Background. We compare the effect of 4 different antiretroviral regimens on limb and visceral fat.

Methods. A5224s was a substudy of A5202, a trial of human immunodeficiency virus type 1 (HIV-1)-infected, treatment-naive subjects randomized to blinded abacavir-lamivudine (ABC-3TC) or tenofovir DF-emtricitabine (TDF-FTC) with open-label efavirenz (EFV) or atazanavir-ritonavir (ATV-r). The primary endpoint was the presence of lipoatrophy ($\geq 10\%$ loss of limb fat) at week 96 by intent-to-treat (ITT) analysis. Secondary endpoints included changes in limb and visceral fat. Statistical tests included linear regression, binomial, two-sample *t* test, and Fisher's exact test.

Results. A5224s enrolled 269 subjects; 85% were male, and 47% were white non-Hispanic. The subjects had a median baseline HIV-1 RNA level of 4.6 log₁₀ copies/mL, a median age of 38 years, a median CD4+ cell count of 233 cells/ μ L, median limb fat of 7.4 kg, median visceral adipose tissue (VAT) of 84.1 cm², and VAT: total adipose tissue (TAT) ratio of 0.31. At week 96, estimated prevalence of lipoatrophy (upper 95% confidence interval [CI]) was 18% (25%) for ABC-3TC and 15% (22%) for TDF-FTC ($P = .70$); this was not significantly less than the hypothesized 15% for both ($P \geq .55$ for both). The secondary as-treated (AT) analysis showed similar results. At week 96, the estimated mean percentage change from baseline in VAT was higher for the ATV-r group than for the EFV group (26.6% vs 12.4%; $P = .090$ in ITT analysis and 30.0% vs 14.5%; $P = .10$ in AT analysis); however, the percentage change in VAT:TAT was similar by ITT and AT analysis ($P \geq .60$ for both). Results were similar for absolute changes in VAT and VAT:TAT.

Conclusions. ABC-3TC- and TDF-FTC-based regimens increased limb and visceral fat at week 96, with a similar prevalence of lipoatrophy. Compared to the EFV group, subjects assigned to ATV-r had a trend towards higher mean percentage increase in VAT.

Clinical Trials Registration. NCT00118898.

Antiretroviral therapy (ART) may be associated with fat wasting (lipoatrophy) and fat accumulation (lipohypertrophy), which are distinct conditions but may coexist. Although lipoatrophy has been linked to nucleoside reverse-transcriptase inhibitor (NRTI)-induced mitochondrial toxicity [1–3], little is known about the cause of lipohypertrophy. Studies of lipohypertrophy have been limited, because few studies have used computed tomography (CT) or magnetic resonance imaging (MRI) scans to discern between

subcutaneous and visceral fat. To date, one study compared fat changes with ritonavir-boosted atazanavir (ATV-r) versus efavirenz (EFV) with tenofovir DF-emtricitabine (TDF-FTC) in ART-naive subjects [4]. In addition, no study has compared body fat changes after initiation of abacavir-lamivudine (ABC-3TC) versus TDF-FTC with ATV-r, a protease inhibitor (PI) with minimal metabolic effects [5, 6], or the nonnucleoside reverse-transcriptase inhibitor (NNRTI) EFV.

METHODS

A5224s was a metabolic substudy of A5202, in which ART-naive subjects ≥ 16 years of age were randomized to blinded ABC-3TC or TDF-FTC with open-labeled ATV-r or EFV. An A5224s coprimary objective assessed prevalence of lipoatrophy ($\geq 10\%$ loss of limb fat from baseline) after ART-initiation with ABC-3TC or TDF-FTC. The second coprimary objective assessing changes in bone density will be reported elsewhere. Secondary objectives compared week 96 changes in limb and visceral fat between ABC-3TC versus TDF-FTC and ATV-r versus EFV. Post hoc endpoints included changes in trunk fat. A5224s exclusion criteria were untreated hypogonadism or thyroid disease, Cushing's syndrome, diabetes mellitus, and the use of growth hormone, anabolic steroids, or glucocorticoids. Study duration was 96 weeks after the last subject was enrolled. Any subject entering A5202 at a site participating in A5224s and meeting substudy criteria was eligible to enroll. Subjects signed an institutional review board-approved written informed consent.

Substudy evaluations included whole-body dual-energy X-ray absorptiometry (DEXA) scans at baseline and weeks 24, 48, 96, 144, and 192 and a single-slice abdomen CT scan at the L4-L5 level at baseline and week 96. Fat distribution was measured by DEXA in anteroposterior view (with use of Hologic or Lunar scanners). Technicians were instructed to use the same machine on the same subject throughout the study. CT was used to quantify visceral adipose tissue (VAT) and total adipose tissue (TAT). DEXAs and CT scans were standardized and centrally read (at Tufts University) by personnel blinded to subjects characteristics.

On 25 February 2008 [7], the Data Safety and Monitoring Board (DSMB) recommended unblinding the study for subjects with screening human immunodeficiency virus type 1 (HIV-1) RNA levels $\geq 100,000$ copies/mL because of excess virological failures associated with ABC-3TC regimens; subjects receiving ABC-3TC were permitted to modify their NRTI regimen [7].

Statistical Analysis

The primary objective was to assess the prevalence of protocol-defined lipoatrophy at week 96 in those assigned to ABC-3TC or TDF-FTC in addition to ATV-r or EFV. A5224s was powered using a factorial design with 125 subjects per NRTI (combined across the ATV-r and EFV arms), 80% power to conclude that

the prevalence of lipoatrophy at week 96 was less than the pre-specified 15%, assuming true prevalence was $\leq 6.5\%$, 20% loss to follow-up, and 1-sided test with a .05 significance level.

Primary analyses used intent-to-treat (ITT) principles based on randomized treatment assignment in which all available data were used and modifications to randomized treatment and missing values were ignored. Secondary as-treated (AT) analyses excluded values after a change in randomized NRTI component (when comparing NRTI components) and PI-NNRTI component (when comparing NNRTI-PI components). Supplemental analyses included assessing changes by ITT at week 48. Comparisons were performed using a factorial analysis approach in which, after assessing for treatment effect modification by the other factor, the NRTI effect was assessed by combining the EFV and ATV-r arms and vice versa. No significant treatment effect modification was observed in any ITT analyses ($P \geq .48$). Missing values were ignored. P values $< .05$ were interpreted as statistically significant. Analyses were performed with SAS, version 9.1.3 (SAS Institute).

Within each component, tests included 1-sample t or binomial tests. Comparisons between components used 2-sample t , Fisher's exact, or log-rank tests (with Kaplan-Meier estimation of survival probabilities), as appropriate. Analyses adjusting for baseline factors and exploring associations with baseline factors used linear regression.

RESULTS

Baseline Characteristics

A5224s enrolled 271 subjects from 37 AIDS Clinical Trials Group (ACTG) sites in the United States and Puerto Rico, with 2 subjects excluded from analysis due to eligibility violation. Enrollment spanned from 5 October 2005 to 7 November 2007; 65 subjects were randomized to ATV-r + ABC-3TC, 65 were randomized to ATV-r + TDF-FTC, 70 were randomized to EFV + ABC-3TC, and 69 were randomized to EFV + TDF-FTC. Baseline characteristics are summarized in Table 1; 85% of the subjects were male, and 47% were white non-Hispanics. The median age of the subjects was 38 years, the median body mass index (BMI) was 24.9 kg/m², median limb fat was 7.4 kg, median trunk fat was 9.4 kg, median VAT was 84.1 cm², median CD4+ cell count was 233 cells/ μ L, and median HIV-1 RNA level was 4.6 log₁₀ copies/mL. Baseline characteristics were balanced across arms. A5224s participants and A5202 subjects who did not participate in the substudy were not significantly different at baseline, except that Hispanics were less likely than other subjects to participate in A5224s (16% vs 24%; $P = .005$).

Subject Disposition

Overall, 66 (25%) of the A5224s subjects prematurely discontinued the substudy, and an additional 4 (1%) died (Figure 1).

Table 1. Baseline Characteristics of Study Subjects by Randomized Arms

Variable	EFV + TDF-FTC (n = 69)	EFV + ABC-3TC (n = 70)	ATV-rtv + TDF-FTC (n = 65)	ATV-rtv + ABC-3TC (n = 65)	Total (n = 269)

NOTE. Data are median value (interquartile range), unless otherwise indicated. ABC, abacavir; ATV-r, atazanavir-ritonavir; BMI, body mass index calculated as the weight in kilograms divided by the square of height in meters; EFV, efavirenz; FTC, emtricitabine; HIV-1, human immunodeficiency virus type 1; TAT, total adipose tissue; TDF, tenofovir DF; VAT, visceral adipose tissue; 3TC, lamivudine.

Reasons for discontinuation were as follows: 27 (10%) were unable to get to the clinic, 16 (6%) were lost to follow-up, 9 (3%) were noncompliant with the study protocol, 7 (3%) withdrew consent, 4 (1%) experienced severe debilitation, and 3 (1%) discontinued the study for other reasons. Seventeen percent of the subjects prematurely discontinued the substudy by week 96. Additionally, 31 (12%) discontinued the study because their ACTG site was defunded; 26 of these 31 subjects had week 96 primary endpoint data available. By study arm, 55% of the ATV-r + ABC-3TC group, 68% of the ATV-r + TDF-FTC group, 57% of the EFV + ABC-3TC group, and 70% of the EFV + TDF-FTC group completed the A5224s protocol. There was no significant difference in time to premature study discontinuation between the NRTI ($P = .13$) or PI-NNRTI components ($P = .86$). The median time from randomization to last visit was 165 weeks. Overall, 147 (55%) of the subjects had no modification to their randomized treatment (30 [46%] in the ATV-r + ABC-3TC group, 48 [74%] in the ATV-r + TDF-FTC group, 24 [34%] in the EFV + ABC-3TC group, and 45 [65%] in the EFV + TDF-FTC group). By Kaplan-Meier estimates, 66% of subjects had no modification by week 96. Overall, 23% of subjects (31 in the EFV group and 31 in the ATV-r group) modified the NRTI and PI-NNRTI components within 7 days of each other, and 10% modified only the NRTI component (22% in the ATV-r + ABC-

3TC group, 0% in ATV-r + TDF-FTC group, 16% in the EFV + ABC-3TC group, and 1% in the EFV + TDF-FTC group). Of the 102 subjects with NRTI modifications, 26 had modifications that occurred at the time of or after DSMB recommendation.

Prevalence of Lipoatrophy at Week 96-Primary Endpoint

Table 2 shows the prevalence of protocol-defined lipoatrophy at week 96 by arm; the overall estimated prevalence was 16.3% (range, 14.3%–18.9%). In factorial analyses combining the ATV-r and EFV groups, within the ABC-3TC arms, prevalence (upper bound of 1-sided 95% confidence interval [CI]) of lipoatrophy was 17.6% (25.0%), which was not significantly less than 15% ($P = .81$). Within the TDF-FTC arms, the prevalence of lipoatrophy was 14.9% (21.5%; $P = .55$). There was no significant difference in the week 96 prevalence of lipoatrophy between NRTI components ($P = .70$) or the PI and NNRTI components ($P = 1.0$). Similar results were seen on sensitivity analyses (with the last observation carried forward and missing data regarded as treatment failure). In post hoc analysis, the week 96 overall prevalence of subjects who lost \geq 20% of limb fat from baseline was 4.9% (95% CI, 2.4%–8.9%), with a range of 0%–8.9% across arms (Table 2) and with no significant differences between NRTI ($P = 1.0$) or PI-NNRTI components ($P = .35$). In post hoc analysis, change in limb fat from baseline to week 24 was an

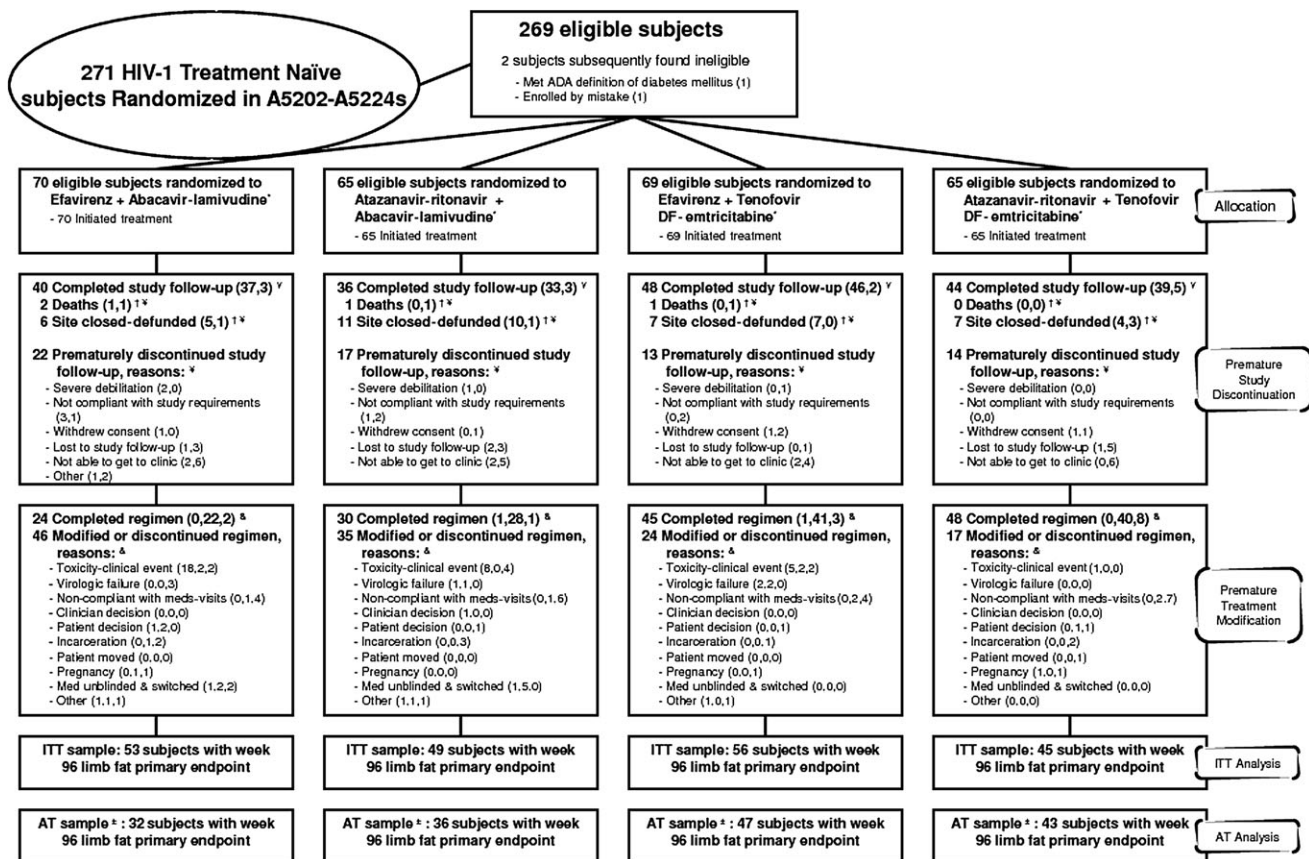

Figure 1. Details of disposition and outcome of study subjects. Subjects were to remain in follow-up regardless of having modified antiretroviral therapy. Nucleoside reverse-transcriptase inhibitors (NRTIs) were double-blinded through 25 February 2008 for those with screening human immunodeficiency virus (HIV) RNA levels of $\geq 100,000$ copies/mL and until final visits starting 1 July 2009 for those with screening HIV RNA levels $< 100,000$ copies/mL. Reasons for study discontinuation are split into no. of subjects with and no. of subjects without week 96 limb fat primary endpoint. Site closure was censored for premature study and treatment discontinuation. Death was censored for premature study discontinuation and counted as the reason for treatment discontinuation if there was no prior modification. Reasons for the first treatment modification are split into no. of subjects before, no. of subjects after, and no. of subjects without week 96 limb fat primary endpoint. Subjects in the as-treated sample continued to receive randomized treatment through the week 96 whole-body dual-energy X-ray absorptiometry.

independent predictor of protocol-defined lipatrophy at week 96 (odds ratio, 0.93; 95% CI, 0.90–0.96; $P < .001$). The odds of week 96 lipatrophy decrease by 7% for every 1% gain in limb fat at week 24.

Changes in Limb Fat (DEXA)-Secondary Endpoint

Table 3 summarizes the estimated changes in limb fat by regimen. Figure 2 plots the changes in limb fat by NRTI and PI-NNRTI components. The estimated mean absolute and percentage limb fat change for all subjects were 1.22 kg and 21%, respectively, at week 48 and were 1.38 kg and 23% at week 96.

Changes by NRTI Components

Limb fat significantly increased in all study arms (Table 3). When combining ATV-r and EFV data, the week 96 analysis (ITT) showed mean absolute and percentage changes in limb fat that were not significantly different between the ABC-3TC (1.66 kg and 24.9%) and TDF-FTC (1.11 kg and 20.9%) groups, a difference

(Δ) of 0.55 kg (95% CI, -0.14 to 1.24 ; $P = .12$) and 4% (95% CI, -6.7% to 14.7% ; $P = .46$). At week 96, AT analysis showed that the ABC-3TC arms had an estimated mean absolute and percentage change in limb fat that was 0.88 kg (95% CI, 0.14 – 1.61 ; $P = .019$) and 9.1% (95% CI, -2.6% to 20.9% ; $P = .13$) larger than the changes in the TDF-FTC arms. At week 48, estimated mean absolute and percentage changes in ABC-3TC arms were not different than those in TDF-FTC arms ($P \geq .30$ for both).

Changes by NNRTI-PI Component

When combining ABC-3TC and TDF-FTC, the week 96 ITT analyses showed estimated mean absolute and percentage change in limb fat that was significantly greater in those assigned to ATV-r (1.88 kg and 30.4%) than in those assigned to EFV (0.96 kg and 16.5%); $\Delta = 0.93$ kg (95% CI, 0.24 – 1.61 ; $P = .008$) and 13.9% (95% CI, 3.3% – 24.5% ; $P = .010$), respectively. AT analyses showed similar results. At 48 weeks, estimated mean absolute and percentage changes in ATV-r arms

Table 2. Estimated Prevalence of Lipoatrophy by Intent-to-Treat Analysis

Variable	EFV + TDF-FTC (n = 56)	EFV + ABC-3TC (n = 53)	ATV-r + TDF-FTC (n = 45)	ATV-r + ABC-3TC (n = 49)	Total (n = 203)
No. of subjects with $\geq 10\%$ limb fat loss	8	10	7	8	33
Prevalence of $\geq 10\%$ limb fat loss (primary analysis), % (95% CI)	14.3 (6.4–26.2)	18.9 (9.4–32.0)	15.6 (6.5–29.5)	16.3 (7.3–29.7)	16.3 (11.5–22.1)
No. of subjects with $\geq 20\%$ limb fat loss	5	2	0	3	10
Prevalence of $\geq 20\%$ limb fat loss (post hoc analysis), % (95% CI)	8.9 (3.0–19.6)	3.8 (0.5–13.0)	0.0 (0.0–7.9)	6.1 (1.3–16.9)	4.9 (2.4–8.9)

NOTE. Loss of lipoatrophy defined as $\geq 10\%$ limb fat and $\geq 20\%$ limb fat from baseline to week 96. ABC, abacavir; ATV/r, atazanavir-ritonavir; CI, confidence interval; EFV, efavirenz; FTC, emtricitabine; TDF, tenofovir DF; 3TC, lamivudine.

(1.46 kg and 25.2%) tended to be larger than those in EFV arms (1.00 kg and 17.3%); $\Delta = 0.46$ kg (95% CI, -0.15 to 1.07 ; $P = .14$) and 7.9% (95% CI, -1.1% to 17.0% ; $P = .086$), respectively.

Changes in Trunk Fat (DEXA)-Post Hoc Endpoint

Table 3 summarizes estimated mean percentage change in trunk fat by study arm. Figure 2 plots estimated changes in trunk fat by study week. The overall estimated mean absolute and percentage change in trunk fat was 1.43 kg and 23.1% at week 48 and 1.83 kg and 28.2% at week 96.

Changes by NRTI Components

Trunk fat increased significantly in all arms. At week 96, by ITT, the mean absolute and percentage changes in trunk fat were not significantly different between the ABC-3TC and TDF-FTC groups; $\Delta = 0.37$ kg (95% CI, -0.58 to 1.32 ; $P = .45$) and 2.2% (95% CI, -11.6% to 15.9% ; $P = .76$), respectively. At week 96, AT analysis showed mean absolute and percentage changes in trunk fat were not significantly different between the ABC-3TC and TDF-FTC groups; $\Delta = 0.96$ kg (95% CI, -0.07 to 1.99 ; $P = .066$) and 8.2% (95% CI, -7.0% to 23.5% ; $P = .29$), respectively. At week 48, estimated mean absolute and percentage changes in the ABC-3TC arms were also not significantly different than in the TDF-FTC arms ($P \geq .34$, by ITT).

Changes by PI-NNRTI Component

At week 96, by ITT analysis, the estimated mean absolute and percentage changes in trunk fat were larger in the ATV-r (2.42 kg; 36.5%) than in the EFV (1.33 kg; 21.1%) study arms; $\Delta = 1.09$ kg (95% CI, 0.15 – 2.03 ; $P = .023$) and 15.4% (95% CI, 1.7% – 29.0% ; $P = .028$). Similar results were seen with AT analyses. However, at week 48, mean absolute and percentage changes in trunk fat in the ATV-r arms were not significantly different than in the EFV arms ($P \geq .27$ for both).

Changes in Visceral Fat by CT Scan-Secondary Endpoint

Table 3 summarizes estimated mean changes in VAT and VAT:TAT ratio by study arm. The overall estimated mean absolute VAT, percentage VAT, and absolute VAT:TAT ratio changes were 10.4 cm², 19.0% , and -0.01 , respectively, at week 96.

Changes by NRTI Components

At week 96, by ITT, estimated absolute and percentage changes in VAT and VAT:TAT ratio were not significantly different between the ABC-3TC and TDF-FTC groups. The ABC-3TC–assigned subjects had an estimated mean difference in VAT absolute change, VAT percentage change, and VAT:TAT ratio change of -2.8 cm² (95% CI, -12.9 to 7.3 ; $P = .58$), -5.1% (95% CI, -21.5% to 11.4% ; $P = .55$), and 0.00 (95% CI, -0.02 to 0.02 ; $P = .94$), compared with the TDF-FTC arms.

Changes by PI-NNRTI Component

At week 96, by ITT, the estimated absolute and percentage changes from baseline in VAT tended to be higher in the ATV-r than in the EFV arms; $\Delta = 7.6$ cm² (95% CI, -2.4 to 17.7 ; $P = .14$) and 14.2% (95% CI, -2.2% to 30.6% ; $P = .090$), respectively. The estimated mean change in VAT:TAT was not significantly different between the ATV-r and EFV arms; $\Delta = 0.00$ (95% CI, -0.02 to 0.02 ; $P = .92$). Similar results were seen with AT analyses. Interestingly, changes in VAT correlated with changes in limb fat ($r = 0.48$; $P < .001$).

Changes in BMI-Post Hoc Endpoint

At week 96, by ITT, there was a trend towards larger gains in mean BMI associated with receipt of ABC-3TC than with receipt of TDF-FTC ($\Delta = 0.63$ kg/m²; 95% CI, -0.12 to 1.38 ; $P = .099$) and statistically significant larger gains in mean BMI associated with receipt of ATV-r than with receipt of EFV ($\Delta = 0.88$ kg/m²; 95% CI, 0.13 – 1.62 ; $P = .022$).

Changes in Limb and Visceral Fat Adjusted for Baseline Covariates

The ITT analyses of prevalence of lipoatrophy and absolute and percentage changes for limb fat, VAT, and VAT:TAT were adjusted for the following baseline covariates that have been associated with body fat changes, first individually, then jointly using linear regression: NNRTI-PI (NRTI for the NNRTI-PI analyses), limb fat (VAT, VAT:TAT ratio for corresponding analysis), sex, age, race/ethnicity, log₁₀ HIV-1 RNA level, CD4+ cell count, and BMI. All adjusted models led to results similar to those obtained with unadjusted analyses.

Table 3. Estimated Percentage Changes in Limb Fat, Trunk Fat, VAT, and VAT:TAT Ratio for All 4 Treatment Arms (Intent-to-Treat Analysis)

NOTE. The duration of the study was 96 weeks since the last subject enrolled in A5202; thus, there was a smaller sample size (N) at later time points. ABC, abacavir; ATV-r, atazanavir-ritonavir; EFV, efavirenz; FTC, emtricitabine; HIV-1, human immunodeficiency virus type 1; SD, standard deviation; TAT, total adipose tissue; TDF, tenofovir DF; VAT, visceral adipose tissue; 3TC, lamivudine.

Association Between Baseline Factors and Changes in Limb Fat, VAT, and VAT:TAT Ratio at 96 Weeks

Linear regression analyses by ITT were performed to assess baseline factors associated with the changes in limb fat, VAT, and VAT:TAT ratio at week 96 (Table 4). In the multivariable analysis, higher baseline log₁₀ HIV-1 RNA level was associated with significant increases in absolute and percentage limb fat change, and older age was associated with significant decreases. Only higher baseline BMI was associated with significant increases in week 96 percentage VAT change, absolute VAT:TAT ratio change, and a trend towards an increase in week 96 percentage VAT:TAT ratio change.

DISCUSSION

This report details the results of a randomized, controlled substudy comparing the effect that initiation of ABC-3TC or TDF-FTC regimens with either ATV-r or EFV in HIV-infected, ART-naive subjects has on body fat. Our data are consistent with the results of Altair [4] and extend the observation of that 48-week study to 96 weeks and extend the comparison of both TDF-FTC and ABC-3TC as initial combinations.

For our study, we deliberately selected a strict cut-off point to define lipoatrophy, a 10% limb fat loss that is likely to be

subclinical [8], because prior studies of TDF- and ABC-containing regimens did not demonstrate the deleterious lipoatrophic effects of thymidine NRTIs (tNRTIs) [9, 10]. With this criteria, lipoatrophy occurred in 16% (95% CI, 12%–22 %) of subjects and was not significantly different between the

ABC-3TC- and TDF-FTC-containing regimens, although we could not conclude that lipoatrophy occurred less than the hypothesized level of 15%. In a post hoc analysis, we determined the prevalence of $\geq 20\%$ loss of limb fat from baseline at 96 weeks, mirroring endpoints of prior studies [4, 11, 12]. Very few

subjects in any study arm met this criterion for lipoatrophy, which was a result that was substantially different from the 50%–70% seen in tNRTI-treated subjects [11, 12].

The initial changes (Table 3, Figure 2) in limb fat are consistent with earlier observations of an increase in limb fat after ART initiation, regardless of the type of therapy [11, 13, 14]. However, unlike with tNRTIs [14, 15], no decrease in limb fat was seen after 96 weeks.

In our study, the rate of lipoatrophy was similar in the ATV-r and EFV arms. This is in contrast with A5142, which was a randomized study in which EFV was associated with higher rates of lipoatrophy, compared with lopinavir-ritonavir [11]. However, in our study, limb fat did increase significantly more in the ATV-r than in the EFV arms. Thus, although the rate of lipoatrophy appears to be different than what was seen in A5142, the higher gains in limb fat with ritonavir-boosted PIs may have counteracted the effect that tNRTIs had on lipoatrophy in that study. Also, within the TDF-FTC arms (but not within the ABC-3TC arms), we found a trend towards higher prevalence of ≥20% loss of limb fat in the EFV arms, compared with the ATV-r arms. Additionally, in our study, limb and trunk fat overall increased more in the ATV-r– than EFV-treated subjects. This effect of ritonavir-boosted PIs may explain why, in another study, lipoatrophy was more prevalent with ATV than with ATV-r [12].

The mechanisms involved in changes in body fat after ART initiation have been partially elucidated. The tNRTIs, particularly stavudine, have been strongly implicated in lipoatrophy through mitochondrial toxicity [1–3]. In multivariable analyses exploring baseline factors associated with limb fat changes at week 96, we found that randomization to ATV-r and higher HIV-1 RNA levels were associated with larger increases in limb fat, the latter consistent with the possibility of limb fat increasing after ART initiation being mediated by the return-to-health phenomenon. The only factor independently associated with a decrease in limb fat was older age, as seen by others [16].

The pathogenesis of lipohypertrophy is poorly understood, and the role of PIs is debated. Early studies attributed “lipodystrophy” to PI-based ART [17, 18]; however, recent studies have refuted this association [6, 11, 19]. These discrepancies may be due, in part, to some studies using trunk fat measurement by DEXA, rather than visceral fat measurement by CT or MRI. In addition, in most studies, the backbone NRTIs consisted of tNRTIs, which are known to induce significant metabolic abnormalities, including insulin resistance [20, 21], dyslipidemias [22], and perhaps contribute to visceral fat accumulation [19]. Also, as seen with other complications [5, 23], PIs may differ in their capacity to affect body composition changes, so that our observations pertain only to ATV-r. In our study, ATV-r–containing regimens led to higher gains in limb and trunk fat and a trend towards higher gains in VAT, compared with EFV regimens, with no change in VAT:TAT. Thus, it is likely that the absence of tNRTIs

and the lack of resultant limb fat loss allowed us to see a greater net gain in fat in all compartments with ATV-r-based therapy, compared with EFV-based therapy.

In our study, we showed that VAT increased significantly at week 96 in all arms, except for the ABC-3TC + EFV arm (Table 3). In multivariable analysis that explored factors associated with visceral fat changes at week 96, only higher baseline BMI was associated with larger increases in VAT:TAT. This could be linked to the enhanced inflammation associated with obesity [24], which could also play a role in visceral fat accumulation in individuals with HIV-1 infection [25].

Our study has some limitations, including the lack of data on changes in diet, alcohol intake, and physical activity; the open-labeled administration of NNRTIs and PIs; the large number of comparisons performed; and the relatively high amount of missing data. However, sensitivity analyses led to similar results. Lastly, there was a relatively high frequency of changes in NRTIs; however, AT analyses of limb and visceral fat indices yielded results similar to those of the ITT.

In summary, we showed that ART-initiation with ABC-3TC or TDF-FTC as backbone NRTIs over 96 weeks, on average, similarly increased limb fat and visceral fat and caused relatively little lipotrophy, although we could not conclude that <15% of subjects would have protocol-defined lipotrophy. In addition, ATV-r-containing regimens induced larger increases in limb and trunk fat, with a trend towards larger percentage increases in visceral fat, compared with EFV-containing regimens. Although lipotrophy has become rare with decreased use of tNRTIs, lipohypertrophy remains an ongoing complication. Studies aimed at better understanding and preventing lipohypertrophy after ART initiation are needed.
