shed light on the increased rate29 of fibril formation in the A $\beta$ -lactam[D23-K28] peptides. The simulations of A $\beta_{10-35}$ [D23-K28] can be used to infer if the increased rate in aggregation is due to the decrease in conformational entropy of the A $\beta$  monomer due to the salt bridge constraint or the decrease in the desolvation penalty - an enthalpic effect. Our results suggest that the enhanced fibril formation rate in the lactam congener is helped by entropic restriction in the monomer with the constrained salt bridge. However, enthalpic effects also contribute to the reduction in the free energy barrier to nucleation and growth of  $A\beta_{1-40}$ -lactam[D23-K28] fibril relative to the WT. The reduction in the conformational entropy and the increased probability of occupying a state, in which the monomer structure closely resembles the one in the fibril, rationalizes the 1000 fold increase in the rate of fibril formation of  $A\beta_{1-40}$ -lactam[D23-K28] congener. The robustness of our conclusions is established by performing simulations of a number of systems using two force fields.

# THEORETICAL METHODS

#### Peptides

To gain insights into the role of preformed D23-K28 salt bridge in the aggregation process, we simulated several systems each constructed from the A $\beta$  peptide. It is suspected16 that the fibrils of A $\beta_{10-35}$  are structurally similar to the full length peptide, thus making the shorter peptide a good surrogate for the A $\beta_{1-40}$  system. In order to examine the effect of interpeptide interactions we simulated the [A $\beta_{10-35}$ ]<sub>2</sub> dimer. We used two methods to constrain the salt bridge between D23 and K28.

**Constraining D23-K28 using harmonic potential**—The influence of a stable D23-K28 salt bridge on the free energy landscape of the monomer and the dimers are assessed using simulations that constrain the  $C_{\gamma}$  atom of residue D23 and  $N_{\zeta}$  atom of residue K28 by

a harmonic potential,  $U(r) = \frac{k}{2}(r - r_o)^2$ . Here, *r* is the distance between the C<sub> $\gamma$ </sub> atom of residue D23 and N<sub> $\zeta$ </sub> atom of residue K28, (Fig. 1(a)), and  $r_o = 3.8$ Å is the corresponding equilibrium distance. The value of  $r_o$  is approximately the distance between the C<sub> $\gamma$ </sub> and N<sub> $\zeta$ </sub> atoms of the salt bridge in the A $\beta_{1-40}$  fibrils29. We used k = 100.0 kcal/mole.Å<sup>2</sup>. The peptide with the constraint is labeled A $\beta_{10-35}$ [D23-K28].

**Direct simulation of the lactam construct**—In order to establish the generality of the results, we also carried out limited set of simulations for  $A\beta_{10-35}$ -lactam[D23-K28] where there is a lactam bond between the side chain of Asp23 and Lys28, and  $A\beta_{9-40}$  monomers. Just as for  $A\beta_{10-35}$ , we used molecular dynamics simulations for the  $A\beta_{10-35}$ -lactam[D23-K28], WT  $A\beta_{9-40}$  and  $A\beta_{9-40}$ [D23-K28] in which the salt bridge is constrained.

The advantage of simulating  $A\beta_{10-35}$ [D23-K28] over  $A\beta_{10-35}$ -lactam[D23-K28] is that the harmonic restraint induces similar kind of fluctuations in the peptide as the lactam construct. In addition, we can assess if the bend formed by the residues 23 to 28 due to the constraint desolvates the charged salt bridge forming atoms. In the presence of the lactam construct,

the salt bridge forming atoms are always desolvated due to the presence of a neutral amide bond between the  $\beta$ -carbon of Asp23 and  $\epsilon$ -carbon of Lys28. The comparison between the two simulations allows us to more fully explore the free energy landscape of the constrained peptides.

#### Simulations with two force fields

We performed all atom molecular dynamics simulations in explicit solvent using the NAMD32 simulation package with PARAM2233 forcefield of the CHARMM program and the TIP3P model for water. To check for robustness of results we also performed a limited set of A $\beta_{10-35}$ -lactam[D23-K28] monomer simulations using the all atom OPLS force field34. Simulations using the OPLS force field are referred to as A $\beta_{10-35}$ -lactam[D23-K28] (OPLS).

In the simulations, which were done in a cubic cell with periodic boundary conditions, electrostatic interactions were calculated using the particle mesh Ewald summation35. The initial coordinates for the  $A\beta_{10-35}$  protein were taken from the NMR structure12 determined at pH 5.6 (Protein Data Bank ID code 1hz3). We used one of the representative structures (Fig. 1(b)) which has a preformed salt bridge between the residues D23 and K28. The monomer from the fibril structure was used as the initial structure in the simulations of  $A\beta_{9-40}$  monomers. At pH 5.6, the peptides  $A\beta_{10-35}$ ,  $A\beta_{10-35}$ -lactam[D23-K28] and  $A\beta_{9-40}$  are charged, and a chloride ion was added to neutralize the effective charge. The N and C-terminals of the protein are acetylated and amidated respectively. The simulations were performed in the NPT ensemble with the temperature, T = 300K. Pressure was maintained36·37 at 1 atm using a Langevin piston. The hydrogen atoms were constrained to the equilibrium positions using the SETTLE32 algorithm, and a time step of 2 fs is used to integrate the equations of motion.

For the  $A\beta_{10-35}$ [D23-K28] monomers, we generated three independent trajectories each 100 nanoseconds (ns) long. For the wild type dimers,  $[A\beta_{10-35}]_2$ , and for the D23-K28 salt bridge constrained dimers,  $[A\beta_{10-35}$ [D23-K28]]\_2, we generated three trajectories each of 70 ns long. Dimer simulations are performed by placing two monomers at random orientations in a cubic box of size 60 Å. Multiple trajectories (between 3–5) of  $A\beta_{10-35}$ -lactam[D23-K28],  $A\beta_{10-35}$ -lactam[D23-K28](OPLS),  $A\beta_{9-40}$  and  $A\beta_{9-40}$ [D23-K28] are generated and typically the duration of each trajectory is between 15–20 ns. These limited set of simulations were performed to ensure that there are no qualitative differences in the conclusions based on  $A\beta_{10-35}$  and  $A\beta_{9-40}$  peptides, and in using the harmonic constraint as a surrogate for the lactam bond.

#### Principal Component Analysis

We used Dihedral Principal Component Analysis (DPCA)38<sup>-40</sup> to extract the conformations frequently sampled by the A $\beta_{10-35}$  monomer in the wild type A $\beta_{10-35}$  dimer and A $\beta_{10-35}$ [D23-K28] monomer and dimer simulations. In DPCA, the backbone dihedral angles,  $\alpha_k$ , where  $\alpha_k \in {\phi_k, \psi_k}$ , are used with the transformation,  $q_k = \cos(\alpha_k)$ ,  $q_{k+1} = \sin(\alpha_k)$ , to uniquely define a distance in the space of periodic dihedral angles. The variable *k* runs form 1 to *N*, where *N* is the total number of backbone dihedral angles. The covariance matrix  $\sigma_{ij} = \langle (q_i - \langle q_i \rangle)(q_j - \langle q_j \rangle)$ , which probes the correlated internal motions is constructed and diagonalized to extract the eigenvectors  $V_n$ , and eigenvalues  $\lambda_n$ , that yield the modes of collective motion and their amplitudes. The free energy surface along the two eigenvectors,  $V_1$  and  $V_2$ , which correspond to the first two maximum eigenvalues,  $\lambda_1$  and  $\lambda_2$ , are given by  $\Delta G(V_1, V_2) = -k_B T[\ln P(V_1, V_2) - \ln P_{max}]$ . Here  $P(V_1, V_2)$  is the probability distribution obtained from a histogram of the MD data. We subtract  $P_{max}$  the maximum of the

distribution, to ensure that  $\Delta G(V_1, V_2) = 0$  for the lowest free energy minimum,  $k_B$  is the Boltzmann constant and T is the temperature.

# RESULTS

#### $A\beta_{10-35}$ [D23-K28] and $A\beta_{10-35}$ -lactam[D23-K28] monomers sample compact conformations

Constraining the salt bridge with a harmonic force or by using a lactam bond forces the peptides to sample compact conformations which is reflected in the probability distributions,  $P(R_g)$ , of the radius of gyration  $(R_g)$ ,  $P(R_{ee})$  of the end-to-end distance  $(R_{ee})$ , and  $P(R_{23-28}^{\alpha})$  of the distance,  $R_{23-28}^{\alpha}$ , between the  $C_{\alpha}$  atoms of the residues D23 and K28 (Fig. 1). The probability distributions for the A $\beta_{10-35}$ [D23-K28] peptides in the monomer and dimer, A $\beta_{10-35}$ -lactam[D23-K28] and A $\beta_{10-35}$ -lactam[D23-K28](OPLS) sample smaller values compared to the WT A $\beta_{10-35}$  peptide in the dimer. The distributions P( $R_g$ ) for all the three systems peak at  $R_g$  between 9 – 10 Å, (Fig. 1(c)). The mean  $\langle R_g \rangle$  (=  $\int R_g P(R_g) dR_g$ ) of the peptide in A $\beta_{10-35}$ [D23-K28], A $\beta_{10-35}$ -lactam[D23-K28] and A $\beta_{10-35}$ -lactam[D23-K28] (OPLS) is 10.3, 10.7 and 9.7 Å respectively, while  $\langle R_g \rangle$  of the monomer in the [A $\beta_{10-35}$ [D23-K28]]<sub>2</sub> and [A $\beta_{10-35}$ ]<sub>2</sub> is nearly the same as in the A $\beta_{10-35}$ [D23-K28] monomer, the WT monomer extensively samples conformations with  $R_g$  between 12 and 16 Å, (Fig. 1(c)).

The distributions  $P(R_{ee})$  of  $A\beta_{10-35}[D23-K28]$  monomer and the  $A\beta_{10-35}$  dimer, (Fig. 1(d)), show prominent peaks at  $R_{ee} \approx 15$  Å and 4 Å respectively.  $A\beta_{10-35}$  peptide has hydrophobic residues, Y10 and V12, at the N-terminus, while the C-terminus contains I31/32, L34 and M35. The conformations with low  $R_{ee}$  are due to the favorable interactions of the hydrophobic residues at the two termini. The peaks at  $R_{ee} \approx 15$  Å in the  $P(R_{ee})$  of monomer  $A\beta_{10-35}[D23-K28]$  and the one at  $R_{ee} \approx 4$  Å in  $[A\beta_{10-35}]_2$  arise from contacts between the N-terminal residues Y10, E11 and V12, and the C-terminal residues A30, I31, I32, L34 and M35. The distribution of  $P(R_{23-28}^{\alpha})$ , which shows the stability of the bend comprising of residues 23–28, reveals that constraining the peptides by a harmonic force or by lactam bond forces it to sample conformations with compact bends, (Fig. 1(e)). The distances in the bend-stabilized conformations with  $R_{23-28}^{\alpha}$  in the 4–8 Å range are rarely sampled by the WT  $A\beta_{10-35}$  peptides.

#### E22-K28 salt bridge is unstable in Aβ<sub>10-35</sub>[D23-K28]

The formation of D23-K28 and E22-K28 salt bridges is probed by the time dependent changes in the distance between the  $C_{\delta}$  atom of E22 and  $N_{\zeta}$  atom of K28, and the distance between the  $C_{\gamma}$  atom of D23 and  $N_{\zeta}$  atom of K28 (Fig. 1(a)). The harmonic constraint forces the D23-K28 salt bridge to remain stable. However, even with the constraint, the E22-K28 salt bridge is unstable (Fig. 2(a)). Fig. 2(b), shows the number of water molecules,  $N_w$ , near the  $C_{\delta}$  atom of E22,  $C_{\gamma}$  atom of D23 and  $N_{\zeta}$  atom of K28 in A $\beta_{10-35}$ [D23-K28] as a function of time. Due to the harmonic constraint, the number of water molecules near K28 does not vary significantly as the E22-K28 salt bridge breaks and forms (Fig. 2(b)). As the E22-K28 salt bridge forms between 15–20 ns, the number of water molecules near the  $C_{\delta}$  atom of residue E22 decreases (Fig. 2(b)). The anticorrelation between the occupancy of water near the charged residues and the propensity to form salt bridges shows that desolvation barrier prevents spontaneous interaction between E22-K28 even though K28 is spatially localized.

Charged residues in A $\beta_{10-35}$ [D23-K28] remain solvated. The harmonic constraint on the D23-K28 salt bridge in the monomer, which stabilizes the bend structure comprising of residues 23 to 29, does not render the D23-K28 salt bridge inaccessible to water. The average number of water molecules,  $\langle N_w \rangle$ , near the salt bridge forming atoms of residues

E22, D23 and K28 from the three simulations of  $A\beta_{10-35}$ [D23-K28] are 6.7, 5.1 and 4.4 respectively. These results are in accord with the previous study7 that showed in the WT  $A\beta_{10-35}$ , residues D23 and K28 make stronger contacts with water than water with itself. Moreover, D23 forms greater number of contacts with water than K28. The values of  $\langle N_w \rangle$  near the E22, D23 and K28 in the WT  $A\beta_{10-35}$  dimer are 6.7, 6.1 and 4.8 which are similar to that found in the  $A\beta_{10-35}$ [D23-K28] monomer. We conclude that the residues D23 and K28 in the A $\beta_{10-35}$ [D23-K28] monomer, with a stable bend structure formed by the residues 23 to 29, remain solvated. Thus, the enhanced fibril formation rate in  $A\beta_{1-40}$ -lactam[D23-K28] conformer relative to the WT is not merely due to a significant decrease in the desolvation barrier.

# Influence of interpeptide interactions in WT $[A\beta_{10-35}]_2$ on the stability of E22-K28 and D23-K28 salt bridges

Because the intrapeptide D23-K28 salt bridge is solvated in the isolated monomer and in A $\beta_{10-35}$ [D23-K28], it follows that the dehydration of the salt bridge must arise from inter peptide interactions. To assess the extent to which interpeptide interactions render the salt bridges stable, we generated three 70 ns trajectories with dimers with a preformed D23-K28 salt bridge. In the three simulations in which we monitor the stability of the salt bridges in the six peptides, the distance between the salt bridge forming atoms, (Fig. 1(a)), in five monomers increases in less than 8 ns (data not shown). In one of the peptides, D23-K28 salt bridge is metastable for about 17 ns, which is long enough to probe the factors that contribute to its transient stability (Fig. 2(c)). The distance  $(R_{sb})$  between the salt bridge forming atoms,  $C_{\gamma}$  of residue D23 and N<sub> $\zeta$ </sub> of residue K28 (Fig. 2(c)), hops between 3 Å (salt bridge intact) and 15-20 Å (absence of salt bridge). The hop correlates with solvation which is indicated by the increase in the number of water molecules near D23 and K28, Fig. 2(d). As the salt bridge reforms after 60 ns, there are fluctuations in the number of water molecules near D23 and E22 due to the exchange of water molecules between the bulk and the vicinity of the salt bridge. A representative structure of the dimer (Fig. 3(a)), shows that the kinetic stability of the D23-K28 salt bridge (Fig. 2(c)) in one monomer is due to the shielding of the salt bridge from water molecules by the other monomer. The D23-K28 salt bridge comes out from the plane of the bend, encompassed by the residues 22–29, and is close to the second monomer which prevents water molecules from solvating the salt bridge. The shielding of water can be inferred by comparing the radial distribution function between the  $C_{\gamma}$  atom of residue D23 and the water oxygen atoms when the D23-K28 salt bridge is kinetically stable between 0–17 ns and when the salt bridge is broken between 34–46 ns (Fig. 3(b)). In the conformation with the intact salt bridge, the solvent is depleted near D23.

Comparison of the distributions,  $P(R_{sb})$  of the salt bridge distances,  $R_{sb}$ , in the WT A $\beta_{10-35}$ and the A $\beta_{10-35}$ [D23-K28] peptides shows that the probability of formation of the E22-K28 salt bridge increases in A $\beta_{10-35}$ [D23-K28], (Fig. 4). We calculated P( $R_{sb}$ ) by averaging the data from both the A $\beta_{10-35}$ [D23-K28] monomer and the dimer simulations. The probability for the formation of the E22-K28 salt bridge is negligible in the WT peptides.

From the set of  $A\beta_{10-35}$  simulations, we conclude that the stability of the D23-K28 salt bridge requires (a) the charge residues be desolvated, and (b) the conformational fluctuations be suppressed by interpeptide interactions. The second requirement ensures that the charged residues are prevented from being solvent exposed. Clearly, dimer is not large enough to satisfy both the requirements. It is likely that only after the size of the oligomer exceeds the critical nucleus the salt bridge with an intact bend is stable.

#### Conformational fluctuations in A $\beta_{10-35}$ [D23-K28] and A $\beta_{9-40}$ [D23-K28] are similar

In order to assess whether the instability of the E22-K28 contact and the structural features of  $A\beta_{10-35}$ [D23-K28] are a consequence of the size of the monomer we also performed limited simulations of the  $A\beta_{9-40}$ [D23-K28] monomer. It is suspected that the monomers of  $A\beta_{10-35}$  in its fibril would be arranged in parallel16 as in the fibrils of  $A\beta_{1-40}$ . In the TM, the first nine residues in the N-terminus are disordered and the monomer is stabilized by hydrophobic interactions between the residues in the N and C termini and the salt bridge D23-K28. In the  $A\beta_{10-35}$ , the C terminus is shorter. Nevertheless, similar forces are expected to stabilize the fibril, thus making  $A\beta_{10-35}$  a good model for  $A\beta_{1-40}$ .

Using the initial conformation of the  $A\beta_{9-40}$  monomer from the fibril structure, we produced three 15 ns trajectories by constraining the D23-K28 salt bridge by a harmonic potential (See Methods). In all the three trajectories, the monomer forms kinetically stable structures similar to the one in Fig. 5(a). The hydrophobic patches near the N and C termini, that form extended  $\beta$ -strands, interact to form  $\beta$ -sheets. The constrained D23-K28 salt bridge is perpendicular to the bend formed by residues D23 to K28, and is not buried inside the loop (Fig.5(a)). Thus, the charged residues are solvated as in the A $\beta_{10-35}$ [D23-K28] monomer. The contact map, (Fig. 5(b)), obtained by averaging over the 15 ns simulation data, shows that the hydrophobic contacts are kinetically stable. When the E22-K28 salt bridge forms there is fluctuation in the water molecules near the  $C_{\delta}$  atom of residue E22 (data not shown). The decrease in the number of water molecules as the salt bridge forms is in agreement with the A $\beta_{10-35}$  simulations. The average number of water molecules,  $\langle N_w \rangle$ , near the salt bridge forming atoms of residues E22, D23, K28 from the three trajectories of  $A\beta_{9-40}$ [D23-K28] are 6.6, 5.3 and 4.5 respectively. The values of  $\langle N_w \rangle$  near the E22, D23 and K28 in the  $A\beta_{10-35}$ [D23-K28] monomer are 6.7, 5.1 and 4.4 which are similar to that found in the A $\beta_{9-40}$ [D23-K28] monomer. These results show that the major conclusions found in the more extensive simulations of A $\beta_{10-35}$ [D23-K28] monomer are consistent with those found for A $\beta_{9-40}$ [D23-K28] as well.

# Stability of assembly-competent *N*\* structures require interactions between extended N and C termini strands

A possible explanation for the enhanced fibril formation rate of the  $A\beta_{1-40}$ -lactam[D23-K28] is that the structures that are frequently sampled in this congener is fibril-like. In other words the *N*\* structure is similar to the one the monomer adopts in the fibrils. In order to shed light on the factors that stabilize the fibril-like, *N*\* structures, those with  $\beta$ -strands in the residues near the N and C termini connected by a stable bend with the D23 and K28 close enough to engage in salt bridge formation (see Fig. 5(a)), we performed a number of simulations for the WT  $A\beta_{9-40}$  monomer. In the first, the initial conformations for the MD simulations are taken from the endpoint of the  $A\beta_{9-40}$ [D23-K28] calculations. Starting from the initial structures that are similar to that in Fig. 5(a), we generated three independent 15 ns trajectories. In all cases, the D23-K28 salt bridge is kinetically stable and the fluctuations in the number of water molecules near the salt bridge is similar to that in  $A\beta_{10-35}$ [D23-K28] and  $A\beta_{9-40}$ [D23-K28] simulations (data not shown). We surmise that the salt bridge stability in the WT  $A\beta_{9-40}$  monomer is due to favorable (largely hydrophobic) intra-strand interactions.

To further test the proposal that favorable intrapeptide strand-strand interactions can stabilize the *N*\* structures, we performed WT monomer simulations in which the initial conformations are taken from the TM model and other conformations which have D23-K28 salt bridge but without the hydrophobic interaction between the residues present at the N and C termini. In all trajectories, the distance between D23-K28 and E22-K28 increased (data not shown) when there are no hydrophobic interactions between the residues present at the

N and C termini. Thus, these potential salt bridges are unstable, and the WT monomer adopts a collapsed coil structures without significant interactions between the N and C termini.

In order to ascertain whether a stable D23-K28 salt bridge is necessary, in addition to the hydrophobic interactions between the C and N-terminal residues to the stability of conformers similar to the one shown in Fig. 5(a), we mutated the D23 residue to A23 and generated three trajectories each 12 ns long. These simulations are intended to ascertain the kinetic stability of the mutated conformations. The contact map, (data not shown), obtained by averaging over the 12 ns simulation data of one of the runs shows that the hydrophobic contacts are kinetically stable without the D23-K28 salt bridge when compared to the contact map, (Fig 5(b)). The contact maps  $C_1$  and  $C_2$  will be identical if the contact values at  $C_1(i, j)$  and  $C_2(i, j)$  are similar. The similarity between contact maps  $C_1$  and  $C_2$  can be assessed by taking the dot product between the maps. The contact maps of size  $k \times l$  can be represented as a vector of length  $n = k \times l$ . These vectors are normalized and a dot product is taken between the vectors. The maximum value of 1 indicates high similarity between the contact maps. The dot product between the contact map, Fig. 5(a), and the contact maps of the three trajectories obtained by mutating D23 residue to A23 are 0.9, 0.91 and 0.87 respectively. The root mean square deviation (RMSD) deviation plot of the mutated monomer with respect to the initial conformation as a function of time, (data not shown), shows that the structures are stable without the D23-K28 salt bridge. These results show that the hydrophobic interactions between the C and N-terminal residues play a major role in stabilizing the fibril-like,  $N^*$  species. The high dot product and stable RMSD values show that the hydrophobic contacts are the key for the stability of the conformers of the type shown in Fig. 5(a).

Taken together these results show that the predominant driving force for the formation of  $N^*$  structures is the interaction of the hydrophobic residues at the N and C termini that leads to a  $\beta$ -sheet like structure. In such a structure, the formation of D23-K28 salt bridge is inevitable. If D23-K28 salt bridge is constrained, as in A $\beta_{1-40}$ -lactam[D23-K28] structure, then N and C termini interactions are encouraged, thus leading to the formation of FL conformations that can self assemble rapidly.

# Average monomer structures of $A\beta_{10-35}$ [D23-K28] and $A\beta_{9-40}$ [D23-K28] are similar and fibril-like

The structure of the  $A\beta_{1-40}$  in the TM13<sup>,14</sup> has two  $\beta$ -strand segments, comprising of residues 10–22 and 30–40, along with a bend involving residues 23–29. The monomer is stabilized by an intramolecular interface formed by contacts between residues 19–20 and 33–35, and the D23-K28 salt bridge. The ensemble of low energy structures of  $A\beta_{10-35}$ [D23-K28] and  $A\beta_{9-40}$ [D23-K28] monomer has a similar back bone topology as the  $A\beta_{1-40}$  monomer in the TM. In other words, the fibril like, *N*\* structures are already preformed in the monomer. These structures are stabilized by interactions between the hydrophobic residues in the N and C terminals (Fig 5(a) and 6(a)). The N-terminal residues of the monomer 10–13 are in contact with the C-terminal residues 29–35 along with the bend formed by the residues 22–29. Structures with similar topologies are also observed in the oligomer simulations of  $A\beta_{1-40}$  and  $A\beta_{10-35}$  performed using coarse-grained24 and atomistic description25 of the peptides in implicit solvent.

Globally, the A $\beta_{10-35}$ [D23-K28] is compact. Both  $R_{ee}$  and  $R_g$  shown (Fig. 6(b)) show that the monomer stretches completely between 10–20 ns and then collapses to a structure where the C-terminal and the N-terminal residues are in proximity to form a  $\beta$ -sheet. The contact map in Fig. 6(c), shows that there are two regions in the map where the non-bonded contacts dominate. One is in the bend region consisting of residues 20–29, and the other region is

between the terminal ends of the protein consisting of residues 10–13 and 30–35. The peptide in this conformation is stabilized by contacts especially at the terminal ends between residues 10 and 30, and between residues 11 and 32. The contacts in the bend region are between residues 20 and 28, 23 and 25, and 23 and 28. This structure satisfies PASA, because in this conformation the number of intra molecular hydrophobic contacts are maximized and the potential frustration of burying the charged interaction is eliminated.

The secondary structure analysis using STRIDE41 shows that there is negligible helical content. The residues with the largest  $\beta$  strand contacts calculated by using time averages are : E11(49%), V12(3%), I32(38%), G33(13%) and L34(2%). The overall structure of the A $\beta_{10-35}$ [D23-K28] monomer and the topology of the same region in the A $\beta_{1-40}$  amyloid fibril is strikingly similar. We conclude that the D23-K28 constraint populates an ensemble of structurally related *N*\* conformations that is poised to aggregate.

# Comparison of energy landscapes of $A\beta_{10-35}$ and $A\beta_{10-35}$ [D23-K28] reveal enhanced population of *N*\* species in $A\beta_{10-35}$ [D23-K28]

A visual representation of the most populated basins can be obtained by projecting the energy landscape along the lowest eigen values of the principal component analysis42 based on the dihedral space (see methods). The energy landscape of the  $[A\beta_{10-35}]_2$  (Fig. 7(a)),  $A\beta_{10-35}[D23-K28]$  (Fig. 7(b)), and  $[A\beta_{10-35}[D23-K28]]_2$  (Fig. 7(c)) shows that a number of basins are sampled. However for the systems with intact D23-K28 salt bridge the aggregation prone  $N^*$  structure is populated with substantial probability. Because population of the  $N^*$  is required for oligomerization to begin it follows that the aggregation should occur more easily in  $A\beta_{10-35}[D23-K28]$  than in the wild type. The energy landscape provides a clear pictorial view of the importance of the  $N^*$  in triggering aggregation.

## Secondary structural fluctuations in WT A $\beta_{10-35}$ and A $\beta_{10-35}$ [D23-K28] peptides

It is clear from the present and previous studies that the structures in WT A $\beta_{10-35}$  and A $\beta_{9-40}$  sample conformations in an energy landscape with a number of distinct basins. Simulations10·43 show that, in some of these structures, there are stretches that have helical or  $\beta$ -strand content. Our simulations of  $[A\beta_{10-35}]_2$  also show that there is a propensity for the residues 19–24 to form a  $\alpha$ -helix (Fig. 8). The structures with intact  $\alpha$ -helix, in the 19–24 region, disrupts bend between 22–29. When the residue D23 is part of the helix, the bend is destabilized. More importantly, upon stabilizing the D23-K28 salt bridge with a harmonic constraint, the fluctuating helix is not observed in the simulations involving A $\beta_{10-35}$ [D23-K28](data not shown). The limited set of simulations on A $\beta_{10-35}$ -lactam[D23-K28] and A $\beta_{10-35}$ -lactam[D23-K28](OPLS) also show that the helix propensity of residues 19–24 is negligible. However in the A $\beta_{10-35}$ -lactam[D23-K28](OPLS) peptide, residues 16–18 (7.8%) and residues 25–28 (16.3%) have non-negligible helix propensity. While the details can depend on forcefields, a benchmark study45 concluded that the prediction made by the CHARM22 force field is in good agreement with experiments in predicting helices at the correct positions in the proteins.

It is suggested from previous studies43·46·47 that the disruption of the helical fragments in the middle of the peptide decrease the barriers to protein aggregation. Mass spectroscopy experiments47 on  $A\beta_{1-40}$  suggest that the protease resistant peptide segment formed by residues 21–30 play a key role in the nucleation of the aggregation process. Recent simulations43 suggested that the increased rates of  $A\beta$  aggregation, at pH=6, might be due to the decrease in helical propensity of the residues 17–22. Mutations46 of residue E22Q which reduced the propensity of helix formation in this region also increased the rate of  $A\beta$  amyloid formation.

In contrast, in the  $A\beta_{10-35}$ [D23-K28] congener, harmonic potential greatly destabilizes the fluctuating helix formed by residues 19–24 and stabilizes the bend formed by the residues 23–29 to produce the aggregation prone *N*\*. In  $A\beta_{10-35}$ [D23-K28], conformations with intra molecular contacts among the hydrophobic residues present in the N and C terminals form with high propensity. Frequent sampling of such conformations, which are similar to the peptide conformations in the model amyloid fibril, due to the decrease in conformational entropy compared to the WT peptide could be the reason for the increased rates of aggregation observed in experiments29 when the D23-K28 salt bridge is constrained by a lactam molecule (see below).

# Discussion

#### Importance of N\*

The  $A\beta_{10-35}$  and  $A\beta_{9-40}$  monomers in the WT can be viewed as an ensemble of compact conformations with fluctuating residual structures in different regions. The structures can be clustered into distinct basins7<sup>,8</sup>10. Structures in the most populated A $\beta$  monomer basins are not assembly competent. However, due to the random-coil nature, the peptides also sample conformations in basins with high free energy. A class of high free energy assemblycompetent structures, can collide to form oligomers that can nucleate and grow28. Here, we have shown that such fibril-like, (referred to as  $N^*$ ) that are metastable in the WT structures are similar to the monomers in the amyloid fibril. The  $N^*$  conformations are heterogeneous, and are stabilized by favorable hydrophobic interactions between N and C terminal residues provided they are arranged in  $\beta$ -strand conformations. The two strands are connected by a bend involving residues 23 to 29. The geometry of the  $N^*$  structure brings D23 and K28 in proximity so that they can form a salt bridge with a bend involving residues 23–29 (Fig. 5(a)).

The basic picture of the assembly of the WT A $\beta$  peptides that emerges from this study and earlier all atom simulations 7·9·10, and the more recent lattice model simulations48 is the following (Fig 9). The limited number of assembly competent structures,  $N^*$ , are only populated due to fluctuations and denaturation stress. If a pair of such  $N^*$  molecules collide they can form dimers, which can recruit additional  $N^*$  molecules to form higher order structures. The oligomers of  $N^*$  molecules,  $(N^*)_n$ , undergo substantial structural fluctuations as an additional disordered molecule is added to form38  $(N^*)_{n+1}$ . Only when *n* exceeds the critical nucleus size, which is expected 38·49 to be about 8–10, these oligomers rearrange to form protofilaments and fibrils. In the process of fibril formation,  $N^*$  rearranges further and is stabilized by both inter and intra peptide interactions. Mutations or lactam bridges that enhance the formation of  $N^*$  in the monomer would increase the aggregation rates.

Increasing the population of  $N^*$  conformations requires structural changes in the collapsed coils. First, the N and C terminal hydrophobic residues have to be largely in a  $\beta$ -strand conformation to initiate the formation of an overall  $\beta$ -sheet structure50. Second, the orientation of the bend relative to the strands should facilitate the D23-K28 salt bridge formation. In the A $\beta_{10-35}$ [D23-K28] and A $\beta_{9-40}$ [D23-K28] the salt bridge is preformed although the charged residues are still solvated. The decrease in the conformational entropy in these monomers facilitate the formation of the  $\beta$ -strands, and hence the  $N^*$  species. These structural changes involve overcoming both entropic and enthalpic barriers. As a result, the  $N^*$  conformation is not significantly populated in the WT A $\beta$  peptides. However, the high free energy fibril like  $N^*$  conformations in the A $\beta$  monomer can be stabilized by a affibody protein ( $Z_{A\beta3}$ ) that can stabilize  $N^*$  and prevent it from aggregation50. The NMR structure of  $Z_{A\beta3}$ -A $\beta$  complex further supports the importance of  $N^*$  identified here, as an important monomeric conformation that promotes fibril formation.

#### Reduction in entropic barrier in the formation of N\* in lactam construct

Because the D23 and K28 residues are in a dehydrated environment in the fibril, it is tempting to suggest that the kinetic barrier to desolvating these charged residues could explain the slow fibril formation rate in the WT. Our simulations suggest that the formation of  $\beta$ -strands involving N and C termini residues, and their interaction represents the crucial kinetic step in generating *N*\* structures. The reduction in the conformational entropy in the A $\beta_{10-35}$ [D23-K28] monomer decreases the barrier to  $\beta$ -strand formation, and hence can lead to a significant probability of *N*\* formation. The *N*\* species whose structure in complex with affibody has been determined by NMR50 adopts a hairpin-like conformation. A similar hairpin-like structure is observed in our simulations of the A $\beta_{10-35}$ [D23-K28] monomer (Fig. 6(a)). Thus, one can estimate the reduction in the free energy barrier to *N*\* formation in the lactam-A $\beta$  congener by estimating the free energy cost to form a bend in the WT A $\beta$  (see Fig. 1(e)). Since we postulate that hairpin-like structure of A $\beta$  peptide is aggregation prone, then any mutations or constraints in the peptide which enhance the formation of this structure should speed up the aggregation process. If we assume that the decrease in free energy barrier in the A $\beta_{10-35}$ -lactam[D23-K28] is solely related to the bend formation, then

 $\frac{\Delta G^{\dagger}}{k_B T} = -\ln(k_{1D23-K28]}/k_{WT}) \approx \frac{\Delta G_{bend}}{k_B T}$ , (Fig. 9). Here  $k_{WT}$  and  $k_{[D23-K28]}$  are the rate constants for the  $N^*$  formation in the wild type and the D23-K28 salt bridge constrained monomer,  $k_B$  is the Boltzmann constant and T is the temperature. It is reasonable to assume that free energy ( $\Delta G_{bend}$ ) cost of bend formation is one of the major differences in the rates of the hairpin-like structure formation in these two species. Then, free energy for the bend formation from experiments is given by  $kT \ln(k_{[D23-K28]}/k_{WT}) = k_BT \ln(1000) = 6.9k_BT$ .

Using our simulations, we can estimate  $\Delta G_{bend}$  involving residues 23–28 using the distance between the C<sub>a</sub> atoms of D23 and K28 as an order parameter. Using the probability distribution of P( $R_{23-28}^{\alpha}$ ), where  $R_{23-28}^{\alpha}$  is the distance between the C<sub>a</sub> atoms of the residues

D23 and K28 (Fig. 1(e)), the calculated mean  $\langle R_{23-28}^{\alpha} \rangle$  (=  $\int R_{23-28}^{\alpha} P(R_{23-28}^{\alpha}) dR_{23-28}^{\alpha}$ ) for various D23-K28 salt bridge constrained A $\beta$  peptides is given in Table I. The values of  $\Delta G_{bend}$  is calculated from the wild type A $\beta_{10-35}$  dimer data for P( $R_{23-28}^{\alpha}$ ) using,

$$\Delta G_{bend} = -kT \log \left( \frac{P(R_{23-28}^{\alpha} < \langle R_{23-28}^{\alpha} \rangle)}{P(R_{23-28}^{\alpha} > \langle R_{23-28}^{\alpha} \rangle)} \right), \tag{1}$$

where  $P(R_{23-28}^{\alpha} < \langle R_{23-28}^{\alpha} \rangle) = \int_{\langle R_{23-28}^{\alpha} \rangle}^{\langle R_{23-28}^{\alpha} \rangle} R_{23-28}^{\alpha} P(R_{23-28}^{\alpha}) dR_{23-28}^{\alpha}$  and  $P(R_{23-28}^{\alpha} > \langle R_{23-28}^{\alpha} \rangle) = \int_{\langle R_{23-28}^{\alpha} \rangle}^{\infty} R_{23-28}^{\alpha} P(R_{23-28}^{\alpha}) dR_{23-28}^{\alpha}$ .  $\Delta G_{bend}$  estimated from WT and various D23-K28 salt bridge constrained A $\beta$  peptides is given in Table I. The free energies estimated are in the range  $(4-7)k_BT$ . Thus, a large decrease in barrier ( $\approx \Delta G_{bend}$ ) to  $N^*$ conformation occurs upon using the lactam construct which explains the enhancement in the aggregation of  $A\beta$  peptides with preformed salt bridge between D23 and K28. It should be stressed that the estimates made here explain only qualitatively the origin of enhanced fibril growth rate in the lactam construct. The transition from dimers to protofilaments and fibrils is a complex process. Undoubtedly, a number of other factors play a role in the rate of growth of the amyloid fibril.

#### Dependence of the results on force field

To ensure that the major conclusions of our simulations are robust, we have also performed a limited set of  $A\beta_{10-35}$ -lactam[D23-K28] monomer simulations using all atom OPLS force field34. It is instructive to compare the results obtained using the two force fields.

- 1. The A $\beta_{10-35}$ -lactam[D23-K28](OPLS) peptide samples compact conformations (in agreement with the A $\beta_{10-35}$ [D23-K28] and A $\beta_{10-35}$ -lactam[D23-K28] peptides) compared to the wild type A $\beta_{10-35}$  peptide. The probability distributions of  $R_g$ ,  $R_{ee}$  and  $R_{23-28}^{\alpha}$  sample smaller values compared to the WT A $\beta_{10-35}$  peptide (Fig. 1). These results are qualitatively similar to that found using CHARMM force field.
- 2. Due to the lactam construct, the salt bridge forming atoms  $C_{\gamma}$  atom of residue D23 and  $N_{\zeta}$  atom of residue K28 are not charged. There is a neutral amide bond between the  $\beta$ -carbon of Asp23 and  $\epsilon$ -carbon of Lys28. So the salt bridge forming atoms are desolvated compared to the WT or the A $\beta_{10-35}$ [D23-K28] peptides, which have charged salt bridge forming atoms that can interact with water. Residue E22 in A $\beta_{10-35}$ -lactam[D23-K28] or A $\beta_{10-35}$ -lactam[D23-K28](OPLS) cannot form a salt bridge, since residue K28 is not charged in the lactam construct. Since residue E22 is charged, it is solvated in the lactam construct. The average number of water molecules near the salt bridge forming atoms of residue E22, D23 and K28 in peptide A $\beta_{10-35}$ -lactam[D23-K28](OPLS) is 5.6, 1.4 and 1.7. The numbers for the A $\beta_{10-35}$ -lactam[D23-K28] peptide simulated in the CHARMM force field are 6.5, 2.7 and 2.4. The numbers for the WT dimer and A $\beta_{10-35}$ [D23-K28] are 6.6, 5.3 and 4.5, and 6.7, 5.1 and 4.4 respectively.
- 3. Simulations of  $A\beta_{10-35}$  WT dimer using CHARMM force field show that there is a propensity for the residues 19–24 to form a  $\alpha$ -helix. This fluctuating helix is not observed in the simulations of  $A\beta_{10-35}$ [D23-K28] in which the salt bridge forming atoms are harmonically constrained. The limited simulations of  $A\beta_{10-35}$ -lactam[D23-K28] also shows negligible helix propensity in agreement with the harmonic constraint simulations.  $A\beta_{10-35}$ -lactam[D23-K28](OPLS) monomer simulated in the OPLS force field also shows negligible helix propensity for residues 19–24. However, residues 16–18 (7.8%) and residues 25–28 (16.3%) have non-negligible tendency to adopt helical conformation.
- 4. The most crucial simulation result that was used to rationalize the enhancement of fibril formation rate in A $\beta_{10-35}$ -lactam[D23-K28] is the estimate of  $\Delta G_{bend}$  for bend formation. The estimated free energy for the bend formation in the hairpin-

like structure in the WT A $\beta_{10-35}$  peptide using the  $\langle R^{\alpha}_{23-28} \rangle$  value obtained from the probability distribution of  $R^{\alpha}_{23-28}$  (Fig. 1(e)) in A $\beta_{10-35}$ -lactam[D23-K28](OPLS) peptide is 3.6kT. This is comparable to the values obtained from the other D23-K28 salt bridge constrained peptides (table I).

The key results obtained from the two different force fields for all the constructs show that they are similar. In many cases, the results are almost in quantitative agreement with each other. The finding that there is a reduction in barrier to the formation of fibril-like N\* structure is independent of the force fields. The decrease in the barrier to aggregation prone species arises solely due to the constraints (lactam and harmonic restraint) that ensures the pre-formation of the salt bridge between D23 and K28. Although conclusions reached here are a result of extensive simulations, the inherent limitations (inadequacy of force fields and the inability to sample all allowed conformations of the peptide and water molecules) make it likely that our results are only qualitatively correct. Nevertheless, by using simple arguments and by performing several kinds of simulations using two force fields, we believe that the major results, namely the nature of forces that stabilize the aggregation prone  $N^*$ 

species and the major reduction in the barrier to aggregation relative to the WT in the  $A\beta_{1-40}$ [D23-K28] being entropic in origin, are robust.

Reddy et al.

#### Fig. 1.

(a) The salt bridge forming residues E22, D23 and K28 in the A $\beta$  peptide. Atoms engaged in salt bridge formation are C $_{\delta}$  atom of residue E22, C $_{\gamma}$  atom of residue D23 and N $_{\zeta}$  atom of residue K28. (b) Superposition of a class of NMR structures of A $\beta_{10-35}$  with a salt bridge between D23 and K28 obtained from the Protein Data Bank (1hz3). (c) Probability

distribution, P(R<sub>g</sub>), of the radius of gyration,  $R_g = \sqrt{\frac{1}{2N^2} \sum_i \sum_j \vec{R}_{ij}^2}$ , where  $\vec{R}_{ij}$  is the vector joining the heavy atoms. (d) Probability distribution, P(R<sub>ee</sub>), of the end-to-end distance, R<sub>ee</sub>, defined as the distance between the C-atom of the methyl group in the acetyl cap of the N-

Reddy et al.

terminus and the N-atom in the -NH2 group of the amidated C-terminus. (e) Probability distribution,  $P(R_{23-28}^{\alpha})$ , of the distance between the  $C_{\alpha}$  atoms of residues 23 and 28,  $R_{23-28}^{\alpha}$ . In (c), (d) and (e) green, red, black, blue and yellow lines show the data for WT A $\beta_{10-35}$  dimers, A $\beta_{10-35}$ [D23-K28] dimers, A $\beta_{10-35}$ [D23-K28] monomer, A $\beta_{10-35}$ -lactam[D23-K28] monomer and A $\beta_{10-35}$ -lactam[D23-K28](OPLS) respectively.

#### Fig. 2.

(a) Time dependent changes in the salt bridge distances in the  $A\beta_{10-35}$ [D23-K28] monomer. Green and red lines show the data for D23-K28 and E22-K28 salt bridge respectively. (b) Number of water molecules with in 3.5Å of the salt bridge forming atoms of residues E22, D23 and K28 in the  $A\beta_{10-35}$ [D23-K28] monomer. Black, blue and red lines show the data for residues E22, D23 and K28 respectively. (c) Time dependent changes in the salt bridge distances in WT  $A\beta_{10-35}$  monomer. Two arrows pointing downwards point to the 17 ns time interval during which the D23-K28 salt bridge is kinetically stable. Arrow pointing to the right shows the reformation of the salt bridges after nearly 60 ns. Color codes are the same as in (a). (d) Number of water molecules with in 3.5Å of the salt bridge forming atoms of residues E22, D23 and K28 in WT  $A\beta_{10-35}$  monomer. Color codes are the same as in (b). The number of water molecules are averaged over 0.25 ns.

#### Fig. 3.

(a) Structure from the WT  $[A\beta_{10-35}]_2$  simulation. The stable salt bridge between D23 and K28 in the monomer on the left (cyan) is shielded from the water molecules by the monomer on the right (red). Figures are prepared using VMD51. (b) Radial distribution function between C<sub> $\gamma$ </sub> atom of residue D23, (Fig 1(a)), and the water oxygen atoms. Plot in circles is obtained by averaging the data from 0–12 ns during which the D23-K28 salt bridge is stable, and the plot in squares is obtained by averaging the data from 34–46 ns where the D23-K28 salt bridge is ruptured (Fig. 2(c)). When the salt bridge is intact, it is in a dehydrated environment.

#### Fig. 4.

Probability distribution of the D23-K28 and E22-K28 salt bridge distances. Here  $R_{sb}$  is the distance between the salt bridge forming atoms of residues D23 and K28 in case of D23-K28 salt bridge, and the distance between the salt bridge forming atoms of residues E22 and K28 for the E22-K28 salt bridge. Atoms engaged in salt bridge are  $C_{\delta}$  atom of residue E22,  $C_{\gamma}$  atom of residue D23 and N<sub>{\zeta}</sub> atom of residue K28, (Fig. 1(a)). Blue, red and green lines represent the data for D23-K28 salt bridge in WT A $\beta_{10-35}$ , E22-K28 salt bridge in WT A $\beta_{10-35}$ , and E22-K28 salt bridge in A $\beta_{10-35}$ [D23-K28] respectively. The sharp peak in the green curve shows that constraining the D23-K28 distance enhances the probability of forming the E22-K28 interaction.

#### Fig. 5.

(a) Snapshot of a  $A\beta_{9-40}$ [D23-K28] monomer where the C and N terminal hydrophobic residues interact to form  $\beta$ -sheet. This assembly-competent structure, labeled as  $N^*$ , is similar to that found in the fibril. (b) Contact map of the  $A\beta_{9-40}$ [D23-K28] monomer obtained by averaging 15 ns of the trajectory from which the structure in (a) is taken. Monomers are in contact if the center of mass of two residues is  $\leq 6$  Å.

#### Fig. 6.

(a) Structure of the *N*<sup>\*</sup> state of A $\beta_{10-35}$ [D23-K28] monomer. There are a lot of similarities between the *N*<sup>\*</sup> conformation and the structure of the monomer in the model fibril structure. Residues D23 and K28, which form the salt bridge, and the C and N terminal hydrophobic residues E11, V12 and L34 are in contact. (b) R<sub>g</sub> and R<sub>ee</sub> as a function of time of the monomer. The peptide is compact and samples manifolds of collapsed structures (see Fig. 1). (c) Contact map of the monomer obtained by averaging 40 to 100 ns of the trajectory from which the structure in (a) is taken. Monomers are in contact if the center of mass of two residues is  $\leq 6$  Å.

#### Fig. 7.

Projection of the free energy landscape for the  $A\beta_{10-35}$  monomer on to the lowest two eigenvectors of the dihedral principal component analysis. The scale for the free energy in units of  $k_BT$ , where  $k_B$  is the Boltzmann constant and T is the temperature, is given on the right. (a)Wild type dimer: (b)Monomer  $A\beta_{10-35}$ [D23-K28]: (c) Dimer  $A\beta_{10-35}$ [D23-K28].

Reddy et al.

# Fig. 8.

Helical propensity of residues in dimer simulations of the WT A $\beta_{10-35}$ . The percentage propensity is calculated by using  $N_H^k/N_T$ , where  $N_H^k$  is the number of conformations in which residue *k* forms a helix, and  $N_T$  is the total number of conformations obtained. We used the criterion given in STRIDE41 to ascertain if a residue is in a helical conformation.

## Fig. 9.

Schematic free energy profile for the conversion of  $A\beta$  and  $A\beta$ [D23-K28] to assemblycompetent N\* structure. Although we have shown only a single structure for the unfolded conformation it should be stressed that both the WT and  $A\beta$ [D23-K28] sample a number of distinct conformations. Thus, these structures as well as N\* should be viewed as an ensemble. The rates of nucleus formation is dependent on the ease of populating the assembly-competent N\* structure. Both mutations and preformed salt bride can decrease the barrier to N\* formation. On the right a schematic for the aggregation mechanism is presented. The A $\beta$  peptide transiently populates the assembly-competent N\* structure. These N\* structures collide to form the critical nucleus that can subsequently grow to form protofilaments and fibrils.

#### TABLE I

Free energy cost for bend formation in  $A\beta$  peptides.

Aβ D23-K28 salt bridge constrained peptides	$\langle R^{\alpha}_{23-28} \rangle_a$	$\Delta G_{bend}/k_B T^b$
Αβ <sub>10-35</sub> [D23-K28]	6.6 Å	6.9
$A\beta_{10-35}[D23-K28]_2$	8.1 Å	3.4
$A\beta_{10-35}$ -lactam[D23-K28]	7.2 Å	5.4
Aβ <sub>10-35</sub> -lactam[D23-K28](OPLS)	7.9 Å	3.6
$\left< R^{\alpha}_{23-28} \right>_{\text{of the four above species averaged}}$	7.5 Å	4.6

 ${}^{a}\left\langle R_{23-28}^{\alpha}\right\rangle = \int R_{23-28}^{\alpha} P\left(R_{23-28}^{\alpha}\right) dR_{23-28}^{\alpha}, \text{ where } P\left(R_{23-28}^{\alpha}\right) \text{ is the distribution of the distance between the $\alpha$-carbon atoms of D23 and K28.}$ 

 $^{b}$ The free energy cost for forming a bend (a hairpin-like structure) in WT is given by Eq.(1)
