Nickel-Catalyzed Synthesis of Acrylamides from Alpha Olefins and Isocyanates

Kristin D. Schleicher and Timothy F. Jamison*

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Abstract

The nickel(0)-catalyzed coupling of α -olefins and isocyanates proceeds in the presence of the *N*-heterocyclic carbene ligand IPr to provide α , β -unsaturated amides. Carbon-carbon bond formation occurs preferentially at the 2-position of the olefin. The *N*-tert-butyl amide products can be converted to the corresponding primary amides under acidic conditions.

A major goal of organic chemistry is the elaboration of molecular complexity from simple, inexpensive precursors. Catalytic reactions that effect selective carbon-carbon bond formation facilitate this aim with economy of operations¹ and materials.²

Methodology for the selective coupling of α -olefins and isocyanates to provide acrylamides has potential applications in the field of polymer science. Poly(*N*-alkylacrylamide)s and poly(*N*-alkylmethacrylamide)s have been extensively studied for their properties as temperature-sensitive aqueous microgels.³ The monomers are commonly prepared by reaction of (meth)acryloyl chloride with the corresponding amine. By comparison, direct synthesis of these unsaturated amides from alkenes and isocyanates would afford monomers with a greater variety of substitution patterns of the polymer backbone and avoid the formation of byproducts such as chloride salts.⁴

Several nickel(0)-mediated reactions of isocyanates have been described in the literature. Much of the seminal investigation in this area was done by Hoberg, who first reported the stoichiometric^{5a} and catalytic^{5c} coupling reactions of phenyl isocyanate and ethylene on nickel(0) with trialkyl phosphine ligands to give *N*-phenyl acrylamide. Hoberg proposed that the reaction proceeds via an azanickelacyclopentanone intermediate, which then undergoes β -hydrogen elimination (Scheme 1).

Other α -olefins react with phenyl isocyanate with nickel(0) and phosphine ligands;^{5b,d-h} the major product is the *trans*-disubstituted α , β -unsaturated amide. Formation of a 1,1- disubstituted acrylamide is observed only in two cases as a minor product, in 3% and 13%

yield. In addition, isocyanates have been shown to react on nickel(0) with electronically activated alkenes,⁶ 1,3-dienes,⁷ allenes,⁸ and aldehydes.⁹

Most recently, Louie has demonstrated that an NHC-nickel(0) system efficiently catalyzes the cycloaddition of diynes or alkynes and isocyanates to form pyridones.^{10a} Cycloadditions run with an excess of isocyanate lead to the formation of pyrimidinediones.^{10b} Free NHC ligands themselves are known to rapidly catalyze isocyanate trimerization to urethanes, as well as undergo reversible carboxylation in the presence of carbon dioxide.¹¹

Recent work in our laboratory has shown that *N*-heterocyclic carbene (NHC) ligands can provide very high selectivity for reaction at the 2-position of an α -olefin in the nickelcatalyzed coupling of aldehydes, α -olefins, and silyl triflates.¹² Herein we report the first example of a nickel(0)-catalyzed reaction of an alkene and an isocyanate in which carboncarbon bond formation occurs selectively at the 2-position of the α -olefin, yielding *N*alkylated acrylamides (Table 1).

In the presence of the NHC ligand IPr, excellent conversions were obtained upon heating (Table 1, entry 2) or extended reaction time (entry 1) in the nickel-catalyzed coupling reaction. The NHC ligand gives products with the opposite sense of regioselectivity compared to those obtained when phosphine ligands are used (entries 7 and 8). The observed selectivity for carbon-carbon bond formation at the 2-position of the α -olefin may be attributed to a preference for the substituent on the olefin to be oriented away from the bulky NHC ligand (Figure 1).

A catalyst loading of 10 mol% with respect to the alkene is optimal for yield, although a slightly higher turnover number was noted with 5 mol% catalyst and ligand. Control experiments run in the absence of either $Ni(cod)_2$ or IPr indicate that both species are necessary for catalysis.

The reaction proceeds smoothly in a variety of solvents (Table 2). In the absence of solvent, the coupling of 1-octene and *tert*-butyl isocyanate occurs with good yield (entry 6); however, with cyclohexyl isocyanate a diminished yield is observed (entry 7), perhaps due to incomplete mixing associated with the precipitation of solid cyclohexyl amide products.

Table 3 illustrates the scope and selectivity of the reaction. Reactions of aliphatic olefins with branching at the allylic or homoallylic position proceed in high yields and with excellent selectivity for carboxamidation at the 2-position of the olefin. With allylbenzene, a third product is formed in which the double bond has moved into conjugation with the aromatic ring (entries 7 and 8). The catalytic reaction appears to be selective for monosubstituted olefins (entries 9 and 10). In other experiments, 1,1-disubstituted, *cis*-, and *trans*-olefins react poorly or not at all.¹³ Furthermore, esters and trialkylsilyl-protected alcohols are well tolerated under the reaction conditions. Hex-5-en-2-one reacts cleanly with *tert*-butyl isocyanate, but with cyclohexyl isocyanate the yield is substantially diminished (entries 13 and 14). Since the hexenone differs from other linear aliphatic olefins we have examined only at a position remote to the alkene, we hypothesize that the enhanced selectivity may be due to coordination of the carbonyl group to nickel at a selectivity-determining step in the catalytic cycle.¹⁴

The scope of the reaction with respect to the isocyanate appears to be limited to bulky, electron-rich alkyl isocyanates. In the reactions of ethyl and benzyl isocyanate with 1-octene, small amounts of coupling product can be isolated, but the major products obtained are isocyanate oligomers. Slow or portion-wise addition of isocyanate does little to circumvent this side reaction, and no improvement in yield is observed when Ni(cod)₂ and IPr are allowed to equilibrate in solution for six hours prior to reaction, as done by Louie.^{10a}

Phenyl isocyanate, trichloromethyl isocyanate, and phenyl isocyanatoformate all gave no desired product under the reaction conditions.

In recognition of the prevalence of primary amide motifs in the natural world, we investigated the possibility of forming such amides from our initial products. Deprotection of *N-tert*-butyl amides requires strongly acidic conditions, often coupled with heat,¹⁵ nevertheless, the reaction has been successfully utilized in the contexts of natural product synthesis¹⁶ and drug discovery.¹⁷ Still, it was unclear whether 1,1-disubstituted acrylamides would emerge unscathed from the forcing conditions necessary to effect deprotection. Gratifyingly, we were able to obtain the primary amides from several of the coupling products after heating in neat trifluoroacetic acid at reflux overnight (Table 4).

In summary, we have described a new preparation of acrylamides via the nickel(0)-IPrcatalyzed reaction of simple α -olefins and isocyanates. The NHC ligand gives products with the opposite sense of regioselectivity compared to those obtained using phosphine additives. Acid treatment converts the *N-tert*-butyl products to free amides. In addition to more conventional synthetic operations, compounds prepared by this method may find application as novel monomers for polymer synthesis.
