Regulation of *IL-2* gene expression by *Siva* and *FOXP3* in human T cells

Virginia K Hench^{1,2} and Lishan Su^{1,2,3*}

Abstract

Background: Severe autoinflammatory diseases are associated with mutations in the *Foxp3* locus in both mice and humans. *Foxp3* is required for the development, function, and maintenance of regulatory T cells (T_{reg} s), a subset of CD4 cells that suppress T cell activation and inflammatory processes. *Siva* is a pro-apoptotic gene that is expressed across a range of tissues, including CD4 T cells. *Siva* interacts with three tumor necrosis factor receptor (TNFR) family members that are constitutively expressed on T_{reg} cells: CD27, GITR, and OX40.

Results: Here we report a biophysical interaction between FOXP3 and *Siva*. We mapped the interaction domains to *Siva*'s C-terminus and to a central region of FOXP3. We showed that *Siva* repressed IL-2 induction by suppressing *IL-2* promoter activity during T cell activation. *Siva*-1's repressive effect on *IL-2* gene expression appears to be mediated by inhibition of NFkappaB, whereas FOXP3 repressed both NFkappaB and NFAT activity.

Conclusions: In summary, our data suggest that both *FOXP3* and *Siva* function as negative regulators of IL-2 gene expression in T_{reg} cells, via suppression of NFAT by *FOXP3* and of NFkappaB by both *FOXP3* and *Siva*. Our work contributes evidence for *Siva*'s role as a T cell signalling mediator in addition to its known pro-apoptotic function. Though further investigations are needed, evidence for the biophysical interaction between FOXP3 and *Siva* invites the possibility that *Siva* may be important for proper T_{reg} cell function.

Background

The transcription factor Foxp3 is essential for immune system regulation due to its role in the development and function of regulatory T cells (T_{regs}) [1,2]. The dramatic autoimmune phenotype that is caused by mutated *Foxp3* in both mice and humans led to its initial identification [2,3]. In the absence of Foxp3, lethal autoimmunity ensues. Sequencing of the *FOXP3* genes from IPEX (Immune polyendocrinopathy, enteropathy, X-linked) patients revealed function ablating mutations throughout domains critical for FOXP3 function [4,5]. The *scurfy* mouse is an autoimmune mutant that has a spontaneous truncation mutation in *Foxp3*. In addition to its well-studied role in T_{regs} , an emerging body of work has revealed Foxp3 to be a tumor suppressor in breast cancer [6,7]. Foxp3 activates and suppresses a broad range of genes, but the mechanisms by which this happens are not well-understood [8-10]. By understanding the relationship between FOXP3

and its binding partners, we hope to illuminate how FOXP3 operates as a powerful regulator of immune activation.

Already, FOXP3 is reported to reside in a supramolecular complex [11] and a number of specific interactions have been identified [12]. Co-immunoprecipitation (Co-IP) demonstrated binding between FOXP3 (or Foxp3) and the following partners: the NFkappaB p65 subunit [13], TIP60, HDAC7, HDAC9 [14], FOXP1 [11], Runx1/AML1 [15], the AP-1 constituent, cJUN [16], RORalpha [17], RORgamma [18,19], and Eos [20]. Also, Foxp3 homo-oligomerizes [11,21]. Wu *et al* [22] demonstrated that Foxp3 inhibits the transcriptional enhancing effects of NFAT and AP-1 by disrupting their interaction.

Regulation of *IL-2* gene expression is critical to immune tolerance, T_{reg} development and T_{reg} function [23,24]. Foxp3 inhibits *IL-2* production in T_{regs} and confers *IL-2* suppressive function *in trans* [25]. Even before T_{regs} and *Foxp3* became inextricably coupled, researchers investigated the effect of Foxp3 on *IL-2* transcription [26]. While *IL-2* is not the sole target of Foxp3 [9], coordinated investigations into molecular interactions localized to the *IL-2*

promoter have been a successful strategy thus far, towards understanding Foxp3's function as a transcriptional regulator.

Here we report a previously unidentified FOXP3 binding partner, Siva. The novel interaction was exposed in a yeast two-hybrid screen for FOXP3 binding partners. We were interested in Siva for its known cell death promoting properties [27,28]. The possibility of a pro-apoptotic molecule that might confer T_{reg} properties was intriguing. Also, Siva binds tumor necrosis factor receptor (TNFR) family members associated with (but not exclusive to) the T_{reg} surface phenotype: CD27, GITR (glucocorticoid-induced TNFR-related protein), and OX40 [27-33]. Siva was first identified based on its CD27-binding activity, which was demonstrated by Co-immunoprecipitation (Co-IP) studies in 293T cells transiently transfected with CD27 and GFP-tagged Siva [27]. In a subsequent study, the same group showed that the CD27 cytoplasmic tail mediated the interaction between both isoforms, Siva-1 and Siva-2 [28]. The cytoplasmic region of CD27 shares a high degree of homology with GITR, and OX40, which prompted the investigation and confirmation that these other TNFR family members also interact with Siva [29]. GITR is highly expressed on T_{regs} and attributes suppressive properties under certain conditions [34,35]. In a transient transfection system, Siva and GITR functionally interacted to exacerbate apoptosis [29]. Thus, we investigated Siva because of its pro-apoptotic properties and its ability to bind TNFR family members that are associated with the T_{reg} surface phenotype.

Our data shows a physical interaction between FOXP3 and Siva protein exogenously expressed in 293T cells. We mapped the FOXP3-interacting domain to the C-terminus of Siva. The central portion of FOXP3 (amino acids (AAs) 106-332) contains Siva-binding activity. We found that Siva repressed IL-2. The repressive effect of Siva on IL-2 appears to be mediated by NFκB, as our data and others show a negative regulatory effect for Siva on NFκB activity [36]. Consistent with previous reports [13,22], we observed that FOXP3 repressed NFκB and NFAT. To conclude, while the pro-apoptotic effect of Siva has been thoroughly demonstrated and documented, this analysis of Siva's effect on IL-2 contributes evidence for Siva's role in T cell signalling.

Results

Siva physically interacts with FOXP3

A yeast two-hybrid screen for FOXP3-binding partners was performed with a human thymus cDNA library. Six full-length clones for Siva-1 were identified in the screen. We chose Siva-1 for further investigation for two reasons. First, Siva regulates T cell apoptosis and, second, because Siva associates with TNFR family members that might

contribute to T_{reg} function: CD27, GITR, and OX40 [29-33].

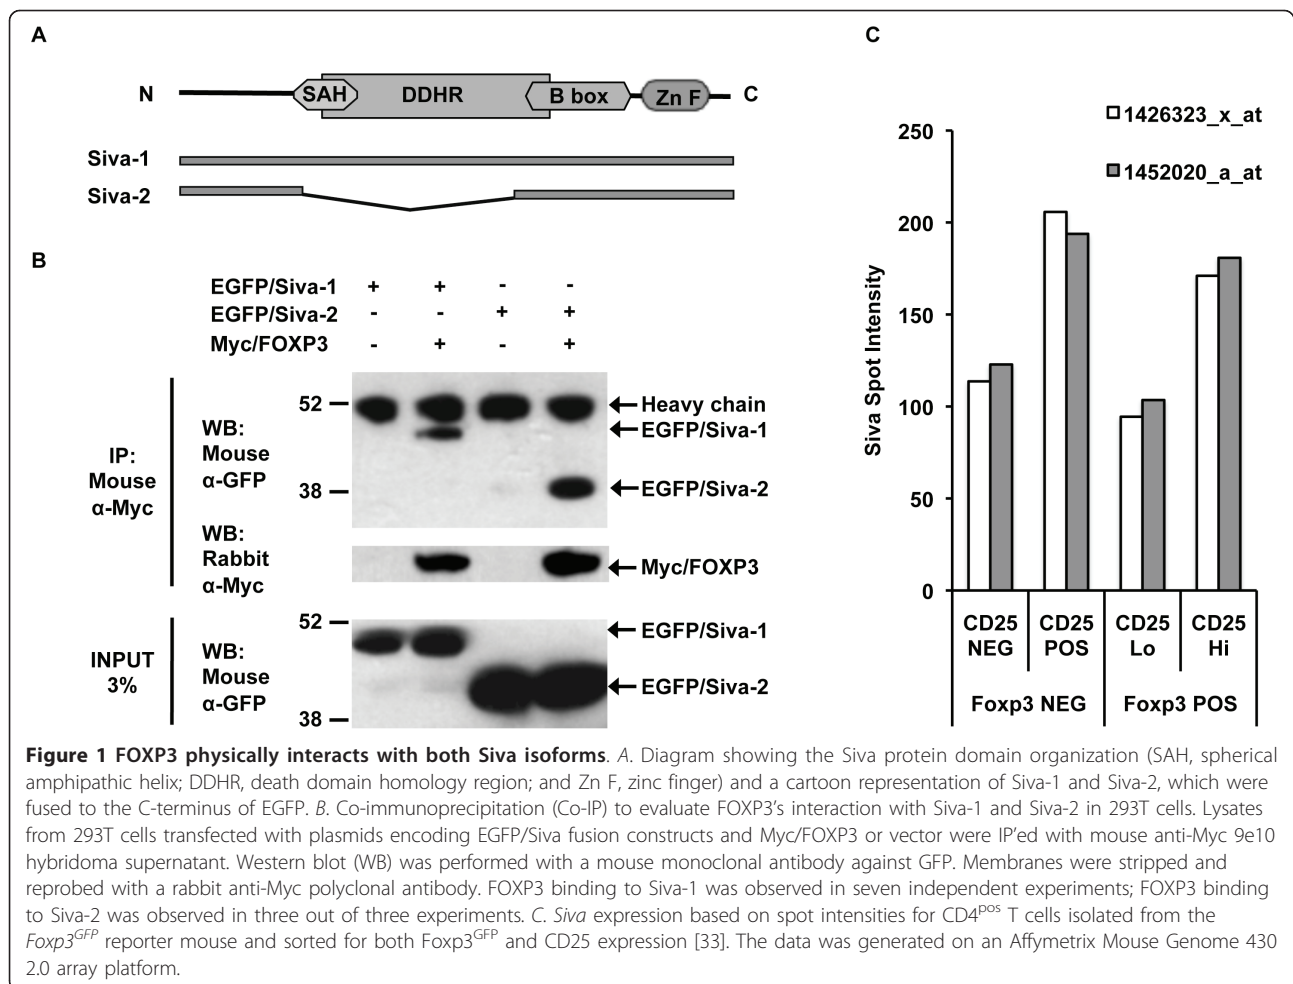

We tested whether FOXP3 and Siva could interact in mammalian cells. Two isoforms, Siva-1 and Siva-2 [28], have been described and their protein domain organization is depicted in Figure 1A [GenBank: NP_006418, NP_068355]. Siva-2 lacks the second exon, resulting in a protein that is missing most of the spherical amphipathic helix (SAH) and death domain homology region (DDHR) [28]. We performed co-immunoprecipitation (Co-IP) experiments with transfected 293T cell lysates. We transfected 293T cells with expression plasmids for EGFP-tagged Siva isoforms and Myc-tagged FOXP3, or the appropriate vector control. Myc/FOXP3 was immunoprecipitated with a mouse anti-Myc hybridoma supernatant, 9E10. As shown in Figure 1B, by western blotting (WB) with an antibody against GFP, we detected Co-IP of Siva-1 and Siva-2 in the presence of Myc/FOXP3, but not in its absence. EGFP alone did not Co-IP with FOXP3 (data not shown). Thus both Siva-1 and Siva-2 specifically interact with FOXP3.

Next, we wanted to know whether Siva was expressed in FOXP3-expressing T_{reg} cells. We examined Siva expression profiles contained within the microarray dataset generated by Fontenot *et al.* from Foxp3^{GFP} knock-in mice [33]. Fontenot *et al.* sorted CD4^{pos} T cells for CD25 and Foxp3^{GFP}. The data shown in Figure 1C demonstrates that Siva is expressed in CD4^{pos} T cells that are both positive and negative for Foxp3 expression. Siva is preferentially associated with CD25, a marker associated with both the T_{reg} phenotype and T cell activation. Thus, Siva and Foxp3 are co-expressed in mouse T_{regs} that express the CD25 surface marker.

Siva-binding activity is contained within FOXP3's central region

Major domains of the FOXP3 protein are associated with specific functional activities and binding partners (Figure 2A) [GenBank: NP_054728, NP_001107849] [12]. The Foxp3 N-terminus is required for NFAT-mediated repression of IL-2 [22] and is involved in binding to the RORγt and RORα transcription factors [19]. The leucine zipper (L zip) domain mediates homodimerization of Foxp3, which contributes to T_{reg} suppressive function [11,21]. The C-terminal Foxp3 forkhead (Fkh) domain is required for DNA binding and nuclear localization [26]. A short stretch of amino acids between the zinc finger (Zn F) and the Fkh domain is involved in Runx1/AML1 binding and is involved in IL-2 repression [15].

We used Myc/FOXP3 truncation mutants to characterize the region involved in binding to Siva by Co-IP in 293T cells (summarized in Figure 2A). Mutants lacking

the Fkh domain (Δ Fkh) or the N-terminus (Δ 1-71; Δ 1-105) bound to Siva with similar efficiency as full length FOXP3 (Figure 2B). The FOXP3 Fkh mutant repeatedly showed lower expression than other FOXP3 mutants (Figure 2B and not shown). The reduced level of expression might have contributed to the lack of binding between FOXP3 Fkh and EGFP/Siva-1. Still, based on the Siva-binding activity of the Δ Fkh mutant, we conclude that the FOXP3 Fkh domain is not necessary for Siva-binding activity. FOXP3's Siva-binding activity is located within the protein's central region (AAs 106-332), which spans the leucine zipper, the zinc finger and Runx1-binding domains.

The Siva C-terminus is sufficient to bind FOXP3

As shown in Figure 3A, we designed Siva truncation mutants fused to EGFP's C-terminus to cover major domains that have been previously described and associated with functional properties [27,28,37]. We performed Co-IPs to map Siva's FOXP3-binding activity. Our analysis definitively showed no interaction between

FOXP3 and Siva mutants lacking the C-terminus (Figure 3B). In contrast, all mutants containing some portion of the cysteine rich Siva C-terminal domain interacted with FOXP3. Given that the Siva C-terminus mutant and the Δ Zn F mutant both contain the B box domain and both interacted with FOXP3, we hypothesized that the Siva B box domain might be necessary and sufficient to bind FOXP3. To test our hypothesis, we designed mutants encompassing the Siva B box domain and full length Siva lacking the B box domain (Δ B box). Subsequent Co-IP experiments demonstrated a very weak, but detectable interaction between FOXP3 and the Siva B box domain. The Siva Δ B box mutant was fully competent to bind FOXP3. Thus, the Siva B box domain appears unnecessary and insufficient to bind FOXP3 (Figure 3C).

Siva negatively regulates IL-2 gene expression

We next investigated Siva's effect on IL-2 gene expression. In order to evaluate the effect of Siva overexpression on endogenous IL-2, we transduced Jurkat T cells with pHSP-EGFP/Siva-1 or pHSPG-Siva-1 retrovirus

A FOXP3 protein organization & FOXP3 truncation mutants

Figure 3 The Siva C-terminus is sufficient to bind FOXP3. A. Diagram showing the Siva protein domain organization (SAH, spherical amphipathic helix; DDHR, death domain homology region; B box; and Zn F, zinc finger) and Siva truncation mutants, which were fused to the EGFP C-terminus and tested in Co-IPs shown in B and C. B. Co-IP to map Siva's FOXP3-binding activity (hc, antibody heavy chain; lc, antibody light chain). These Siva truncation mutants were tested three times for FOXP3-binding activity. C. Co-IP to test the FOXP3-binding activity of the Siva B box and ΔB box mutants. These mutants were each tested twice for FOXP3-binding activity.

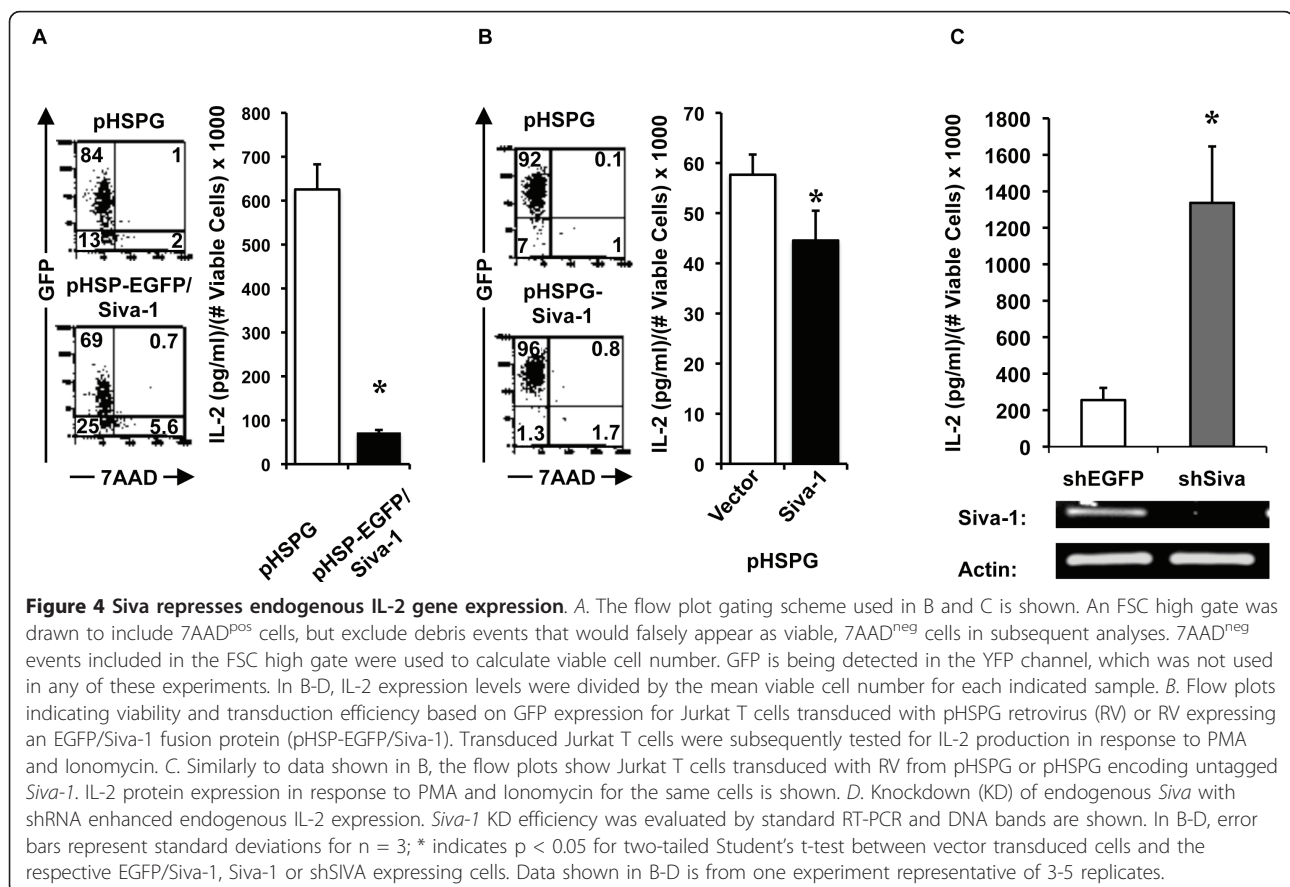

(RV). Figure 4A shows a representative gating scheme used to measure cell viability and transduction efficiency. This basic gating scheme was used in subsequent experiments throughout this report. For each experiment, GFP^{neg} cells were used to determine the position of all gates and quadrant boundaries. We normalized IL-2 expression levels to viable cell counts in order to examine Siva's effect on IL-2 separate from Siva's effect on apoptosis. The repressive effect of EGFP/Siva-1 and Siva-1 on endogenous IL-2 in Jurkat T cells are shown in Figures 4B & 4C, respectively. EGFP/Siva-1 repressed endogenous IL-2 by nearly 90% compared to pHSPG transduced cells (Figure 4B). In a separate experiment, overexpression of Siva-1 also repressed endogenous IL-2 gene expression (Figure 4C). Next, we tested the effect of *Siva* knockdown (KD) on endogenous IL-2 gene expression (Figure 4D). Jurkat T cells were transduced with pLKO lentivirus (LV) expressing *shSiva* or *shEGFP*, as a control shRNA. The DNA gel confirms *Siva* KD based on RT-PCR using primers specific for both *Siva* isoforms. *Siva* KD enhanced IL-2 gene expression compared to the *shEGFP* control, providing further evidence that *Siva* acts as a negative regulator of *IL-2* gene expression.

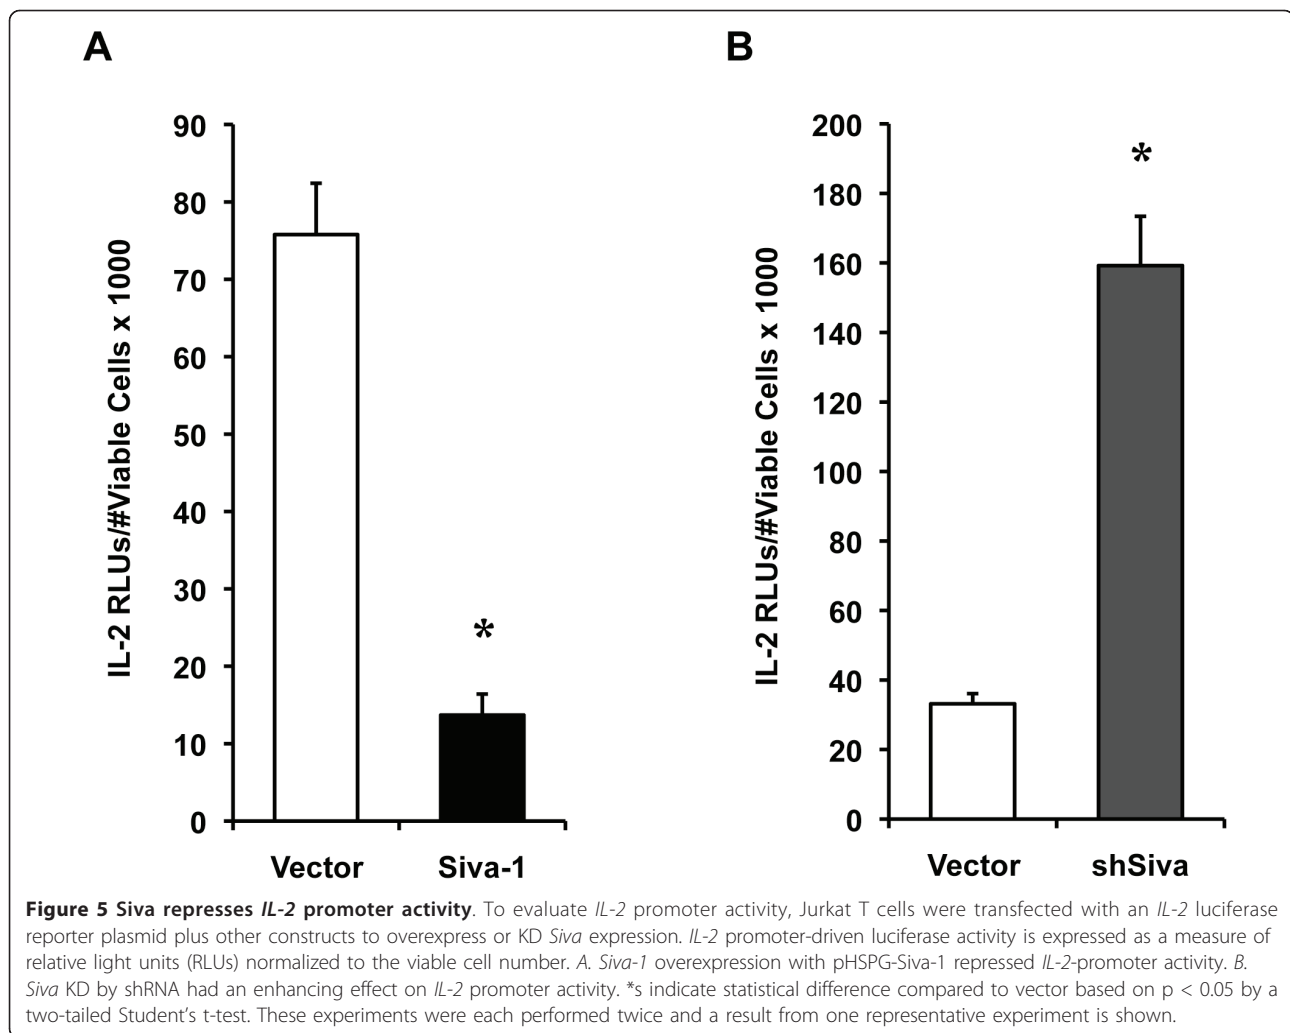

Siva negatively regulates *IL-2* promoter activity

In addition to measuring *Siva*'s effect on endogenous *IL-2* protein levels, we tested the effect of *Siva* gene expression on *IL-2* promoter activity. A minimal enhancer element located 300 base pairs immediately upstream of the *IL-2* start site regulates transcription through the binding of transcription factors and alterations in the chromatin structure [38,39]. Distal regulatory elements also contribute to *IL-2* gene regulation and the minimal enhancer region is sometimes referred to as the proximal promoter. In order to investigate *Siva*'s effect on *IL-2* transcriptional activation, we used a reporter plasmid containing the *IL-2* proximal promoter driving expression of the luciferase enzyme. Again, in order to examine *Siva*'s effect on *IL-2* separate from *Siva*'s effect on apoptosis, we normalized *IL-2* transcriptional activity to viable cell counts. *Siva* overexpression inhibited *IL-2* transcriptional activity (Figure 5A) and *Siva* KD enhanced *IL-2* transcription (Figure 5B).

FOXP3 and *Siva* repress endogenous *IL-2* gene expression

In order to test whether *FOXP3* and *Siva* functionally interact to repress endogenous *IL-2*, we co-expressed *FOXP3* and *Siva-1* in Jurkat cells by transduction with

pHSPG RV (Figure 6A). As expected, *FOXP3* and *Siva-1* each repressed endogenous *IL-2* independently (Figure 6B). The combination of *FOXP3* and *Siva-1* failed to repress *IL-2* further than *FOXP3* alone. We also examined the combined effects of *Siva* KD and exogenous *FOXP3* on *IL-2*. Figure 6C shows the efficiency of *Siva* KD in Jurkat T cells transduced with pLKO LVs expressing hairpin RNA against *Siva* or *EGFP* and PG RV expressing *FOXP3*. Consistent with data shown above, *Siva* KD enhanced *IL-2* gene expression (Figure 6D). *FOXP3* effectively repressed *IL-2* gene expression independent of endogenous *Siva* expression levels. Thus, in this experimental system, *FOXP3*-mediated repression of endogenous *IL-2* appears to be independent of *Siva* gene expression levels.

Effect of *FOXP3* and *Siva* on *IL-2* promoter activity

In addition to evaluating the combined effects of *FOXP3* and *Siva* on endogenous *IL-2* gene expression, we investigated whether the two genes might functionally

interact to repress *IL-2* transcriptional activity. First, we tested the effect of *FOXP3* and *Siva-1* overexpression on the transcriptional activity of the *IL-2* proximal promoter in the Jurkat T cell luciferase assay. We transfected Jurkat T cells with the *IL-2* reporter plasmid and different combinations of pHSPG, pHSPG-*Siva-1* and pHSPG-*FOXP3* in equal plasmid DNA mass. As indicated by the data in Figure 7A, both *Siva-1* and *FOXP3* repress *IL-2* transcriptional activity independently. The repressive effect of *FOXP3* is stronger than *Siva-1*. We do not see an additive effect on *IL-2* repression between *Siva-1* and *FOXP3*. In addition, we tested the combined effect of *Siva* KD and *FOXP3* overexpression on *IL-2* transcriptional activity (Figure 7B). As expected, *Siva* KD enhanced *IL-2* transcriptional activity. However, *FOXP3* over expression masked the *IL-2* enhancing effect of *Siva* KD. Thus, similar to the endogenous *IL-2* experimental results, the *IL-2* transcriptional activity assays suggest that *FOXP3*'s repressive effect masks the repressive effect of *Siva*.

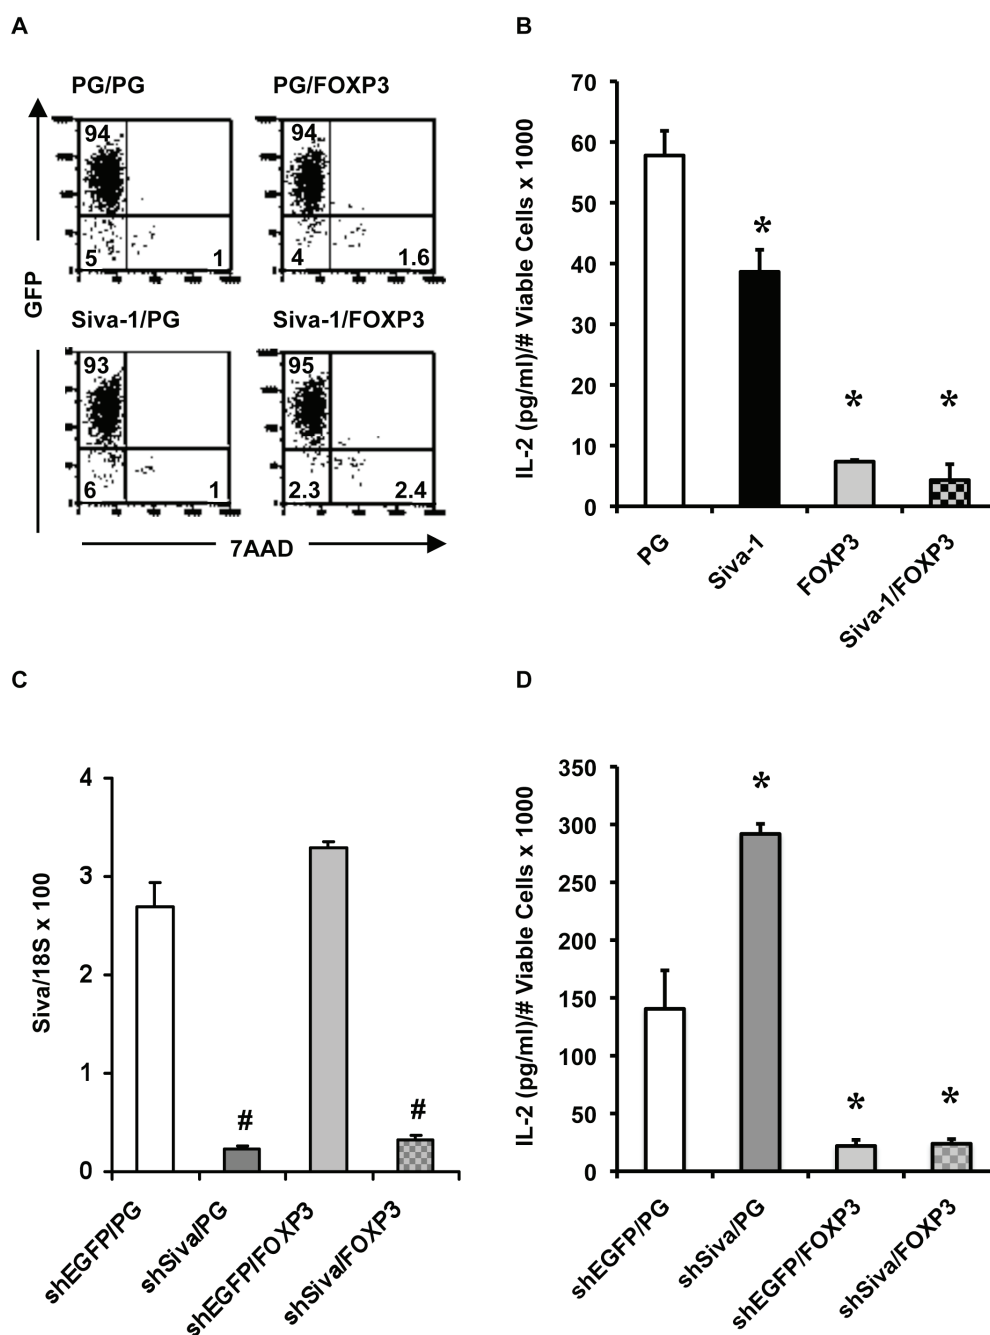

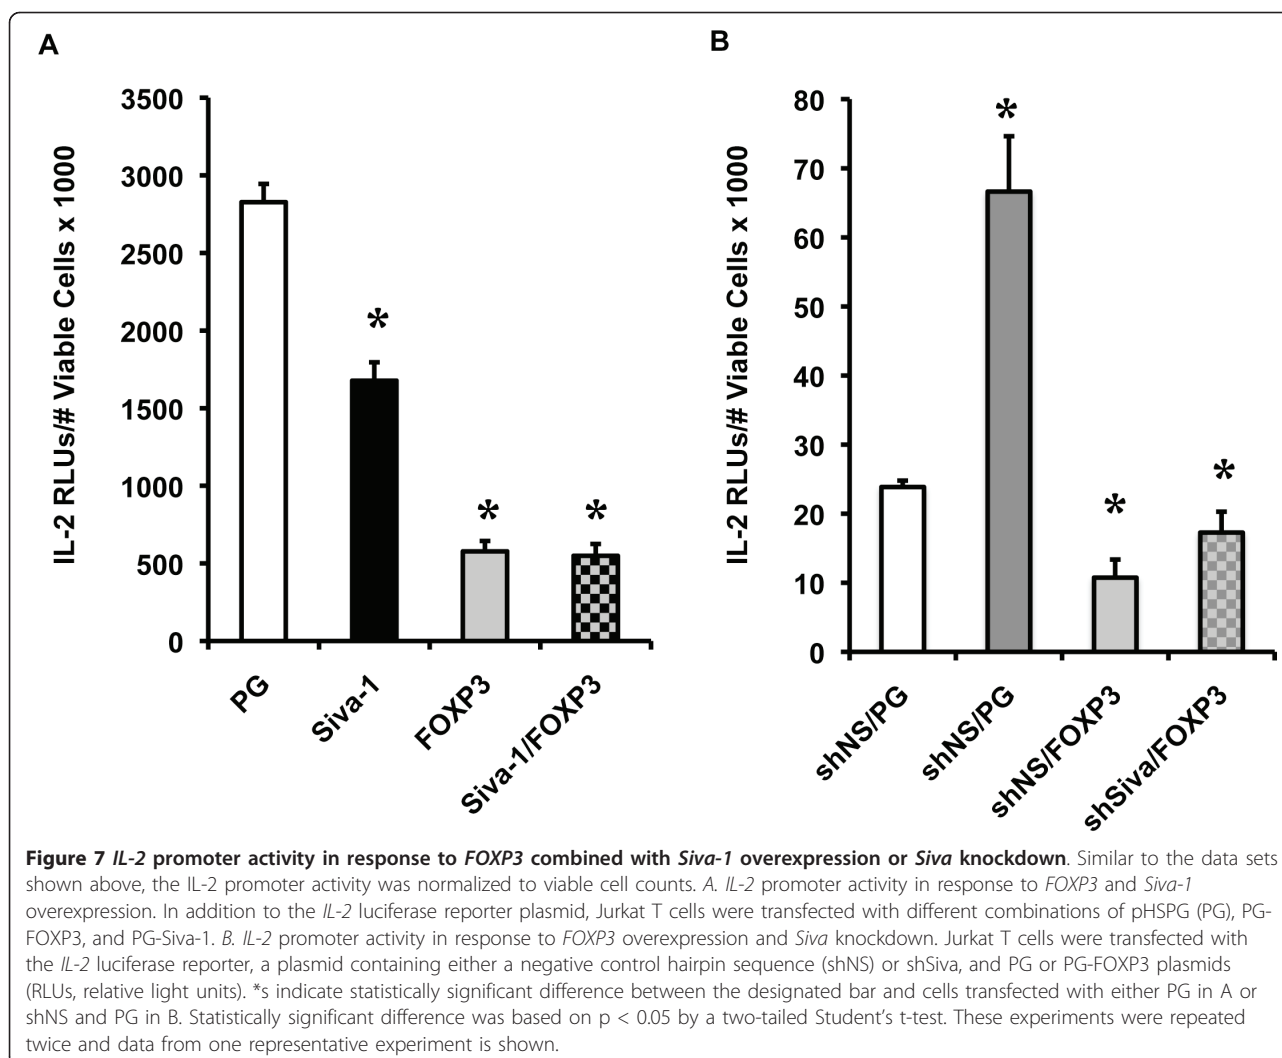

Figure 6 Endogenous IL-2 in response to exogenous FOXP3 combined with Siva-1 overexpression or Siva knockdown. Jurkat T cells were transduced with two rounds of RV or LV and then activated with PMA and Ionomycin. Following stimulation, cell viability was determined using the gating method shown in Figure 4A and endogenous IL-2 expression was measured by ELISA. **A.** Flow cytometry for GFP expression and viability in unstimulated Jurkat T cells transduced with different combinations of pHSPG (PG), PG-Siva-1, and PG-FOXP3 RV. Plots shown have already been gated to exclude debris events using a gating scheme similar to the one shown in 4A. **B.** Endogenous IL-2 in response to FOXP3 and Siva-1 overexpression was determined using the cells shown in A. The IL-2 concentration was divided by the mean viable cell count for each indicated sample. **C.** Siva KD efficiency was determined by quantitative realtime PCR for Siva and 18S in unstimulated Jurkat T cells transduced with PG or PG-FOXP3 RV and pLKO-shEGFP or pLKO-shSIVA LV. The realtime PCR primers used in this experiment do not distinguish between the two Siva isoforms. The error bars indicate standard deviation between technical replicates. #s indicate statistically significant difference between the indicated bar and the adjacent, shEGFP-transduced control. **D.** Endogenous IL-2 in response to FOXP3 overexpression and Siva KD, using the transduced Jurkat T cells described in C. *s indicate statistically significant difference between the indicated bar and the PG- or shEGFP/PG-transduced control, in B and D, respectively. Statistically significant difference was based on $p < 0.05$ by a two-tailed Student's t-test. These transduction experiments were performed twice and representative experiments are shown.

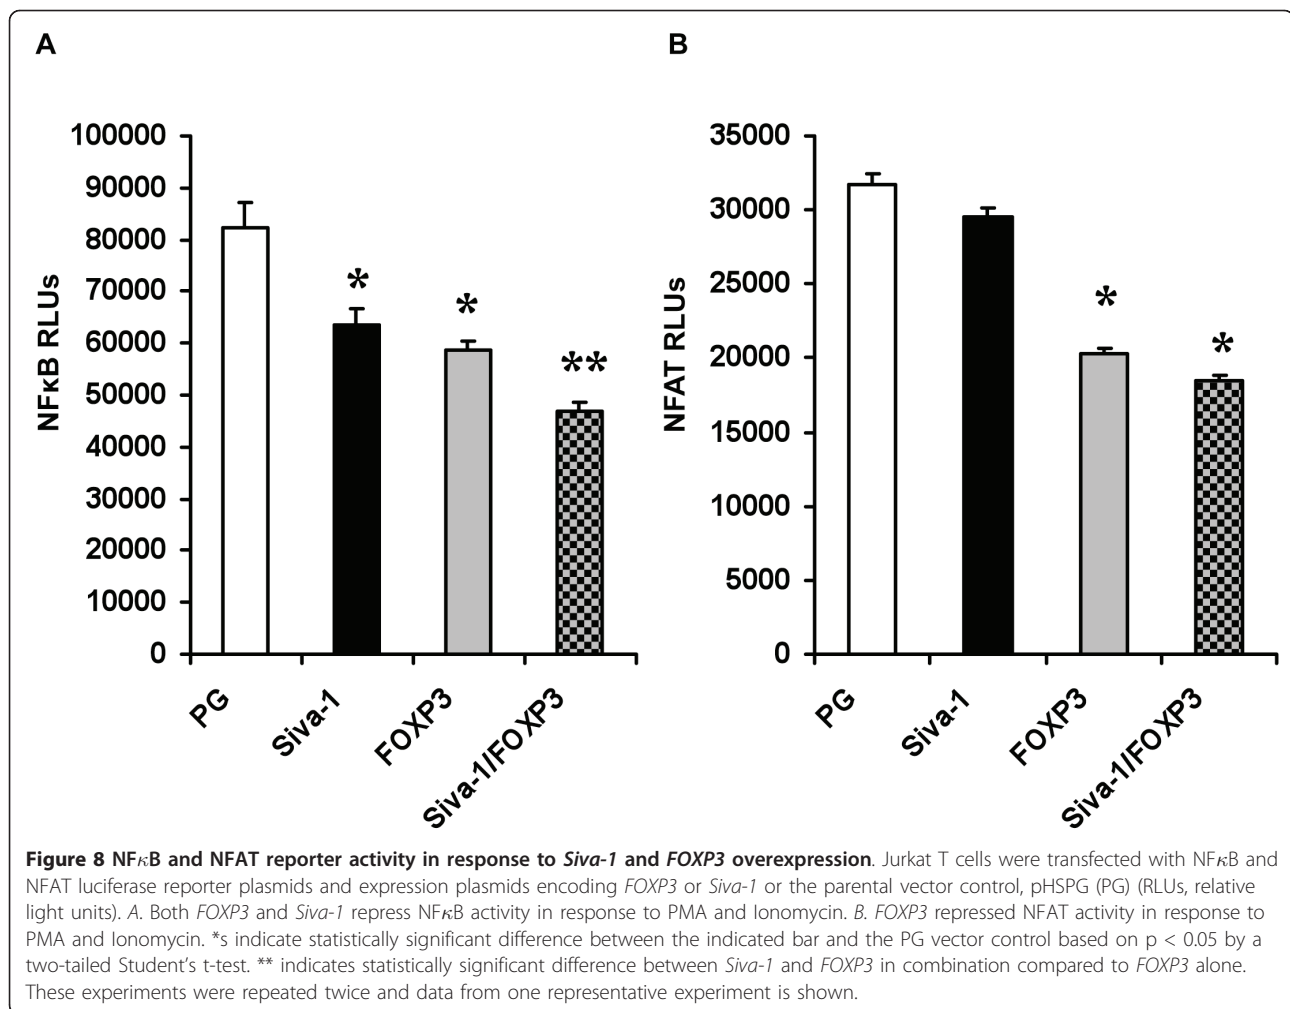

Effects of *FOXP3* and *Siva-1* on $\text{NF}\kappa\text{B}$ and NFAT activity

IL-2 is regulated by multiple transcription factors and chromatin modifications [38,39]. We tested the effects of *Siva-1* and *FOXP3* on the transactivating potential of two major *IL-2* transcriptional regulators, $\text{NF}\kappa\text{B}$ and NFAT. In these experiments, the reporter construct contains a luciferase gene that is regulated by three tandem repeats of either the $\text{NF}\kappa\text{B}$ consensus sequence from the MHC class I promoter [40] or the NFAT binding site from the human *IL-2* gene promoter [41]. Consistent with published reports and shown in Figure 8, *FOXP3* inhibits $\text{NF}\kappa\text{B}$ [13] and NFAT [13,22] transactivation potential in Jurkat T cells. *Siva* repressed $\text{NF}\kappa\text{B}$ (Figure 8A), but had no effect on NFAT activity (Figure 8B). The combination of *FOXP3* and *Siva-1* repressed $\text{NF}\kappa\text{B}$ activity more than *FOXP3* alone. Even though the $\text{NF}\kappa\text{B}$ repressive effect of the two genes in combination was slight (~20%), the effect was reproducible with statistical significance.

Discussion

In this report we have shown that *FOXP3* and *Siva* physically interact. We have mapped the binding activities to limited domains within each protein. *FOXP3* and *Siva-1* both independently repressed *IL-2* gene expression. One mechanism by which *Siva-1* represses *IL-2* is via inhibition of $\text{NF}\kappa\text{B}$. In contrast, *FOXP3* repressed the activity of both *IL-2* transactivators tested here, $\text{NF}\kappa\text{B}$ and NFAT. Although we did not reveal a functional interaction between *FOXP3* and *Siva* with regards to *IL-2* repression, the biophysical interaction invites questions regarding how *Siva* might contribute to regulation of *FOXP3*-expressing T_{reg} cells.

The physical interaction was demonstrated through a standard protein-protein interaction, Co-IP assay. Two *Siva* isoforms have been identified and both *Siva* isoforms interact with *FOXP3*. The *Siva-2* isoform lacks the second exon that encodes for the SAH and DDHR domains [28,37], which were found to be dispensable for binding

FOXP3 in subsequent Siva truncation Co-IP experiments. The Siva C-terminus, which encompasses both the putative B box and Zn F domains, contained FOXP3 binding activity.

The Siva C-terminus is enriched with cysteine residues that could be important to the protein's tertiary structure and function. Paired cysteine residues are associated with intramolecular disulfide bond formation. The Siva C-terminus contains six paired cysteine residues. Nestler *et al* [42] used truncation mutants to show that Siva coordinates three zinc ions, two of which are associated with the C-terminus [42]. Although a few groups have found that the Siva C-terminus is necessary to interact with other binding partners [43-45], no one has described whether specific C-terminal point mutations block Siva function. Future site-directed mutagenesis studies of the Siva C-terminal cysteine residues could be informative to further characterize the physical interaction between Siva and FOXP3.

FOXP3's Siva-binding activity is contained within a broad central region that includes the zinc finger, the

leucine zipper and the RUNX1 binding domain (amino acids 106-332). Mutants missing either the first 105 N-terminal amino acids or the C-terminal forkhead domain sustained binding to Siva-1. Further experiments are needed to define a minimal region of FOXP3 involved in binding to Siva-1. The FOXP3 leucine zipper domain is required for homodimerization, *IL-2* repression, and T_{reg} suppressive function [11,21,46]. Given that the leucine zipper domain is within the region that binds Siva-1, one question we are interested in addressing in the future is whether known leucine zipper IPEX mutations ($\Delta 250$, $\Delta 251$) [11,21] interfere with FOXP3 binding to Siva-1.

One limitation of this study was that technical challenges obstructed our efforts to detect a biophysical interaction between endogenously expressed FOXP3 and Siva. Also, we have not yet performed sufficient experiments to address whether the biophysical interaction could be linked to any functional interaction. In order to test whether the biochemical interaction between FOXP3 and Siva-1 affects their functional interaction, a minimal region of biochemical interaction for at least one protein

needs to be identified. More extensive point mutant Co-IP experiments for at least one of the proteins could be informative towards defining the relationship between the biophysical interaction and any proposed functional interaction for FOXP3 and Siva-1.

Our initial hypothesis was that *FOXP3* and *Siva-1* might functionally interact to repress *IL-2* gene expression. We did not observe an additive repressive effect between *FOXP3* and *Siva-1* on *IL-2* gene expression. Instead, our data suggests that *FOXP3* might be a dominant suppressor that masks the repressive effects made by *Siva-1* on *IL-2* gene expression.

Our analysis of two *IL-2* transactivators supports the assertion that *Siva-1* and *FOXP3* affect shared and different *IL-2* regulatory mechanisms. Consistent with previous reports, *FOXP3* repressed NF κ B [22] and NFAT [13,22] transactivation reporters. *Siva-1* inhibited NF κ B, but had no effect on NFAT in cells stimulated with PMA and Ionomycin. We observed a small, but significant additive repressive effect between *FOXP3* and *Siva-1* on NF κ B activity.

The NF κ B-repressive effects that we observed for *FOXP3* and *Siva-1* are consistent with published reports. The effects of each gene on NF κ B activity may be partitioned into distinct cytoplasmic and nuclear signalling events. In resting cells, cytoplasmic I κ B α sequesters the canonical NF κ B subunits p65 and p50, preventing their nuclear translocation. In response to stimulus, I κ B α breaks down and releases the NF κ B subunits, which translocate to the nucleus [47]. *Siva* blocked NF κ B nuclear accumulation via stabilization of cytoplasmic I κ B α [36]. On the other hand, *FOXP3* blocked NF κ B transactivation potential by mechanisms independent of nuclear translocation and DNA binding [13]. Further, our group showed that *FOXP3*'s promoter-dependent effects on NF κ B transactivating potential were independent of nuclear translocation. FOXP3 enhanced HIV-1 gene expression by increasing the amount of NF κ B p65 subunit bound to the LTR (long terminal repeat) [10]. To summarize, in separate experimental systems, inhibition of NF κ B activity by *Siva* has been shown to occur upstream of I κ B α degradation and nuclear translocation, whereas FOXP3 inhibits NF κ B activity downstream of I κ B α degradation. The biophysical interaction that we have presented suggests that another regulatory mechanism could be occurring that would involve co-localization of FOXP3 and Siva-1 within the same subcellular compartment.

Given that Siva has displayed both nuclear and cytoplasmic subcellular localization [43,48-51], the possibility remains that Siva could regulate gene transcription from within the nucleus in addition to its cytoplasmic effect on NF κ B. As of yet, published reports of a nuclear specific function for Siva are lacking. Most detailed investigations

of Siva function have examined Siva in relation to transmembrane signalling molecules or mitochondrial-associated apoptosis regulators thought to be present in the cytoplasm, not in the nucleus [28,29,37,43,44,50,52-54]. In future studies, it will be interesting to look into whether Siva displays nucleus-specific activities such as direct binding to DNA or chromatin.

Conclusions

To conclude, we have carried out an analysis of *IL-2* gene regulation by *FOXP3* and *Siva* in Jurkat T cell lines. *FOXP3* and *Siva* both repress *IL-2* gene expression independently, though the repressive effect of *FOXP3* appears to be dominant over *Siva* in both assays used here. We have shown that *FOXP3* and *Siva* appear to have a slight, but significant, additive repressive effect on NF κ B activity. Many questions remain, most importantly, those regarding Siva's contribution to T_{reg} development and function. Additional efforts are needed to address these intriguing possibilities.

Methods

Cell culture and plasmids

293T cells were grown in DMEM-10% FetalPlex (Gemini). Jurkat cells were grown in RPMI 1640-10% fetal bovine serum supplemented with 2 mM L-glutamine, 100 U/ml penicillin, and 100 mg/ml streptomycin. When needed, Jurkat cells were selected in 1 μ g/ml puromycin (puro). Puro selection took 3-10 days, depending on the transduction efficiency. Puro selection was judged to be complete once cellular debris events measured by Gauva EasyCyte reached less than 10%. Unless otherwise stated, all tissue culture reagents were purchased from Invitrogen.

Myc/FOXP3 full length and all derivative truncation mutants were expressed in pCDNA3.1 and made as previously described [10].

The human *Siva-1* cDNA clone [corresponding to GenBank: NM_006427] was purchased from ATCC (ATCC#: MGC-17039). By PCR subcloning, we transferred *Siva-1* from pCMV-SPORT6 into pEGFP-C1 to generate an enhanced green fluorescent protein (EGFP)/Siva-1 fusion construct. All Siva truncation mutants were derived from pEGFP/Siva-1 by PCR subcloning. The splice overlap extension method was used to generate the Siva-2 [GenBank: NM_021709] and Δ B box mutants [55]. *Siva-1* was subcloned into the pHSPG retroviral vector under control of the MSCV promoter [56]. pHSP-EGFP/Siva was generated by replacing the EGFP cassette with EGFP/Siva under control of the PGK promoter.

A panel of five pLKO lentiviral (LV) vectors expressing short hairpin targets against Siva was purchased and tested for knockdown (KD) efficiency (Open Biosystems). All shSIVA KD experiments in this report used Open

Biosystems clone TRCN0000118302. pLKO contains a puro selection cassette and the U6 promoter controls hairpin expression. pLKO-shEGFP and pLL5.0-NS served as a negative controls in designated experiments. Dr. James Bear's lab provided the pLL5.0-NS construct [57]. The IL-2 and NFAT luciferase reporters were originally acquired from Dr. Gerald Crabtree's lab [41]. Dr. Albert Baldwin provided us with the NF κ B luciferase reporter, a construct that was originally designed by Dr. Bill Sugden's group [40,58].

Yeast two-hybrid screen

A human thymus cDNA library was screened for FOXP3 binding partners. The bait plasmid contained the full length *FOXP3* sequence in-frame with the Gal4 DNA binding domain (BD). The prey plasmids contained human thymus library cDNA clones adjacent to the Gal4 activation domain (AD). cDNA clones were amplified using random primers and oligo (dT) primers to generate partial and full-length cDNA clones, respectively. Interaction between the DNA-BD and AD permits transcription of reporters for histidine (*His*), adenine (*Ade*), and β -galactosidase (β -gal) synthesis. *His*-/*Ade*- dropout media and blue/white screening for β -gal activity permitted selection of clones containing FOXP3 interacting partners. Another level of selection criteria was provided by increasing doses of the histidine production inhibitor, 3-Amino-1,2,4-triazole (3-AT).

Mouse *Siva* gene expression analysis based on microarray data

We used microarray data from Fontenot *et al.* [33] to determine *Siva* expression levels in mouse T cell subsets. Accordingly, CD4^{pos} T cells from the *Foxp3*^{GFP} mouse were sorted based on *Foxp3*^{GFP} and CD25 surface expression. The dataset, "CD4+ T cells expressing transcription factor *Foxp3* and various amounts of CD25" (GDS1113 record), was accessed through NCBI's GEO database [59].

The Affymetrix Mouse Genome 430 2.0 array used in this study includes four spots representing *Siva*. Each spot contains 11 probes. In order to determine which spots were likely to reveal the most accurate *Siva* gene expression profile, we investigated where each individual probe aligned to the mouse genome. We accessed the UCSC genome browser via the NetAffxTM Analysis Center and observed probe alignment locations throughout the mouse genome. A few probes aligned to regions outside of the *Siva* coding region on chromosome 12. We determined the ratio of correct to incorrect probe alignments (# of *Siva*-aligning probes/# of probes aligning to non-*Siva* regions) and discarded spots with a ratio less than 2. The spots shown in this report, 1426323_X_AT and 1452020_A_AT, exhibited ratios of 3 and 7, respectively.

293T transfections, Co-IPs, and antibodies

293T cells were co-transfected with Effectene according to the manufacturer's protocol (Qiagen). 4 μ g total plasmid DNA was added to sub-confluent cells in 10-cm dishes. At 48-hours post-transfection, lysates were harvested in PBS, washed once and stored at -20°. Cell pellets were lysed in modified RIPA (Tris-HCl, pH 7.35, 50 mM; NaCl, 150 mM; EDTA, 1 mM; NP-40 1%; NaDeoxycholate 0.25%) supplemented with Complete EDTA-free Protease Inhibitor (PI, Roche), phenylmethylsulfonyl fluoride (PMSF, 100 mM), and sodium fluoride (NaF, 50 mM). Immunoprecipitations (IPs) were performed in ~1 ml total volume PBS (supplemented with PI, PMSF and NaF). 500 μ g protein lysate and 40 μ l mouse anti-Myc 9E10 hybridoma supernatant (kindly provided by Dr. Yue Xiong) were added to PBS. The protein lysate comprised 5-10% of the IP volume. IPs were incubated on a rotator at 4° overnight. Inputs were mixed with SDS loading dye and stored at 4°. A 1:1 mixture of Immobilized Protein A (Invitrogen) and Protein G Agarose (ThermoScientific) beads was prepared and washed three times with PBS. 40 μ l of bead mixture were added to each IP. IPs with beads were incubated 2-4 hours at 4° on a rotator. Beads were washed four times with cold PBS (no supplements). Washed beads were resuspended in 20 μ l SDS loading dye and heated to boiling in a 95° sand bath (~10 minutes). Boiled samples were run on 10% NuPage minigels according to the manufacturer's instructions (Invitrogen). Following transfer, PVDF membranes were blocked with PBS-Tween (0.2% Tween, 5% milk), which was used for all subsequent antibody incubation steps. Membranes were incubated with mouse α -GFP (Clontech, Living Colors A. v. Monoclonal Antibody (JL-8), 100 ng/ml) to detect immunoprecipitation of EGFP/*Siva* fusion constructs. Membranes were stripped and reprobed with rabbit α -Myc sera (Also, provided by Dr. Yue Xiong).

Standard RT PCR and quantitative PCR

The Qiagen RNeasy isolation kit was used to isolate mRNA from frozen cell pellets preserved at -80° in Qiagen RLT buffer containing β -mercaptoethanol. Reverse transcription reactions were performed with random primers and M-MLV reverse transcriptase in the presence of RNase inhibitor. The following primer sequences were used in semi-quantitative RT PCRs: *Siva For*, 5'- TAC AGCTCAAGGTCCGCGTGA GC-3', *Siva Rev*, 5'-TCAC TGCAGTCCACGAGGCCACA-3', β -actin *For*, 5'- TCA CCCACACTGTGCCATCTACGA-3', β -actin *Rev*, 5'- CAG CGGAACCGCTCAT TGCCAATGG-3'. Quantitative Taq-Man PCR was performed using primers from Applied Biosystems. For *18S* PCRs, cDNA templates were diluted 1:1000. Relative quantities were determined by correlating C_T values to a standard curve. Relative *Siva* quantities were normalized to the relative *18S* quantity.

Retrovirus production and transduction

Retroviral (RV) and lentiviral (LV) supernatants (SN) were produced by using the calcium phosphate method to transfect 293T cells with pHSPG, VSV-G, and gag/pol plasmids [60]. SN's were collected at 48 and 72 hours and titered on Jurkat cells by spinoculation, as has been described [56]. Efficiency of infectivity was determined based on %GFP expression using a Gauva EasyCyte flow cytometer. For subsequent experiments, the %-infected was used to calculate the volume of RV SN needed to obtain 99% transduction efficiency for a fixed cell number. Dual transductions with pHSPG-Siva-1 and pHSPG-FOXP3 RV were performed as follows. A fixed number of cells was transduced with either pHSPG or pHSPG-Siva-1 on day 0. Two days later, high transduction efficiency was confirmed, the cells were counted and equal cell numbers were distributed and mixed with RV for either pHSPG or pHSPG-FOXP3. Since both sets of RV use GFP to mark transduction efficiency, GFP^{neg} Jurkat cells were transduced in parallel to control for transduction efficiency.

In Siva KD experiments, Jurkat T cells were transduced with pLKO-shEGFP or pLKO-shSiva LV and selected in puromycin (see *Cell culture and plasmids* above). Next, the same cells were transduced with PG or PG-FOXP3 RV.

IL-2 ELISA

To evaluate endogenous IL-2, transduced Jurkat T cells were distributed in 96-well plates at a concentration of 2×10^5 cells/well. Cells were activated with phorbol 12-myristate 13-acetate (PMA, 25 ng/ml) and Ionomycin (1 μ M). At the end of ~18 hours, cell viability was evaluated on a Gauva EasyCyte. Plates were spun down and supernatants were collected and stored at -20°. IL-2 concentrations were determined with a BD OptEIA™ Human IL-2 ELISA kit.

Jurkat transfections and luciferase reporter assays

In order to perform luciferase assays, Jurkat cells were transfected by electroporation in cytomix buffer [61]. Jurkat cells were harvested, counted and redistributed to yield 5×10^6 cells/transfection. Cells were washed once in PBS before being suspended in cytomix buffer supplemented with fresh 2 mM ATP (300 μ l buffer/transfection). While cells were being washed, plasmid DNA was prepared: 1 μ g reporter plasmid (see *Cell culture and plasmids* above) was mixed with differing amounts of plasmid expressing genes of interest or the vector control (10 μ g DNA total). Cells in cytomix buffer were mixed with DNA mixtures and transferred to cuvettes on ice (Biorad Gene Pulser Cuvette, 0.4 cm). A Biorad Gene Pulser Xcell was used to electroporate cells at 300 V, 500 μ F, and infinite

resistance. Immediately following electroporation of all samples, the shocked cells were diluted in pre-warmed culture media (RPMI 10% FBS described above). Cells were cultured in 6-well plates. After resting for 12-24 hours, cells were distributed into 96-well plates and activated with PMA, 25 ng/ml and ionomycin, 1 μ M. Duration of activation ranged from 6-12 hours. At the assay endpoint, 20 μ l/well was removed to measure viability and transfection efficiency on a Gauva EasyCyte mini flow cytometer. Plates were spun and cells were washed once with PBS to remove growth media. Cells were lysed in 45 μ l 1 \times Promega Reporter Lysis Buffer and frozen at -80°. Plates were read on a Veritas Microplate Luminometer according to the manufacturer's instructions. The amount of promoter-driven reporter activity was expressed as a measure of relative light units (RLUs).

Statistical analysis

A two-tailed Student's t-test was used to evaluate statistical difference between experimental treatments and a p-value < 0.05 was set as the cut-off for statistically significant difference.

Acknowledgements

We thank Robert Hales, DO and Dr. William Ince for performing the yeast two-hybrid screen for FOXP3 binding partners. We thank Dr. Derek Holmes and Dr. Stephanie Mackey-Cushman for creating some of the FOXP3 truncation plasmids used in this study. This work was supported by a grant from the National Institutes of Health.
