### Abstract

Mutations in the human L1CAM gene cause X-linked Hydrocephalus and MASA syndrome. In vitro studies have shown the L1 cytoplasmic domain (L1CD) is involved in L1 trafficking, neurite branching, signaling, and interactions with the cytoskeleton. L1cam knock-out (L1<sup>KO</sup>) mice have hydrocephalus, a small cerebellum, hyperfasciculation of corticothalamic tracts and abnormal peripheral nerves. To explore the function of the L1CD, we made three new mice lines in which different parts of the L1CD have been altered. In all mutant lines L1 protein is expressed and transported into the axon. Interestingly, these new L1CD mutant lines display normal brain morphology. However, the expression of L1 protein in the adult is dramatically reduced in the two L1CD mutant lines that lack the ankyrin-binding region and they show defects in motor function. Therefore, the L1CD is not responsible for the major defects observed in L1<sup>KO</sup> mice, yet it is required for continued L1 protein expression and motor function in the adult.

### Keywords

hydrocephalus; axon guidance; fasciculation; myelin; L1-CAM

### Introduction

The cell adhesion molecule L1 is a member of the immunoglobulin superfamily and is essential for development of the human and mouse nervous system (Dahme et al., 1997; Kamiguchi et al., 1998a; Kenwrick et al., 1996). In humans, mutations in the L1CAM gene cause X-linked Hydrocephalus (OMIM #307000) and MASA syndrome (Mental retardation, Aphasia, Shuffling gait, Adducted thumbs, OMIM #303350). L1 has been implicated in different aspects of neural development, including neurite outgrowth (Lagenaur and Lemmon, 1987), axon fasciculation (Stallcup and Beasley, 1985), myelination (Barbin et al., 2004), and synapse formation (Godenschwege et al., 2006). These multiple functions of L1 depend on complex interactions with diverse molecules that associate with L1's extracellular and cytoplasmic domain (Hortsch et al., 2009; Maness and Schachner, 2007).

The extracellular domain participates in adhesion by homophilic interactions with L1 itself (Grumet and Edelman, 1988), or heterophilic interactions with CNTN2/axonin-1/TAG-1 (Kuhn et al., 1991), integrins (Ruppert et al., 1995), neuropilin-1 and SemaIIIa (Castellani et al., 2000), and other ligands (Haspel and Grumet, 2003).

The L1 cytoplasmic domain (L1CD) is highly conserved, being identical at the amino acid level in all mammals and shows strong conservation between invertebrates and vertebrates (Hortsch, 2000). Mutations in the L1CD cause MASA syndrome (Fransen et al., 1997). In neural tissue, the L1CD includes an alternatively spliced miniexon, RSLE, which is preceded by a tyrosine. The resulting YRSL sequence confers binding to a clathrin adaptor, AP-2 (Kamiguchi et al., 1998b) that is important in L1 trafficking (Dequidt et al., 2007; Kamiguchi et al., 1998b; Yap et al., 2008). L1 can be coupled to the actin cytoskeleton through interactions with either ankyrin 2 (Ank2) (Davis and Bennett, 1994; Yap et al., 2008) or ezrin-radixin-moesin (ERM) proteins (Dickson et al., 2002; Sakurai et al., 2008). Ank2 binding to L1 stabilizes its location on the cell surface (Gil et al., 2003; Hortsch et al., 2009; Scotland et al., 1998). ERM binding to L1 is important for L1 mediated axonal branching and guidance (Cheng et al., 2005a; Mintz et al., 2008).

Because numerous studies implicate the cytoplasmic domain of L1 in the protein's function and human mutations in the L1CD cause Central Nervous System (CNS) deficits, we were motivated to generate three new mutant mice lines. One line has a point mutation (Y1176>A) previously shown in vitro to influence L1 trafficking and interaction with ERMs. The other two lines have truncations that remove approximately one half or nearly the entire L1CD (L1<sup>1180</sup> and L1<sup>1152</sup>, respectively). We examined the brains of the L1CD mutant mice, focusing on regions that show abnormalities in L1<sup>KO</sup> mice. Surprisingly, we observed no gross morphological or histological abnormalities in the CNS or Peripheral Nervous System (PNS) that are present in L1<sup>KO</sup> mice. All the L1CD mutant mice express L1 protein in the usual pattern in young animals, but expression of L1 protein in adults is very low in the two L1CD mutant lines that lack the Ank2 binding region. In addition, these two L1CD mutant lines showed a defect in motor function. These data show that the L1CD is not essential for several interesting defects present in L1<sup>KO</sup> mice, but is critical for sustained L1 protein expression, which in turn may be necessary for motor coordination.

## Materials and methods

### Antibody Characterization

Primary antibodies include: Rabbit anti L1total (Brittis et al., 1995) produced in the Lemmon lab. Rabbit anti L1CD (Schaefer et al., 2002) produced in the Lemmon lab to recombinant L1 cytoplasmic domain; Rabbit anti FIGQY (gift from Dr. Matthew N. Rasband) (Ogawa et al., 2006), produced to a small peptide corresponding to a highly conserved cytoplasmic sequence found in all L1-CAMs; Rat anti L1ex (gift from Dr. Fritz Rathjen)(Lindner et al., 1983; Rathjen and Schachner, 1984), the original monoclonal antibody to mouse L1 made by Fritz Rathjen. All of the antibodies to L1 have been tested and do not bind to western blots of L1KO brain membranes (for example, see Fig. 9). When used to immunoprecipitate mouse brain, they give only proteins with the expected bands at 220 kDa, 180 kDa and 80 kDa. The anti FIGQY antibody recognizes the L1 family members and when immunoprecipitation was also performed with the FIGQY antibody only the expected bands at 220 kDa and 80 kDa were observed. Mouse anti GAPDH (Cat # AM4300, 1:10000; Ambion, Austin, TX). This antibody was used as a loading control for westerns and only detected a single band at the expected molecular weight at about 39 kDa. Chicken anti- $\beta$ tubulin 3 (Cat number TUJ, 1:1000; Aves Labs, Tigard, Oregon), when used to visualize neurites in culture, gave the expected staining pattern and did not stain glia or fibroblasts. Mouse anti-neurofilament (RT97, 1:1000) obtained from the Developmental

Studies Hybridoma Bank. When used to stain axons in brain sections to examine fasciculation, it gave the expected staining pattern, consistent with earlier reports (Johnstone et al., 1997; Shin et al., 2003).

## Animals

All animal experiments described in this manuscript have been approved by the Case Western Reserve University and the University of Miami IACUCs. L1<sup>Y1176A</sup>, L1<sup>1180</sup> and L1<sup>1152</sup> mice were generated using a Cre/lox approach (Fig. 1A). The L1cam gene has 29 exons, 28 of which are coding and one containing a 5' –untranslated sequence (Meech et al., 1999). 9.7 kb of *Xba* I DNA fragment including exon12 to exon 29 was obtained from 129/SvJ genomic BAC clone containing the entire L1cam gene (Caltech 129/SvJ mouse genomic library clone Citb/CJ7/567G9, purchased from Open Biosystems). A fragment from *Pml* I located in exon 14 and a *PshA* I located at 2.1kb downstream from the stop codon were chosen as the ends of the 5' –arm and 3' –arm respectively. A mutated fragment was substituted for corresponding wild type sequences. A neomycin resistance cassette, with a MC1 promoter and polyadenylation signal and flanked loxP sites, was inserted into the *Bgl* I site located between exon 26 and exon 27 for positive selection. To provide for negative selection, the L1cam 5' –arm-neomycin resistance cassette-L1cam 3' –arm fragment (9.4kb) was replaced with a neomycin cassette of pPNT (Tybulewicz et al., 1991) containing HSV-Thymidine kinase gene with the phosphoglycerate kinase-1 promoter. Following digestion with *Not* I, the linearized construct was electroporated into embryonic stem cells (ES PC3 cells (Protamine-Cre recombinase transgene including embryonic stem cells)) (O'Gorman et al., 1997). ES cells were cultured in G418 containing media, and surviving cells were screened by Southern hybridization. The wild type (WT) gene has a 9.7 kb *Xba* I-*Xba* I fragment. The mutant gene generates a *Xba* I site in the lox P cassette, so after *Xba* I digestion it gives a shorter fragment. Two probes were prepared for confirmation of 5' –and 3' – recombination. Probe L, detecting 5' – homologous recombination is 0.6 kb upstream of *Pml* I site, and probe R, detecting 3' – homologous recombination, is 0.9 kb downstream of the *PshA* I site. The probes detect 5.6 kb and 5.3 kb fragments respectively.

Prior to initiating analysis of the 3 lines, the mice were backcrossed onto the 129S2/Sv (129S2/SvPasclrf) and the C57BL/6 background using MAX-BAX<sup>sm</sup> (Marker-Assisted Accelerated Backcrossing) speed congenics until the lines were congenic.

## Mutagenesis

: A 0.3 kb of *Bam*H I – *Sac* I fragment containing exon 27 and exon 28 was subcloned into pBluescript SK + (Stratagene, La Jolla, CA) for mutagenesis template. Oligonucleotides containing a mutation that generates a stop codon just before RSLE, 5' – GACCTTCGGCGAGTACTAGTGAGCAGGGACAAA AG-3' and 5' – CTTTTGTCC CTGCTCACTAGTACTCGCCGAAGGTC-3', 1176 Tyr residue changed into Ala, 5' – GAGACCTTCGGCGAGGCCAGGTGAGCAGGGAC-3' and 5' –GTCCCTGCTCACCTG CCTCGCCGAAGGTCTC-3', and a stop codon just after RSLE, 5' – GACTTCAGGTCCCTGGAGTAGGTAAGATGTGACAGTAGG-3' and 5' – CCTACTGTACATCTTACCT ACTCCAGGGACCTGAAGTC-3' were designed for the mutagenesis. QuickChange II Site Directed Mutagenesis Kit (Stratagene, La Jolla, CA) was used following the manufacture's instructions. Each mutated fragment was substituted with original (wild type) *Bam*H I and *Sac* I sites of corresponding DNA sequences.

## Preparation of membrane proteins

Mouse brain homogenates were prepared by homogenizing brains in a buffer containing 50 mM Tris (pH 7.2), 0.32 M sucrose and protease inhibitor (Roche Diagnostics, Indianapolis, IN). The solution was layered over a sucrose gradient consisting of two discontinuous layers

of 0.8 M and 1.2 M sucrose dissolved in 50 mM Tris, pH 7.2, and centrifuged at  $40,500 \times g$  for 1.5 hrs in a Beckman SW 28. The membrane fraction at the 0.8 M- 1.2 M sucrose interface was collected and diluted with 1 vol of 50 mM Tris, pH 7.2, and centrifuged at  $230,000 \times g$  for 20 min in a Beckman Ti 70.1. For some experiments the membrane pellets were resuspended in 0.1M PBS. For other experiments, the pellets were resuspended in 1% Triton-X-100, 50 mM Tris, pH 8.0, sonicated and centrifuged at  $230,000 \times g$  for 30 min. The supernatant (membrane extract) was reserved for subsequent use.

### Immunoprecipitation

For some western blot experiments, L1 immunoprecipitation was performed. Protein A-sepharose beads (Pearce, Rockford, IL) were coated with L1ex antibody which recognizes the extracellular region of L1 (Rathjen and Schachner, 1984). The L1ex-coated beads were incubated with membrane extract at 4°C over night, spun down and washed with 1% Triton-X in 50 mM Tris, pH 8.0. Protein was eluted by adding 2x SDS-PAGE sample buffer (100 mM Tris-HCl pH 6.8, 4% SDS, 0.2% bromophenol blue, 5% glycerol and 12% 2-mercaptoethanol) and heating at 100°C for 5 min.

### Western blotting

The membrane extracts were subjected to SDS-PAGE and western blotting either directly or after immunoprecipitation. Samples were separated by electrophoresis in 8.5% polyacrylamide gels and transferred to PVDF membrane (Millipore Corporation, Bedford, MA). Membranes were blocked at room temperature for 1 hr with Odyssey blocking buffer (LI-COR, Lincoln, NE). Blots were then incubated with primary antibody in Odyssey blocking buffer at 4°C overnight. Primary antibodies used include: anti L1total (1:5000) (Brittis et al., 1995), anti L1CD (1:5000) (Schaefer et al., 2002), anti FIGQY (1:200) (Voas et al., 2007), anti L1ex (1:10000) (Lindner et al., 1983), and anti GAPDH (1:10000; Ambion, Austin, TX). For detection, the blots were incubated with secondary antibody for either anti rabbit (1:5000) or anti rat (1:500) or anti mouse (1:5000) IRdye800 or IRdye700 (LI-COR, Lincoln, NE) at room temperature for 1 hr, then scanned using an Odyssey infrared imaging machine (LI-COR, Lincoln, NE).

### Preparation of substrate

For these experiments we used Human L1-Fc or laminin for the substrate. For L1-Fc substrate, anti-human-Fc (Rockland, Gilbertsville, PA) ( $8 \mu\text{g} / \text{well}$ ) was incubated in 96 well plates (Packard View Plates, Packard Bioscience, CO) overnight at room temperature. Following several washes with PBS, L1-Fc ( $4 \mu\text{g} / \text{well}$ ) was incubated overnight at room temperature. For laminin substrate, poly-D-lysine ( $100 \mu\text{g} / \text{ml}$ ) was incubated in 96 well plates (Packard View Plates, Packard Bioscience, Meriden, CT) or on cover glass overnight at room temperature. Following several washes with HBSS, laminin ( $10 \mu\text{g} / \text{ml}$ ) was incubated overnight at room temperature. Plates or coverslips were washed with PBS before plating neurons.

### Primary hippocampal cultures

Postnatal day 2-3 mouse hippocampi were removed in Hibernate E (Brain Bits, Springfield, IL) and incubated with 20 units / ml papain (Worthington Biochemical Corporation, NJ) and 0.1 mg/ ml DNase (Sigma-Aldrich, St.Louis, MO) for 30 min at 37 °C, followed by washing with Hibernate E and 1x B27 (Invitrogen, Carlsbad, CA), then incubated with 0.25% Trypsin (Invitrogen). After washing with Hibernate E and B27, cells were incubated with Enriched Neurobasal (ENB) media (1x Penicillin-Streptomycin liquid (Invitrogen), 1x insulin (Sigma-Aldrich), 1 mM sodium pyruvate (Invitrogen), 1x T3 (Sigma-Aldrich), 1x L-glutamine (Invitrogen), 1x NAC (Sigma-Aldrich), 1x B27 (Invitrogen), 4 mg transferrin (Sigma-

Aldrich), 4mg BSA (Sigma-Aldrich), 2.5 µg progesterone (Sigma-Aldrich), 0.64 mg putrescine (Sigma-Aldrich), 1.6µg sodium selenite (Sigma-Aldrich)) during 3 days.

### Immunostaining for hippocampal primary cultures

The cultures were fixed with 4 % PFA (Sigma-Aldrich, St. Louis, MO), 4 % Sucrose (Sigma-Aldrich), PBS, for 15 min. Neurons were blocked with 0.03 % Triton-X and 0.2 % Gelatin at room temperature for 1 hr, followed by incubation with primary antibody at 4°C overnight and secondary antibody at room temperature for 1 hr. Primary antibodies were used for immunostaining as follows: L1total (1:100; (Brittis et al., 1995)), anti-βtubulin 3 (1:1000; Aves Labs, New Orleans, LA), and anti-neurofilament (RT97, 1:1000).

### Semi-quantitative measurements of L1 expression on hippocampal neurons

To measure the intensity of L1 and tubulin, hippocampal neurons from all three mutant mice and L1<sup>WT</sup> mice were prepared, cultured and stained on the same day using the same conditions and antibodies. Images were acquired using a Zeiss LSM 410 confocal microscope. The intensity of L1 and tubulin was measured by MetaMorph software (Molecular Devices, Sunnyvale, CA) with no adjustments to the acquired images. To produce magenta/green images for Fig. 2 the red/green images obtained from the LDM 410 were imported into Photoshop (10.0 for the Mac) and the red channel was adjusted so the brightest pixels were about 250. The red channel was then imported into ImageJ ( 1.42 for the Mac) and the red channel was copied into the blue channel to produce magenta. Finally, the red and blue channels were merged in ImageJ with the green channel to give the magenta/green/white images that show co-localization of L1 and tubulin.

### Morphometry of hippocampal neurons

Images of neurons in 96 wells were taken and analyzed using a Cellomics VTI Arrayscan High Content Screening Microscope (Thermo Fisher Scientific, Pittsburgh, PA). These data were analyzed by Spotfire software (Tibco, Palo Alto, California). Parameters of special interest were the longest neurite length, neurite total length, number of branches of the neurites and the number of neurites emerging from the soma.

### Immunohistochemistry

Fixation and staining were performed as described previously (Nakamura et al., 2006). Briefly, young mice (7 days of age) and adult mice (7 weeks of age) were anesthetized by an i.p. injection of Ketamine and Xylazine, and perfused transcardially with 4% PFA in PBS. Brains were removed and post-fixed at 4°C overnight in the same fixative, followed by immersion in 30% sucrose. Frozen 30-µm-thick coronal sections were used for immunohistochemistry. The sections were blocked in 5% BSA in PBS, and incubated with primary antibodies at 4°C over night. Sections were rinsed in PBS and incubated in biotinylated secondary antibodies at 4°C over night (1:500; Vector Laboratories, Burlingame, CA). Bound antibodies were detected by staining for 2 hrs with the ABC Vectastain kit (Vector Laboratories, Burlingame, CA) and then for 5 min with 0.05% 3,3'-diaminobenzidine tetrahydrochloride (DAB) in 50 mM Tris-HCl, pH 7.5, containing 0.01% H<sub>2</sub>O<sub>2</sub>. Primary antibodies were used for immunostaining as follows: L1ex (1:2000) (Lindner et al., 1983), anti-neurofilament (RT97, 1:1000).

### Real-time quantitative PCR analysis

cDNA was produced from 7-week-old mouse brains by a reverse transcription PCR kit (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. Quantitative reverse transcriptase-PCR (qRT-PCR) was performed by QuantiFast SYBR Green RT-PCR Kit

(QIAGEN, Valencia, CA). Expression data were normalized to  $\beta$ -actin. The primers are as follows: L1cam left: 5'-acctgaggcattacacctg-3', L1cam right: 5'-agttctgggtccgaaggtt-3'.

### Morphological and histological analysis

For detection of hydrocephalus, brains were cut coronally at -0.9 mm from bregma. To examine the cerebellum and corpus callosum, brains were cut sagittally at the midline. The brains were observed with a stereo microscope (Wild Heerbrugg-M650 microscope, Switzerland), imaged with a Spot 2.3.0 camera and SPOT software (Diagnostic Instruments, Sterling Heights, MI). To measure the area of the cerebellum, digital images from the midline were traced with ImageJ software (National Institutes of Health, Bethesda, MD). To measure the pyramidal tract, coronal serial slices were obtained at 30  $\mu$ m-thickness using a vibratome, after paraformaldehyde perfusion. Wet slices in 0.1 M PBS, pH 7.4 were put on glass slides allowing the pyramidal tract to be detected microscopically (using a Olympus BX51 light microscope, and image capture with a Microfire camera (Optronics, Goleta, CA)). Images of the pyramidal tract just rostral to the decussation were collected, and the cross-sectional area was traced with ImageJ software (National Institutes of Health, Bethesda, MD).

### Pyramidal tract tracing

Mice were anesthetized with a mixture of ketamine / xylazine cocktail by intraperitoneal injection. The skull was opened and 10 % BDA (MW 10,000; Molecular Probes, Eugene, OR) was injected into 3 sites (1  $\mu$ l/site) into motor cortex using a Hamilton syringe. After surgery, the mice were kept on a heating pad until completely recovered from anesthesia. Mice were transcardially perfused 6 days after injection of BDA, then 20  $\mu$ m coronal sections were taken. BDA was detected using streptavidin Alexa Flour 594 conjugate (1:200; Invitrogen, Carlsbad, CA).

### Electron Microscopy

Sciatic nerves of adult mice were removed and fixed at 4 °C in 2% PFA, 2% glutaraldehyde in 0.1 M PBS, pH7.4. Then sciatic nerves were put in 2% OsO<sub>4</sub> for 1 hr at room temperature before being embedded in Embed plastic (Electron Microscopy Science, Fort Washington, PA). Thin sections were stained with uranyl acetate and lead citrate and examined using a Philip CM-10 electron microscope (FEI Company, Hillsboro, OR).

### G-ratio

For measuring g-ratio, one micron semithin sections of sciatic nerve were prepared and stained with toluidine blue/methylene blue/sodium borate. Threshold images were obtained by ImageMagick software (ImageMagick Studio LLC, Landenberg, PA). For measuring g-ratio (ratio of myelin thickness to axon size), the threshold images were measured with ImageJ software (National Institutes of Health, Bethesda, MD).

### Spatial learning and memory in the radial-arm water maze

The radial-six arm water maze is a hybrid of the Morris water maze and a radial arm maze, which combines the simple motivation provided by water immersion along with scoring errors obtained with a radial arm maze (Alamed et al., 2006). Each mouse was placed on the platform for 20 sec, followed by a 1-min swimming period starting from each arm and ending when the mouse found the platform. This session was repeated 3 times during 3 successive days of training, followed by 1 test trial on each of the next 2 days.

## Motor function

Mice were placed on a rotating rod (IITC 755 Rotarod, IITC Life Sciences, Woodland Hills, CA) facing the opposite direction to the motion of the rod, which was set to accelerate from 0 to 30 rpm over 3 min. Automatic timers scored the latency for the mice to fall off the rod into the chamber below. Mice were trained for 2 weeks then tested for 1 week, with one trial per day.

## Statistics

In all cases Analysis of Variance was performed with a level of significance set at 0.05.

## Results

### Production of three kinds of L1CD mutant mice (L1<sup>Y1176A</sup>, L1<sup>1180</sup>, L1<sup>1152</sup>)

We generated three L1CD mutant mice (Fig. 1). In our experimental design we wanted to make mutations with minimum impact on L1cam gene organization to reduce the possibility of altered gene expression and/or other unanticipated complications. Initially we chose to focus on making constructs that would distinguish between the roles of Ank2 and the critical region at the RSLE mini-exon that is involved in clathrin mediated endocytosis and ERM binding. The L1<sup>Y1176A</sup> mice had one amino acid substitution from tyrosine to alanine, therefore lacking the AP-2 binding site and a site involved in ERM interactions with L1, but preserving the rest of the L1CD. The other two L1CD mutant mice have truncation mutations. L1<sup>1180</sup> mice have a stop codon after the E1180 codon, thereby preserving binding to AP-2 and ERM proteins but not binding to Ank2 or RanBPM. Our original plan was to produce a mutant line with a truncation at Y1176, i.e. before the mini exon that codes for RSLE. This required altering the sequence at the end of exon 28 by converting Y1176 to a stop codon. Sequencing of genomic DNA from the three new lines confirmed that they all had the expected mutations that were introduced into the ES cells (data not shown). It is well established that the genetic background influences the phenotype of L1cam mutant mice. Consequently, we backcrossed the mice onto 129S2/Sv (129S2/SvPasclrf) and C57BL/6J using speed congenics, and only performed experiments on mice that were at least 98% congenic, based on analysis of 110 microsatellite markers.

Next we checked the sequence of the L1 mRNA from the 3 new mutant mice lines. The sequence of the mRNA for L1<sup>Y1176A</sup> and L1<sup>1180</sup> was the expected sequence based on our design and the sequence of the genomic DNA. However, the sequence of the putative L1<sup>1176</sup> was not. Rather, the L1 sequence ended at what corresponds to exon 26, followed by 78 apparently random nucleotides. We conclude that the mutation introduced at the end of exon 26 disrupted splicing, leading to skipping of exon 27. While the resulting mice were not what we had originally planned, indeed we believe they are even more informative because the introduced mutation resulted in the elimination of 105/114 of the highly conserved amino acids in the L1CD. Henceforth we will refer to this mutant as L1<sup>1152</sup>.

Western blotting was performed on the new lines to confirm that L1 protein was expressed. For the initial characterization, several antibodies against different regions of L1 were used for western blotting. To reduce the background and increase the band density for western blotting, we immunoprecipitated L1 from mouse brain extracts. This experiment does not provide information about the expression level of L1 protein in different L1cam mice lines, but provides information about whether these mutant mice express L1 protein of the expected size. Using a polyclonal antibody to L1, L1<sup>WT</sup>, all three L1CD mutant mice showed two clear L1 bands, ~ 220 kD (full length L1) and ~ 140 kD (cleaved form of L1) (Fig. 1C), while L1<sup>KO</sup> mice did not show any bands (data not shown, but see Itoh et al, 2004). The two lines with truncated L1 (L1<sup>1180</sup> and L1<sup>1152</sup>) showed bands at lower

molecular weights  $L1^{WT}$ , as expected. Using a polyclonal antibody that recognizes the L1CD,  $L1^{1152}$  did not show any band, demonstrating that  $L1^{1152}$  mice lack the majority of the L1CD. Using the FIGQY monoclonal antibody that recognizes the FIGQY sequence in the Ank2 binding site, only  $L1^{WT}$  and  $L1^{Y1176A}$  mutant mice showed L1 bands. Therefore, the data for the sequence of L1 mRNA and western blotting show that 1) L1 protein is expressed in the brains of the three new lines, 2)  $L1^{Y1176A}$  mutant protein has a similar molecular weight to  $L1^{WT}$ , 3)  $L1^{1180}$  has a truncation missing the Ank2 binding region and 4)  $L1^{1152}$  has a larger truncation.

### L1 protein in hippocampal neurons is transported into axons in L1CD mice

It has been shown that the transportation of L1 from the cell body to the neurites is inhibited by mutating the extracellular domain of L1 (C264Y), leading to L1 being concentrated in the cell body (Runker et al., 2003). It has also been shown in DRG neurons that disruption of the tyrosine based sorting motif prevented transport of L1 into neurites (Kamiguchi and Lemmon, 1998), while similar mutations in Ng-CAM had less of an effect in hippocampal neurons (Sampo et al., 2003; Wisco et al., 2003; Yap et al., 2008). To determine whether the L1CD is necessary for transport of L1 from the cell body into axons, we examined cultured hippocampal neurons and assessed the distribution of L1 in axons. After 3 days in culture, axons and dendrites were distinguishable based on morphological and immunohistochemical criteria on laminin substrates (Dotti et al., 1987). An axon was observed in cultured hippocampal neurons from all three L1cam mutant mice and L1 was observed all the way to the growth cone of the longest neurites, similar to  $L1^{WT}$  mice (Fig. 2A). Additionally, the intensity of L1 immunoreactivity in L1CD mice was comparable to  $L1^{WT}$  mice (Fig. 2D, G, J). Interestingly, the  $L1^{1152}$  mutant actually has higher expression in the axon than  $L1^{WT}$  under these conditions (Fig. 2M, N), in contrast to the situation in the adult brain (see below). These results showed that L1CD mutant mice can express L1 protein similar to  $L1^{WT}$  mice and that the L1CD is not essential for the transportation of L1 from the cell body to the axon.

### The L1CD is important for L1-mediated neurite extension and branching

The L1CD has been implicated in neurite extension and branching, which could be important for pathfinding of axons during brain formation (Buhusi et al., 2008; Kamiguchi and Lemmon, 2000b; Wiencken-Barger et al., 2004). To examine the role of L1CD in neurite outgrowth, hippocampal neuronal morphology was examined. These cultures were grown on laminin for 3 days. (Fig. 3A-D). We focused on four categories (longest neurite length, neurite total length, number of branches from neurites and number of neurites extending from the soma) to characterize neuronal morphology. The methods used to automatically trace and analysis neuronal morphology using High Content Analysis methodologies have the advantage providing large numbers of cells and no investigator bias. But they also have some limitations in that staining with axonal markers, such as anti-Tau, are not possible because the software can not connect the Tau staining to the somas in a reliable way. As a result we can not make strong statements about branching of axons versus dendrites. Nonetheless, if the morphological criteria of Dotti and Banker regarding E18 rat hippocampal neurons (Dotti et al., 1987) can be applied to our slightly older (P3) mouse hippocampal neurons, it is likely the large differences in branching are in axons and not dendrites.

The longest neurite length and number of neurites extending from the soma were not perturbed in L1CD mutant mice, but the number of branches was reduced (~20%) in  $L1^{1152}$  mice. This particular result was not anticipated, but M. Grumet and associates have previously reported that antibodies to Ng-CAM, the chick homologue of L1, can perturb growth on laminin (Grumet et al., 1993), and it is well established that L1 interacts with

integrins (Montgomery et al., 1996), so this may account for this observation. Neurite outgrowth was significantly greater on L1-Fc substrates compared to laminin (Fig. 3). The length of the longest neurite was increased in neurons from all three L1CD mutant mice on L1-Fc substrate, which shows the cytoplasmic region of L1 is not essential for neurite extension on L1 substrates. Interestingly, the number of branches in L1<sup>1152</sup> neurons was not enhanced on L1-Fc substrate compared to laminin. However, L1<sup>Y1176A</sup> and L1<sup>1180</sup> neurons showed an increase in the number of branches on an L1 substrate compared to laminin, similar to L1<sup>WT</sup>. These data indicate that the juxtamembrane ERM binding site (Cheng et al., 2005a) has an important role in L1 dependent neurite branching but the ERM binding site involving the YRSL region is not (Dickson et al., 2002). The data from the L1<sup>1180</sup> and L1<sup>1152</sup> hippocampal neurons is similar to that reported using overexpression approaches in cerebellar granule cells (Cheng et al., 2005a) and do not support L1-ankyrin playing an essential role in axonal extension or branching as has been previously suggested (Kamiguchi and Lemmon, 2000b; Nishimura et al., 2003).

### L1CD mutant mice have normal morphology and histology

All three lines of L1CD mutant mice were born in nearly Mendelian ratios of 1:3 (percentage of L1<sup>mut/Y</sup> mice was 29% for L1<sup>Y1176A</sup>, 24% for L1<sup>1180</sup>, and 22% for L1<sup>1152</sup>) demonstrating normal survival, while L1<sup>KO</sup> was only 9%. L1CD mutant mice did not show any of the prominent features observed in L1<sup>KO</sup> mice, such as a domed head. The average body weight of 8-week-old L1<sup>Y1176A</sup> mice ( $26.2 \pm 0.8$  g;  $n = 8$ ), L1<sup>1180</sup> mice ( $26.0 \pm 1.1$  g;  $n = 6$ ) and L1<sup>1152</sup> mice ( $28.7 \pm 1.0$  g;  $n = 5$ ) were not significantly different when compared with L1<sup>WT</sup> mice ( $25.7 \pm 1.1$  g;  $n = 6$ ).

L1<sup>KO</sup> mice show gross abnormalities including hydrocephalus, smaller hippocampus and cerebellum, corpus callosum hypoplasia, hyper fasciculation, and pyramidal tract abnormalities (Cohen et al., 1998; Dahme et al., 1997; Demyanenko et al., 2001; Fransen et al., 1997; Ohyama et al., 2004; Rolf et al., 2001; Wiencken-Barger et al., 2004). To investigate whether the L1CD contributes to the defects observed in the L1<sup>KO</sup> mice, we examined the morphology and histology of the brains of L1<sup>Y1176A</sup>, L1<sup>1180</sup> and L1<sup>1152</sup> mice. Because genetic background is a critical issue for brain development of L1<sup>KO</sup> mice (Dahme et al., 1997), we focused on the genetic background with the most severe phenotype, C57BL/6J.

Morphologically, these three types of mutant mice showed no hydrocephalus (Fig. 4B-D); the number of mice having hydrocephalus: L1<sup>WT</sup> 0 / 10, L1<sup>Y1176A</sup> 0 / 9, L1<sup>1180</sup> 0 / 9, L1<sup>1152</sup> 0 / 9, L1<sup>KO</sup> 5 / 5). In addition, no morphological abnormalities of the cerebellar lobes (Fig. 4G-I) or hippocampus (Fig. 4M-O) were observed, even though L1<sup>KO</sup> mice show obvious abnormalities in these brain regions (4E, J, P). It has also been shown that L1<sup>KO</sup> mice sometimes have corpus callosum hypoplasia (Demyanenko et al., 2001). In contrast, these three L1CD mutant mice have corpus callosum with similar cross-sectional areas as L1<sup>WT</sup> mice (L1<sup>WT</sup> =  $0.91 \pm 0.094$ , L1<sup>Y1176A</sup> =  $0.92 \pm 0.070$ , L1<sup>1180</sup> =  $0.85 \pm 0.070$ , L1<sup>1152</sup> =  $0.86 \pm 0.052$  mm<sup>2</sup>,  $n = 3$ ,  $p > 0.1$ ).

It has previously been shown that L1<sup>KO</sup> mice have hyperfasciculated axons in the internal capsule (Ohyama et al., 2004; Wiencken-Barger et al., 2004). None of the three L1CD mutant mice showed hyperfasciculated axons, although all of the L1<sup>KO</sup> mice we examined showed hyperfasciculated axons instead of many small axon bundles characteristic of wild type animals. (Fig. 5A-E). Preliminary studies did not detect decreased sizes of the thalamus in the L1CD mice (data not shown).

Corticospinal tract (CST) axons of L1<sup>KO</sup> mice often display pathfinding errors at the pyramidal decussation, and the cross-sectional area of the corticospinal tract is significantly

decreased (Cohen et al., 1998; Dahme et al., 1997). To evaluate whether similar abnormalities occurred in L1CD mice, we determined the area of the corticospinal tract at the caudal end of the medulla (Fig. 5F-J). The area was almost identical between L1<sup>WT</sup> and L1CD mice, although L1<sup>KO</sup> mice showed a significantly smaller area (Fig. 5O). The corticospinal tract was anterogradely labeled by biotinylated dextran amine (BDA) from a unilateral injection in the motor cortex. The labeled axons in the CST were observed coursing contralaterally in the ventral region in the pyramidal decussation area, with no axons going into the ipsilateral CST (Fig. 5K-N), indicating that the pyramidal decussation occurred normally in all L1CD mutant mice, even though L1<sup>KO</sup> mice showed path finding errors (Cohen et al., 1998; Dahme et al., 1997; Itoh et al., 2004).

These data show that common and easily identifiable abnormalities observed in L1<sup>KO</sup> mice were not found in mice with L1CD mutations.

### Normal spatial memory

It has previously been reported that the L1<sup>KO</sup> mice have defects in spatial learning and memory as assessed with the Morris water maze (Fransen et al., 1998). To examine spatial learning and memory, we performed the radial-arm water maze test (Alamed et al., 2006). The average time to reach the platform was not different between L1CD mutant mice and L1<sup>WT</sup> (Fig. 6A). To exclude the possibility that the mouse found the platform by randomly swimming around, we counted how many times a mouse entered the wrong arm. We found no significant difference in the number of errors between L1CD mutant lines and L1<sup>WT</sup> mice (Fig. 6B). These data indicate that the L1CD is not essential for spatial learning and memory. It was noted that the L1CD mutant mice, especially the 1152 mutants actually had “better performance” on the radial-arm water maze, in terms of having shorter times to swim to the platform, although this was not statistically significant. Observations from the tests indicate the shorter latency was likely due to less time spent floating in the water before starting to swim to the platform. It is possible this is due to some difference in anxiety levels in the L1CD mice (Venero et al., 2004).

### Truncations of the L1CD lead to impaired motor function

It has been shown that L1<sup>KO</sup> mice fall easily from an immobile rod because of difficulties in keeping their balance (Fransen et al., 1998), however we found that L1CD mutant mice can stay on an immobile rod without falling. To further examine motor function and coordination of L1CD mutant mice, we performed the accelerated rotarod test to examine their ability to remain on a rotating platform (Pratte et al., 2003). There was no significant difference between the times of L1<sup>Y1176A</sup> and L1<sup>WT</sup> mice, however the L1<sup>1180</sup> and L1<sup>1152</sup> mice performed worse (Fig. 7). The difference in performance of the WT mice used in different experimental series (compare 7B to 7A or 7C is due to different ages of the WT and aged matched L1CD mice: A: 2 months, B: 7-8 months, C: 2-4 months). This data indicates the c-terminal region of the L1CD, including the ankyrin-binding region, is important in motor function in the adult mouse.

### L1CD mutant mice have normal unmyelinated and myelinated axons

Although the cerebellum is a region of the brain that plays an important role in motor control, all L1CD mutant mice, including L1<sup>1152</sup>, did not show detectable abnormalities in cerebellum formation (Fig. 4). The development of myelinated and unmyelinated axons in the PNS is also important for motor function. To examine this we used light and electron microscopic techniques. In the sciatic nerve of L1<sup>WT</sup> mice, Schwann cells ensheath individual axons compactly within separate cytoplasmic processes (Fig. 8A). In L1CD mutant mice (Fig. 8B-D), these axons were also compactly ensheathed, similar to L1<sup>WT</sup> mice (Fig. 8A). This is in contrast to L1<sup>KO</sup> mice (Fig. 8E) and mice lacking the L1<sup>6th Ig</sup>

domain (L1-6D mice), where there are many unmyelinated axons not properly ensheathed by Schwann cell processes (Dahme et al., 1997; Haney et al., 1999; Itoh et al., 2005). To quantify this, we categorized ensheathment into three types; not ensheathed, partially ensheathed and completely ensheathed (Fig. 8F-G). In L1CD mutant mice, the Schwann cell processes wrap each axon similar to L1<sup>WT</sup> mice, in contrast to L1<sup>KO</sup> mice (Fig. 8H).

Next, we examined the ultrastructure of myelinated axons. Myelin membranes were tightly packed and the periaxonal space was appropriately maintained in L1CD mice (Fig. 8A). We analyzed the myelinated axons in the entire cross-sectional area of nerves from four L1<sup>WT</sup> mice and from four of each L1CD mutant mice; about 2500 axons per animal were measured. The g-ratio is the accepted measurement for the thickness of myelin sheaths. The average g-ratio was not significantly different between L1<sup>WT</sup> and L1CD mutant mice (Fig. 8I). The population distribution of g-ratios did not show significant differences between L1<sup>WT</sup> and L1CD mutant mice (Fig. 8J-L), although the g-ratio of L1<sup>KO</sup> mice (Fig. 8M) was significantly larger than L1<sup>WT</sup> ( $P < 0.005$ ), indicating that myelin is thinner in L1<sup>KO</sup> mice than L1<sup>WT</sup> mice. These results show that the development of unmyelinated and myelinated PNS axons is normal in L1CD mutant mice.

### L1 protein expression decreases with age in L1CD mutant mice

We did not detect any gross morphological or histological abnormalities in the CNS and PNS, although L1<sup>1180</sup> and L1<sup>1152</sup> mice exhibited defects in motor function, possibly due to the fact that these two mutant lines do not have Ank2 binding sites. It has been demonstrated that Ank2 binding mediates stationary behavior of L1 (Garver et al., 1997; Gil et al., 2003; Scotland et al., 1998). Although all of the L1CD mutant lines express L1 protein in axons of young hippocampal neurons *in vitro*, we examined the localization of L1 in the brains of mutant mice at postnatal day 7 (P7) and in 7-week-old mice. At P7, there is no obvious difference in the localization of L1 between L1<sup>WT</sup> and L1CD mutant mice using L1 $\alpha$  antibody (Fig. 9A-D). Of particular note, there is no accumulation of L1 in cell bodies of the sort observed in C264Y (Runker et al., 2003), which confirms that the L1CD lines with these particular mutations/truncations can be transported from the cell body to the axon. However, the quantitative data for the expression level of L1 protein at P7 showed that the amount of L1 protein present in the brain was reduced by about 50% in L1<sup>1180</sup> and L1<sup>1152</sup> mice compared to L1<sup>WT</sup> (Fig. 9E-F). The reduction of L1 protein was much more prominent in 7-week-old mice with L1CD truncations. L1<sup>WT</sup> mice and L1<sup>Y1176A</sup> mutant mice had prominent and similarly distributed L1 immunoreactivity in the hippocampus and in the molecular layer of the cerebellar cortex. In contrast, L1<sup>1180</sup> and L1<sup>1152</sup> mice showed faint or no L1 immunoreactivity. Other regions where L1 expression is high in the adult, including the stria terminalis, fimbria and hypothalamus (Munakata et al., 2003) also showed only faint or no L1 immunoreactivity (data not shown). Furthermore, western blot analysis also demonstrated a significant reduction in the level of L1 protein in L1<sup>1180</sup> and L1<sup>1152</sup> mice (Fig. 9-O-P), whereas there was no significant difference in the expression level of L1 mRNA (Fig. 9Q). These data suggest that the L1CD, C-terminal to the RSLE mini exon, is required for the persistent expression of L1 protein after early developmental stages.

### Discussion

These three L1cam mutant mice lines are novel models for studying the highly conserved L1CD (Hortsch, 1996). A variety of cell biological, biochemical and molecular experiments have shown that the L1CD has important binding partners involved in signaling, trafficking and cytoskeletal interactions (Kamiguchi and Lemmon, 2000a; Maness and Schachner, 2007). Mutations in the L1CD cause a form of mental retardation, although not as devastating as mutations in the L1 extracellular domain (L1ED) (Yamasaki et al., 1997). Therefore, it is remarkable that after examining a wide range of features of the CNS and

PNS in the L1CD mice, we conclude that the L1CD is not responsible for the large anatomical defects observed in the L1<sup>KO</sup> mice. However, the L1CD is essential for the persistent expression of L1 protein and for some aspect of motor coordination.

Several binding partners for the L1CD have been found, including AP-2, ERM, RanBPM and Ank2. The interaction with AP-2 enables L1 endocytosis via clathrin-coated pits, and also it is involved in axonal sorting (Kamiguchi and Lemmon, 1998; Kamiguchi et al., 1998b; Wisco et al., 2003). Based on these in vitro experiments, it seemed likely that L1 transportation from the cell body to the axon might be disturbed, but the data from our in vitro and vivo analysis showed that the distribution of L1 in the brain appears normal at P7, even if the L1CD was almost entirely missing. Winckler and associates have published a series of in vitro studies on the sorting of the chicken homologue of L1, called Ng-CAM, into somatodendritic and axonal compartments in neurons (Wisco et al., 2003; Yap et al., 2008). They have found that the tyrosine based signal is important for retrieval of Ng-CAM from the somatodendritic compartment prior to transport into the axon but that direct trafficking to the axon is also possible using a signal in the L1ED (Wisco et al., 2003). Sampo et al. have come to similar conclusions (Sampo et al., 2003). While the extracellular domains of L1 and NgCAM are substantially different, the present studies also show that L1 sorting into the axon does not require the L1CD.

Humans with extracellular domain mutations or truncations usually have defects in the development of the corticospinal tract (Halliday et al., 1986). Similarly, L1<sup>KO</sup> mice often have corticospinal tract defects, including abnormal decussation (Cohen et al., 1998). This abnormal pathfinding is attributed to a loss of L1-neuropilin-1 interactions that mediate Semaphorin 3A signaling (Castellani, 2002; Castellani et al., 2000; Castellani et al., 2002). It is well established that L1 and neuropilin-1 bind to each other via their extracellular domains (Castellani et al., 2000; Castellani et al., 2002). Recently, it has been reported that L1-ERM interactions can both mediate L1/neuropilin-1 internalization and Semaphorin 3A induced growth cone collapse (Mintz et al., 2008). However, it is clear that the L1<sup>Y1176A</sup> and the L1<sup>1152</sup> mice do not depend on L1-ERM or L1-AP-2 interactions to correctly send axons along the corticospinal tract. This would argue that the L1 dependant Semaphorin 3A response that subserves decussation of the corticospinal tract is not dependent on AP-2 or ERM mediated internalization of L1/neuropilin-1 complexes.

Perhaps the most important finding in the present work is that the persistent expression of L1 protein is not required for the maintenance of normal brain morphology or cytoarchitecture or learning and memory as assessed by the radial-arm water maze. The amount of L1 protein decreases to barely detectable levels in adult mice lacking the C-terminal portion of the L1CD (L1<sup>1152</sup> or L1<sup>1180</sup> mutant mice) and is even reduced by approximately 50% at P7. There is no doubt that L1 is essential for axonal growth and pathfinding as well as proper brain formation, because the L1<sup>KO</sup> mice show a variety of morphological abnormalities (Cohen et al., 1998; Dahme et al., 1997; Fransen et al., 1998; Ohshima et al., 2004; Rolf et al., 2001; Wiencken-Barger et al., 2004). Although there is some variation depending on brain region, L1 is expressed at relatively high levels during development and L1 expression decreases somewhat (on average by perhaps 50%) in the adult (Liljelund et al., 1994). The continued expression of L1 in brain regions with substantial neuronal plasticity (hippocampus and cerebellum, for example), would seem to argue for an important role for L1 in adult. Indeed L1 has been implicated in some models of learning (Fransen et al., 1998; Law et al., 2003; Venero et al., 2004; Wolfer et al., 1998), and in synapse formation (Godenschwege et al., 2006; Triana-Baltzer et al., 2008). The data from the L1<sup>1152</sup> and L1<sup>1180</sup> mice allow us to disassociate the effects of loss of L1 function in development from loss of function in the adult. In the adult, after brain formation is complete, if L1 is then lost, it is difficult to find effects on brain morphology,

cytoarchitecture, axonal pathfinding or learning and memory. The only significant alteration we observed was in motor function.

In humans, mutations of the L1CAM gene usually cause spastic paraplegia and adducted thumbs. Adducted thumbs are typically present at birth and might be due to failure of innervation of the adductors in the forearm (Holtzman et al., 1976; Kanemura et al., 2006). Macias et al. found the human mutation (S1181X) that causes the truncation of L1 protein, similar to our L1<sup>1180</sup> mice (Macias et al., 1992; Weller and Gartner, 2001). This human mutation did not cause hydrocephalus or corpus callosum hypoplasia, but it did cause spastic paraplegia and adducted thumbs. Kanemura et al. reported a MASA syndrome case with a truncation at R1166X in exon 27 that is similar to our L1-1552 mouse line. The individual had shuffling gait and adducted thumbs but MRI revealed the brain was relatively normal, in particular no abnormalities in the brainstem or cerebellum were noted (Kanemura et al., 2005). These defects in motor function in humans with truncations in the L1CD could result from similar failures as those observed in our two truncated L1CD mutant mice, so it is plausible that stable expression of L1 in the adult is essential for normal function of the motor system. The root cause of the abnormal motor function in the L1<sup>1180</sup> and L1<sup>1152</sup> mutant mice is not apparent. One possible site of action could be the synapse. Perhaps some aspect of CNS circuitry in the motor system is abnormal but undetected with the methods we used in our survey of brain formation. Alternatively, the site of action could be in the PNS at the neuromuscular junction. It has been shown that L1 is present presynaptically and disruption of L1 function alters neuromuscular junction formation (Triana-Baltzer et al., 2006).

Which region of the L1CD determines the stability of L1 protein in the adult? The decrease of L1 protein was observed only in L1<sup>1180</sup> and L1<sup>1152</sup> mice but not in L1<sup>Y1176A</sup> mutant mice. The two affected mutant lines both lack the region C-terminal to residue 1180, therefore missing the Ank2 and RanBPM binding sites (Cheng et al., 2005b; Davis and Bennett, 1994; Whittard et al., 2006). It has been suggested that L1-ERM interactions predominate early in development but that L1-ankyrin interactions dominate at later developmental stages and in the adult (Hortsch et al., 2009; Mintz et al., 2003). Interestingly, in the Ank2 knock-out mice, L1 expression is dramatically affected, with almost a complete loss of L1 in brain sections and the optic nerve at P7 (Scotland et al., 1998). Recently, Buhusi et al. described a mouse line with a point mutation in the L1CD (Y1229H) that disrupts L1-Ank2 interactions (Buhusi et al., 2008). They reported that L1 was expressed at normal levels in the P0 and P3 brain, but the levels in the adult brain were not reported. No abnormalities in brain morphology were noted but a subtle defect in targeting of some retinal axons to the tectum was reported in P10-12 mice. Taken together, it is likely that the loss of L1-Ank2 interactions accounts for the loss of L1 expression in the adult in our mice.

Although our previous data showed that L1 mediated neurite branching was regulated by two ERM binding sites, the mutation of the juxtamembrane ERM site showed the strongest effect on neurite branching (Cheng et al., 2005a). This paper shows that L1 mediated neurite branching is strongly decreased in L1<sup>1152</sup> mice, but not in L1<sup>Y1176A</sup> or L1<sup>1180</sup> mice. These data suggest that the juxtamembrane ERM-binding site is essential for L1 mediated neurite branching, although we did not observe axon branching or CST guidance abnormalities in vivo.

The highly conserved nature of the L1CD (it is completely conserved in mammals at the amino acid level) is prima facie evidence that it plays an essential role in L1cam function. The fact that so many obvious defects present in the L1KO mice were absent in the L1CD mice indicates that there are likely to be some compensatory mechanisms that ameliorate the

affects that might be expected, especially in signaling and axon guidance. One possibility is that other L1 family members are serving a compensatory role. Neurofascin, Nr-CAM and CHL1 all have cytoplasmic domains that are highly homologous to the L1CD (Hortsch, 2000). They all have the RSLE mini-exon, ankyrin binding regions and a highly conserved juxtamembrane region. An argument in favor of this is the fact that both the L1 and NrCAM knockouts have mild effects on the cerebellum but the double knockout has a very severe effect on cerebellar development (Sakurai et al., 2001) and the double knockouts are much smaller and show lower survival rates than the single knockouts. Alternatively (or perhaps in addition to other L1cam family members), signaling via the EGF or FGF receptors (Chen et al., 2001; Islam et al., 2004; Kulahin et al., 2008), TAG-1 family members (Felsenfeld et al., 1994; Pavlou et al., 2002), or neuropilin (Castellani et al., 2002) could compensate for some loss of signaling via the L1CD

In summary, although the L1 cytoplasmic domain is very highly conserved over evolution, the loss of the L1 cytoplasmic domain appears to have only minor effects on altering brain structure and function in mice. This is in stark contrast to the role of the L1 extracellular domain, which is essential for a variety of critical processes in brain development.

## Acknowledgments

This work was supported by the National Institute of Health (HD39884), the Miami Project to Cure Paralysis and the RIKEN Brain Science Institute.

We thank S. O'Gorman for helping to make the L1CD mutant mice and H. Kamiguchi for discussions. We also thank F. Rathjen and M. N. Rasband for supplying antibodies. V. Lemmon holds the Walter G. Ross Distinguished Chair in Developmental Neuroscience at the University of Miami.

**Figure 1. Production of L1CD mutant mice**

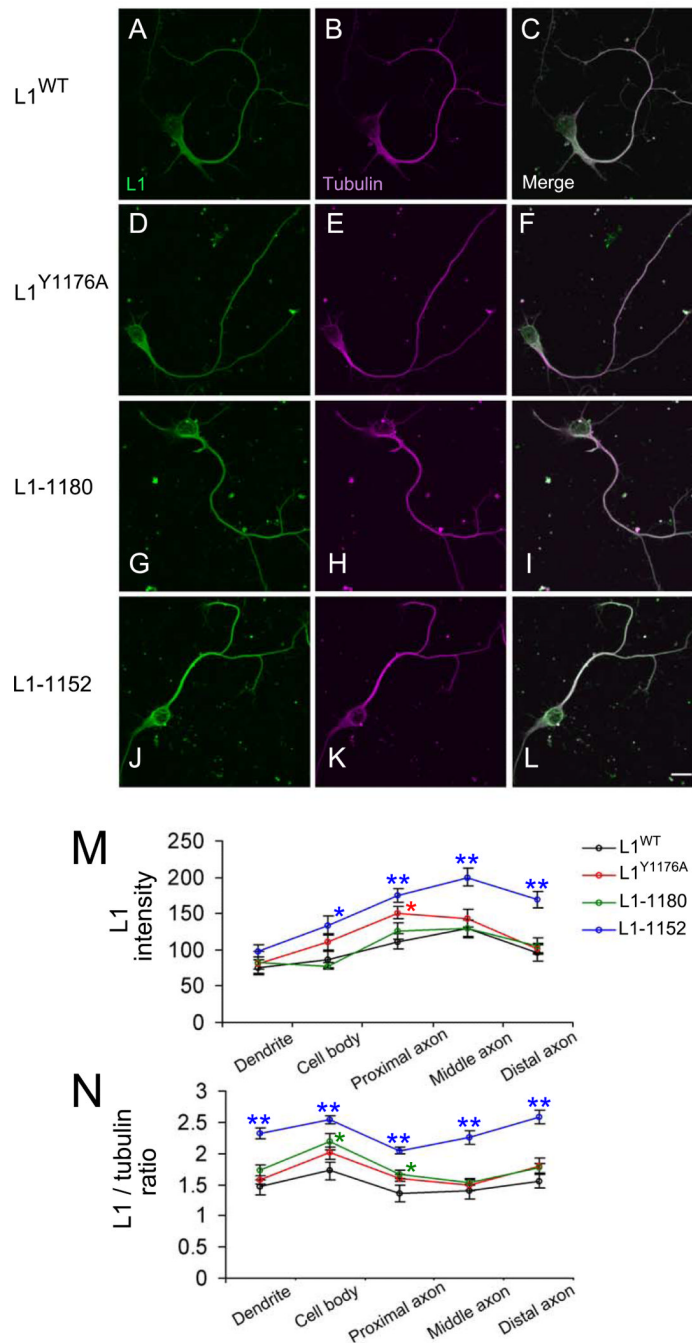

(A) Schematic model of the strategy used to mutate the L1cam gene. The bold line indicates the wild type allele, and the corresponding fragment of the targeting vector is depicted in the white box. (X) in “3’-bit” fragment indicates mutated region. A loxP-neomycin cassette was inserted with reverse orientation into the *Bgl* I site located between exon 26 and exon 27 for positive selection. Probes L and R were prepared for confirmation of 5’ -and 3’ – recombination. *Xba* I digestion gives a 9.7 kb wild type fragment while the mutant allele gives a 5.6 kb 5’ fragment and a 5.9 kb 3’ fragment. Primers for genotyping PCR were designed to amplify a 409 bp wild type fragment and a 494 bp mutant fragment. Cre-

recombinase regulated by the protamine promoter is carried by ES cells and removes the loxP-Neo cassette once it is integrated into the chimera sperm (germ line).

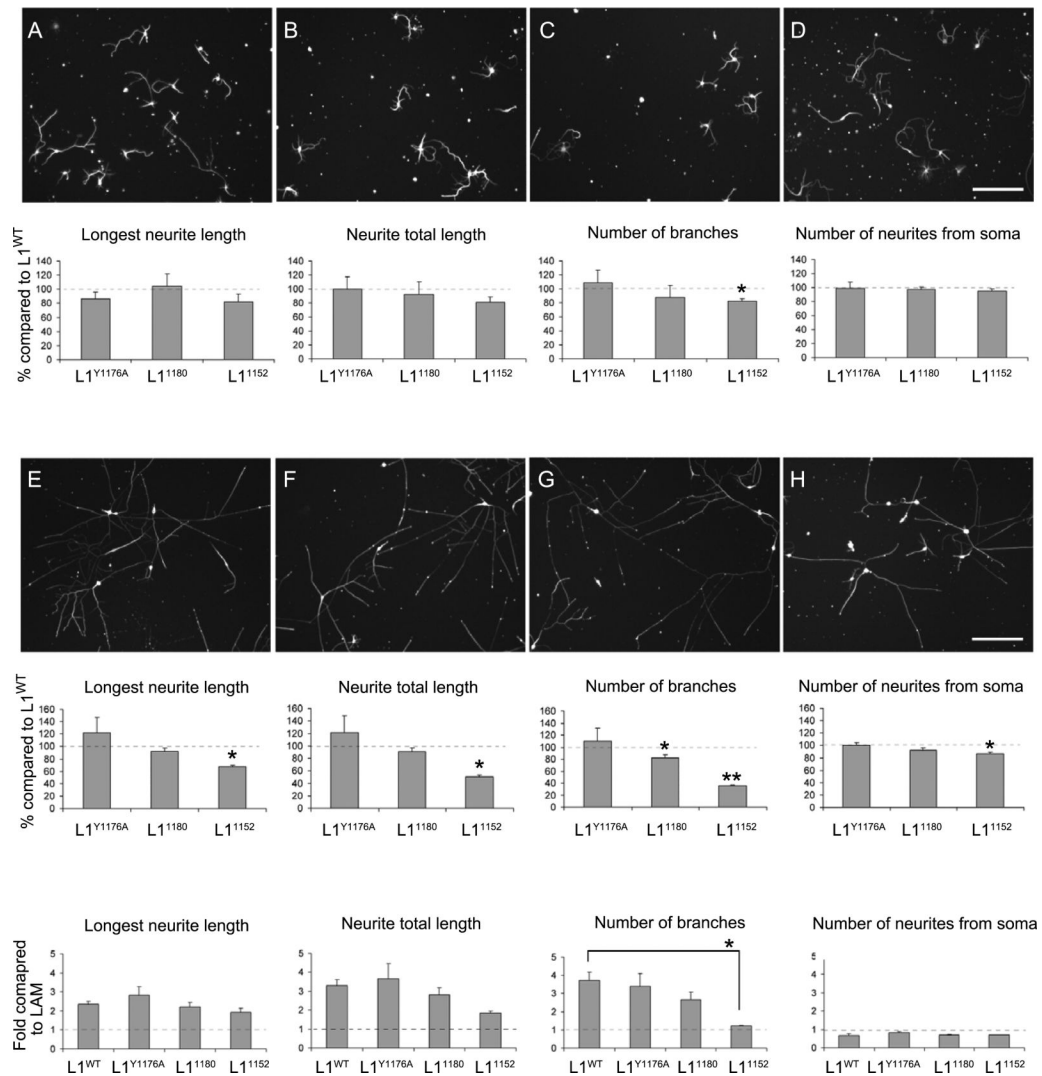

(B) Schematic representation of L1cam in the L1CD mutant mice. The amino acid numbers correspond to their position in the L1CD of L1<sup>WT</sup> (aa 1144-1257). The juxtamembrane region, the ERM binding site, ankyrin binding site and AP-2 binding site are highlighted.

The numbers of the key residues are indicated on top of the corresponding residue. The L1<sup>Y1176A</sup> mice have a single amino acid substitution. The L1<sup>1152</sup> mice have a truncation after the S1152 residue. The L1<sup>1180</sup> mice have truncation after the E1180 residue.

(C) Western blot analysis from whole brain after immunoprecipitation using L1ex antibody. Three different antibodies were used for characterization of L1<sup>WT</sup>, L1<sup>Y1176A</sup>, L1<sup>1180</sup> and L1<sup>1152</sup> mice. L1total polyclonal antibody recognizes L1 extracellular and intracellular regions, L1CD polyclonal antibody recognizes the cytoplasmic region of L1, and FIGQY monoclonal antibody recognizes the FIGQY region in the ankyrin binding site.

**Figure 2. Normal L1 protein expression in hippocampal neurons from L1CD mutant mice**  
 A-L: Hippocampal culture on laminin substrate at 3 days in vitro. These neurons are stained by anti-L1 total antibody (A, D, G, J) and anti-B3 tubulin antibody (B, E, H, K). A-C: WT; D-E: L1<sup>Y1176A</sup>; G-H: L1<sup>1180</sup>; J-L: L1<sup>1152</sup>. The merged images are shown in C, F, I, L. M shows that the intensity of L1 several regions (dendrite, cell body, proximal axon, middle axon and distal axon). Fifteen neurons each from the L1CD lines and L1<sup>WT</sup> were analyzed using confocal images. N shows the relative amount of L1 intensity, which is normalized to the tubulin intensity. All L1CD mutant mice could produce and transport L1 protein into axons. \**p* < 0.05, \*\**p* < 0.001. Scale bar = 10  $\mu$ m.

**Figure 3. Neurite branching on L1 substrates is impaired in L1<sup>1152</sup> mutant mice. A & I: WT; B & J: L1<sup>Y1176A</sup>; C & K: L1<sup>1180</sup>; D & L: L1<sup>1152</sup>**

A-D: Hippocampal neuronal culture grown on laminin substrate at 3 Days In Vitro (DIV). Neurons are stained with anti-tubulin. Total neurite length, longest neurite length, number of neurite branches and the number of neurites extending from soma are quantified. The mean values of neurons of L1CD mutant mice are normalized to mean values of neurons of L1<sup>WT</sup> mice. \* $p < 0.05$ . Scale bar = 100  $\mu\text{m}$ .

I-L: Hippocampal neuronal culture grown on L1-Fc substrate at 3 DIV. The number of neurite branches for L1<sup>1152</sup> mutant mice was significantly lower than L1<sup>WT</sup> mice. \* $p < 0.05$ , \*\* $p < 0.001$ . The mean length or number of neurites on L1-Fc substrate was compared with the laminin substrate. Longest neurite length and neurite total length was increased more than two times, whereas number of branches of L1<sup>1152</sup> mice did not increase on the laminin substrate compared to L1<sup>WT</sup> mice. \* $p < 0.05$ .

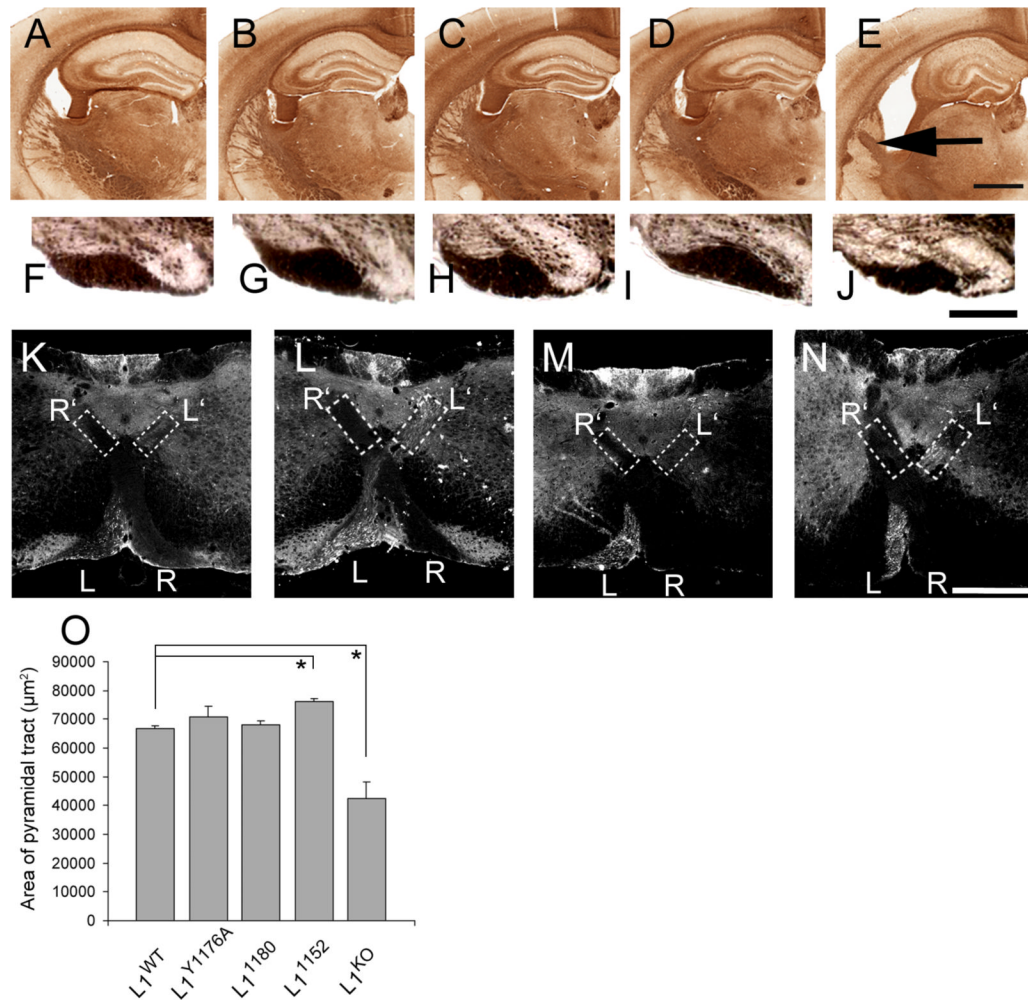

**Figure 4. Lack of gross morphological abnormalities in L1CD mutant mice. A, F, L: WT; B, G, M: L1<sup>Y1176A</sup>; C, H, N: L1<sup>1180</sup>; D, I, O: L1<sup>1152</sup>; E, J, P: L1<sup>KO</sup>**

(A-E) No hydrocephalus in L1CD mutant mice. Coronal section from brains showed that there are no enlarged ventricles in L1CD mice, although L1<sup>KO</sup> mice have enlarged ventricles.  $n = 3$ . Scale bar, 200  $\mu\text{m}$

(F-J) Normal morphology of cerebellar lobe in mid-sagittal sections of brains. The cerebellar lobule shows normal morphology in L1CD mutant mice.  $n=3$ . Scale bar, 1 mm.

(K) Morphometric analysis of cerebellum at the midline of brains. There is no significant difference in the size of the cerebellum of L1CD mutant mice, although the L1<sup>KO</sup> mice cerebella are significantly smaller.  $n = 3$ . \* $p < 0.05$ .

(L-P) Cresyl violet staining for hippocampus region. Formation of hippocampus is normal in L1CD mutant mice compared with L1<sup>WT</sup> mice, although L1<sup>KO</sup> mice have a smaller hippocampus. Scale bar = 500  $\mu\text{m}$

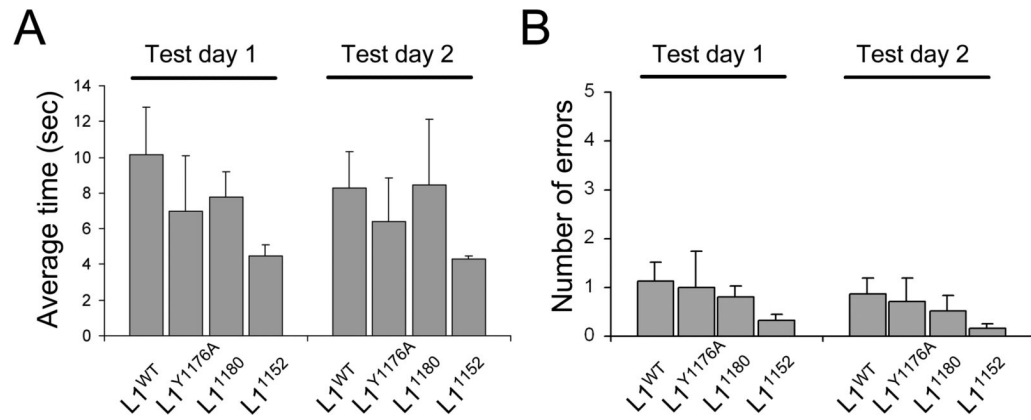

**Figure 5. Normal axonal guidance in L1CD mutant mice.** A, F, K: WT; B, G, L: L1<sup>Y1176A</sup>; C, H, M: L1<sup>1180</sup>; D, I, N: L1<sup>1152</sup>; E, J: L1<sup>KO</sup>. A-E: scale bar = 1 mm, F-J: scale bar = 100 μm. L-O: scale bar = 500 μm

(A-E) Neurofilament staining of brain sections. There is no hyperfasciculation of axons in the internal capsule of L1CD mice, although L1<sup>KO</sup> mice have hyperfasciculated axons (arrowhead). Scale bar, 1 mm.

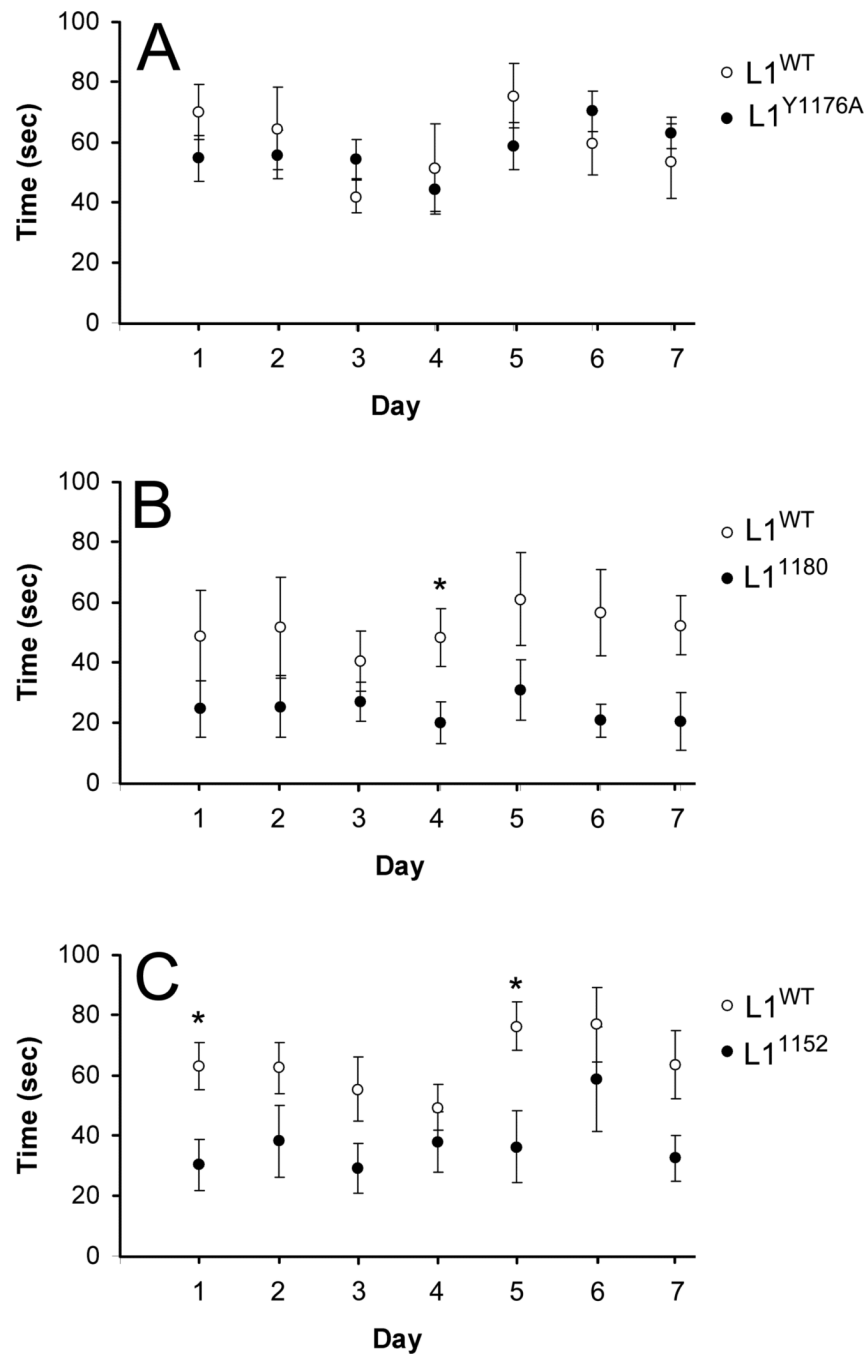

(F-J) Coronal sections in medulla of adult mice. (B-I) The morphology of the pyramidal tract is normal in L1CD mutant mice compared to L1<sup>WT</sup> mice. Scale bar, 300 μm. (O) The size of the pyramidal tract was not significantly different between all L1CD mutant mice and L1<sup>WT</sup> mice, although L1<sup>KO</sup> mice have significantly smaller pyramidal tracts.  $n = 3$ .  $*p < 0.005$ .

(K-N) The pyramidal tract is normal in L1CD mutant mice. BDA was injected into the left side of the motor cortex. At the pyramidal decussation area, the labeled pyramidal tract was observed in the left side of the ventral region (L) and also in the contralateral side of the dorsal region (L') in all L1CD mice and L1<sup>WT</sup> mice. In contrast, the dorsal ipsilateral pyramidal tracts are not labeled. Scale bar, 500 μm.

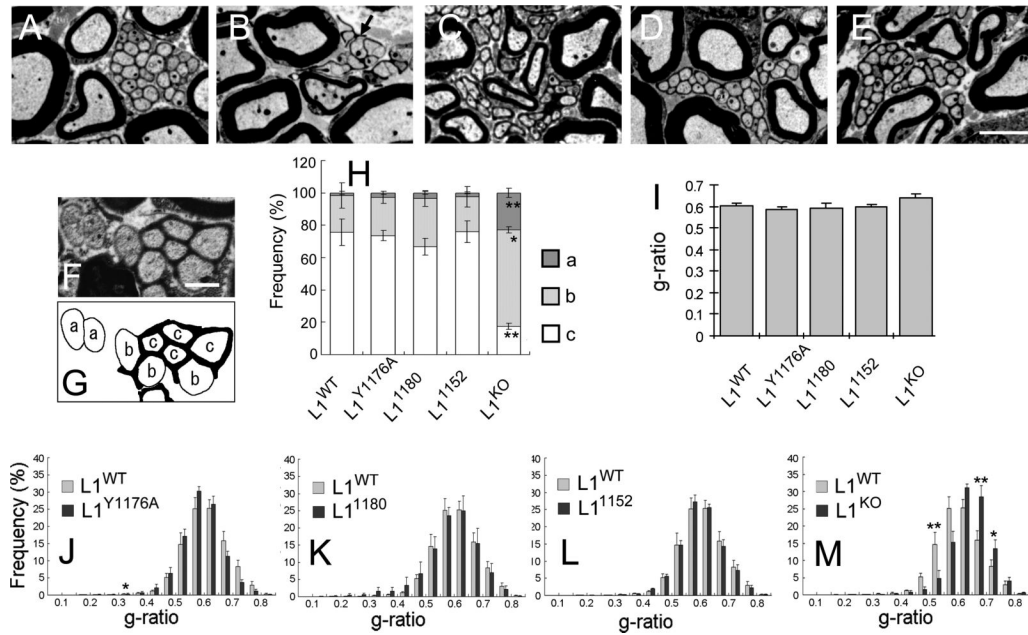

**Figure 6. Normal spatial memory in L1CD mutant mice**

Radial-arm water maze for spatial memory. (A) The average time for finding the platform and (B) the average number of errors were not significantly different between L1CD mutant mice and L1<sup>WT</sup> mice. L1<sup>WT</sup> n = 7, L1<sup>Y1176A</sup> n = 4, L1<sup>1180</sup> n = 7, L1<sup>1152</sup> n = 6

**Figure 7.** Impaired motor function in L1<sup>1180</sup> and L1<sup>1152</sup> mice. The time in balance on the accelerated rotarod was measured using age-matched mice, comparing the L1CD mutant mice and L1<sup>WT</sup> mice. L1<sup>1180</sup> (B) and L1<sup>1152</sup> (C) mutant mice showed a significantly reduced performance compared with L1<sup>WT</sup> mice but the L1<sup>Y1176A</sup> (A) did not. L1<sup>WT</sup> n = 8, L1<sup>Y1176A</sup> n = 7, L1<sup>1180</sup> n = 7, L1<sup>1152</sup> n = 7, \*p < 0.05

### Figure 8. Normal morphology of unmyelinated and myelinated axons

Electron microscopy of sciatic nerves of 8-week-old mice A: L1<sup>WT</sup>, B: L1<sup>KO</sup>, C: L1<sup>Y1176A</sup>, D: L1<sup>1180</sup>, E: L1<sup>1152</sup>. Schwann cells compactly ensheath multiple unmyelinated axons in L1<sup>WT</sup> and in all L1CD mutant mice, although L1<sup>KO</sup> showed abnormal Remak bundles. Myelin membranes were tightly packed around large axons in L1<sup>WT</sup> and in all L1CD mutant mice. Scale bar = 3  $\mu$ m. F-G) Classification scheme of unmyelinated axons depending on the degree of ensheathment.

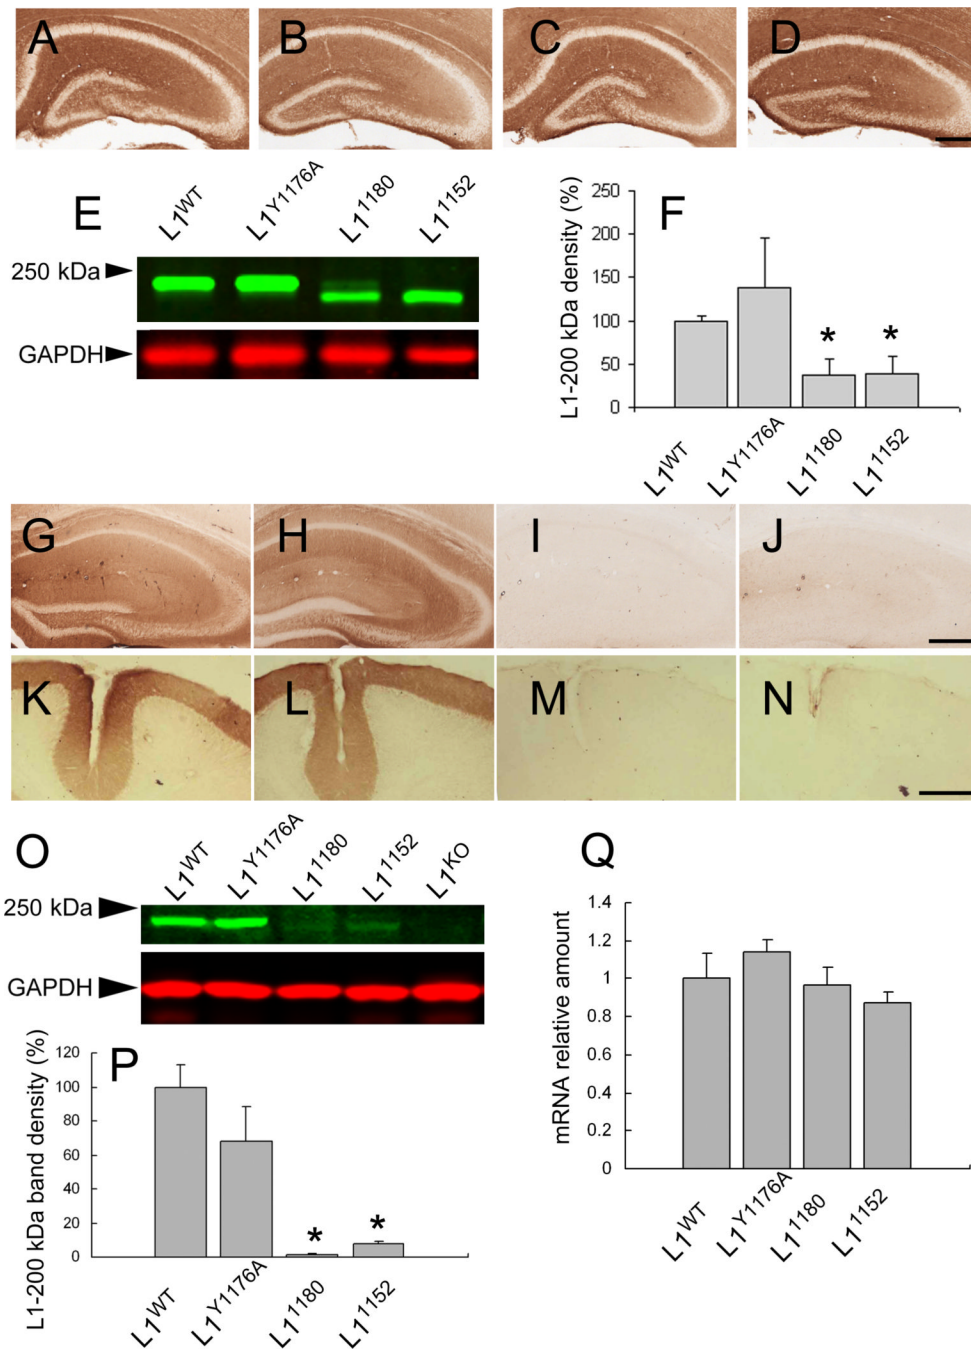

(a) not ensheathed; (b) partially ensheathed; (c) completely ensheathed.

H) The percentage of completely ensheathed unmyelinated axons was almost identical between L1CD mutant mice and L1<sup>WT</sup> mice, while significantly reduced in L1<sup>KO</sup> mice. \*  $p < 0.01$ , \*\*  $p < 0.005$  (B-2).

I) G-ratio averages. There is no significant difference in the average g-ratio of L1CD mice compared to L1<sup>WT</sup> mice.

J-M) Distribution of g-ratios. There is no significant difference in the distribution of g-ratio in L1CD mice compared to L1<sup>WT</sup> mice, although L1<sup>KO</sup> mice have a larger proportion of axons with large g-ratios. \* $p < 0.05$ , \*\* $p < 0.01$

**Figure 9.**

Expression level of L1 mRNA is normal, but L1 protein expression is dramatically reduced in 7-week-old mice with truncations that remove the ankyrin-binding site. L1 protein localization using L1ex antibody in hippocampus in postnatal day 7 mice A: L1<sup>WT</sup>, B: L1<sup>Y1176A</sup>, C: L1<sup>1180</sup>, D: L1<sup>1152</sup>. All L1CD mutant mice show similar distribution of L1 in the hippocampus. Scale bar = 300  $\mu$ m.

E) Western blot analysis of L1 protein in postnatal day 7 mice using L1ex monoclonal antibody. All L1CD mutant mice showed L1 bands, although the band density was a lower in L1<sup>1180</sup> and L1<sup>1152</sup> mice compared to L1<sup>WT</sup> mice. The lower (red) panel shows the

GAPDH loading control. F) shows the relative amount of L1-200 kD band density normalized to GAPDH loading control.  $n=3$ . \* $p<0.05$ .

L1 protein localization using L1ex monoclonal antibody in the hippocampus (G: L1<sup>WT</sup>, H: L1<sup>Y1176A</sup>, I: L1<sup>1180</sup>, J: L1<sup>1152</sup>) and cerebellum (K: L1<sup>WT</sup>, L: L1<sup>Y1176A</sup>, M: L1<sup>1180</sup>, N: L1<sup>1152</sup>) in 7-week-old mice. There was almost no L1 in the hippocampus and cerebellum of L1<sup>1180</sup> and L1<sup>1152</sup> mice, although L1<sup>Y1176A</sup> mice have similar expression patterns to L1<sup>WT</sup> mice. Scale bars = 300  $\mu$ m.

O) Western blot analysis of L1 protein in 7-week-old mice. The L1 band was detected by L1ex antibody in L1CD mice, although there was no band in L1<sup>KO</sup> mice. The band density of L1<sup>1180</sup> and L1<sup>1152</sup> was obviously weaker than L1<sup>WT</sup> and L1<sup>Y1176A</sup> mice. The lower (red) band is the GAPDH loading control. P) shows that the relative amount of L1-200 kD band density which is normalized to the GAPDH loading control. The bands density was significantly lower in L1<sup>1180</sup> and L1<sup>1152</sup> mice compared to L1<sup>WT</sup> mice. L1<sup>WT</sup>  $n = 3$ , L1<sup>Y1176A</sup>  $n = 3$ , L1<sup>1180</sup>  $n = 3$ , L1<sup>1152</sup>  $n = 3$ . \* $p < 0.01$ .

Q) Quantitative analysis of L1 mRNA in 7-week-old mice. The L1 mRNA relative amount, normalized to  $\beta$ -actin, showed no significant difference in L1CD mutant mice compared to L1<sup>WT</sup> mice. L1<sup>WT</sup>  $n = 3$ , L1<sup>Y1176A</sup>  $n = 3$ , L1<sup>1180</sup>  $n = 3$ , L1<sup>1152</sup>  $n = 3$ .

Immunogen	Species	Working dilution
<p>produced in the Lemmon lab to affinity purified Rat L1. Plasma membranes were prepared from P7 rat pups, solubilized in 1% TX-100 and run over a monoclonal anti-L1 column (mab 74-5H7). The rat L1 protein was eluted and used to immunize a rabbit.</p>	Rabbit	1:5000
<p>Recombinant L1CAM cytoplasmic domain expressed in bacteria and purified on nickel column. the C-terminal 114 amino acids of human L1 used are: KRSKGGKYSVKDKEDTQVDSEARPMKDETFGEYRSLSDNEEKAFGSSQPSLNGDIKPLGSDDSLADYGGSVYDVFQFNEEDGSGFIGQYSGKKEKEAAGGNDSSGATSPINPAVALE</p>	Rabbit	1:5000
