ABSTRACT In order to examine the question of whether thyroxine-binding globulin (TBG) influences significantly the peripheral metabolism of 3,3',5-triiodo-L-thyronine (T₈) in vivo, paired studies of the effects of a large intravenous load of L-thyroxine (T₄) on the kinetics of 131 I-labeled T3 metabolism were carried out in five normal subjects. After the T₄ load, both the early distributive loss of labeled T₃ from serum and the volume of T₃ distribution, observed after distribution equilibrium had been attained, were greatly increased. These alterations were consistent with those to be expected from displacement of T₃ from its extracellular binding sites. After the T₄ load, however, the fractional rate of T₈ turnover was decreased. This finding is ascribed either to competition between T₃ and T₄ for common intracellular pathways of degradation or excretion or to displacement of T₃ from sites of more rapid to sites of less rapid metabolism. These effects of alterations in the binding activity of TBG on the peripheral metabolism of T₈, together with those previously reported by others, are consistent with the interpretation that T₈ is significantly bound by TBG in vivo. However, it is suggested that the effects of alterations in the T₃-TBG binding interaction on the metabolism of T₃ are obscured by alterations in the extracellular-cellular partitioning of T₄ that would result from concurrent alterations in T4-binding by TBG.

INTRODUCTION

On the basis of in vitro studies, it is clear that 3.3',5-triiodo-L-thyronine (T_3) is strongly bound by serum proteins since normally no more than a fraction of 1% of

This work was presented in part at the Annual Meeting of the American Thyroid Association in Chicago in October, 1966 and in part at the Third International Congress of Endocrinology in Mexico City in July 1968.

Received for publication 20 June 1969 and in revised form 27 October 1969.

the total T₈ in serum exists in the free or unbound state (1). Electrophoretic studies have indicated that thyroxine-binding globulin (TBG) is the serum protein to which T₃, like L-thyroxine (T₄), is predominantly bound (2, 3). Despite this, it has been reported that clinical states associated with alterations in the binding activity of TBG are not accompanied by alterations in the kinetics of peripheral T₃ metabolism in vivo similar to those which occur in the case of T4 under the same conditions (4-7). This has been taken to indicate that T₈ in contrast to T₄ is not bound by TBG to a significant extent in vivo. To investigate this problem further, we have studied the kinetics of peripheral T₃ metabolism in normal subjects before and after a single large intravenous dose of T. It was anticipated that this maneuver would limit the access of T₃ to binding sites shared by both hormones and therefore would permit an assessment of the influence of such binding sites on the peripheral metabolism of T₃.

METHODS

The effects of T₄ loading on the transport and peripheral metabolism of ¹⁸¹I-labeled T₈ were assessed in paired studies conducted in five normal subjects.¹

Assessment of the kinetics of peripheral T₃ metabolism. This was carried out as described in the companion report (8), except that in four of the five subjects additional blood samples were collected at 20 and 50 min after injection of the ¹³¹I-labeled T₃.² 1 wk after the injection of ¹³¹I-labeled T₃ for the control study, a blood sample was collected for measurement of the residual trichloroacetic acid (TCA)-precipitable ¹³¹I. Immediately thereafter, an intravenous load of 4 mg of T₄ in a 1% (w/v) solution of human serum

¹The five normal subjects studied were among the seven presented in the companion report (8). They included two of the authors, one physician attached to the medical unit, and two fully-informed volunteers. The latter two subjects were hospitalized for the studies.

albumin was administered, followed immediately by a second injection of 50 μCi of ¹³¹I-labeled T₃. In the studies performed after the T₄ load, corrections were made for the concentration in serum of TCA-precipitable ¹³¹I remaining from the first injection. The volumes of distribution of T₃ at 20 and 50 min were calculated as the quotient of the amount of injected ¹³¹I and the concentrations in serum of TCA-precipitable ¹³¹I at the corresponding times. This calculation assumed that significant degradation of T₃ had not yet occurred, a supposition that was borne out by measurement of urinary ¹³¹I at these times. The kinetics of peripheral T₃ metabolism after attainment of distribution equilibrium were assessed as described in the companion report (8).

Assessment of the per cent of T_* in serum bound by TBG. 0.5-ml aliquots of serum samples obtained from four of the five subjects 20 min after injection of the ¹²⁸I-labeled T_* were subjected to conventional electrophoresis in filter paper sheets in glycine (0.2 M)-acetate (0.13 M) buffer at pH 8.6. In the remaining subject, serum obtained 8 hr after injection of the ¹²⁸I-labeled T_* was enriched with a very small quantity of labeled T_* before electrophoresis. Serum enriched with ¹²⁸I-labeled T_* (2 μ Ci/ml) was subjected to electrophoresis in another segment of the same filter paper sheet to serve as a radioactive marker. After electrophoresis, the filter paper sheets were cut into 1 cm strips and then were counted. The counts were plotted on graph paper and the ¹²⁸I in the strips corresponding to the TBG peak in the labeled T_* marker was expressed as a per cent of the total ¹²⁹I in the sample.

Assessment of the per cent of free T_s in serum. The general equilibrium dialysis method of Oppenheimer, Squef, Surks, and Hauer was employed (10). Aliquots (100 µl) of serum samples obtained at least 24 hr after each injection of ¹⁸¹I-labeled T_s were diluted with 2.40 ml of Krebs-Ringer

phosphate buffer (KRP) at pH 7.4 and enriched with 20 μ l of a solution which yielded the equivalent of 0.17 μ g of is I-labeled T₃ added per 100 ml of undiluted serum (final dilution of the serum, 1:25.2). 1 ml of the diluted sample was placed in a sac made from dialysis tubing (Union Carbide Corp., New York, size 20) and dialyzed against 5 ml of KRP in a 25 ml Erlenmeyer flask for 20 hr at 37°C. After dialysis, aliquots were taken from inside and outside the dialysis sac. To these were added equal volumes of serum containing carrier iodide and a few milligrams of propylthiouracil. The protein was precipitated with cold 20% TCA. The precipitates were washed twice with cold 5% TCA, dissolved in 2 N sodium hydroxide, and made up to a standard volume for counting. Sufficient counts were obtained to reduce the probable counting error to a maximum of 3%. The amount of TCA-precipitable 181 J per milliliter of dialysate was expressed as a fraction of the amount of TCA-precipitable ¹⁸¹I in the 1 ml of dilute serum within the dialysis sac. To obtain a value for the per cent of free T₃, this fraction was multiplied by 100 and divided by the dilution factor of the serum within the sac (1:25.2). Serum samples obtained from a given subject during the control study and after the T4 load were always analyzed concurrently and in duplicate.

Serum butanol-extractable iodine (BEI) This was measured by the method of Benotti and Pino (11).⁵

RESULTS

The intravenous T₄ load was well tolerated. Three subjects complained of mild lassitude, but no other untoward effects were encountered. The mean value for the serum BEI was 22.4 µg/100 ml (range, 20.0-26.0)

⁸ Absence of significant deiodination of the administered labeled T₈ during this period was confirmed by the concurrent administration of inorganic ¹⁸⁶I according to a modification of the method of Anbar, Guttman, Rodan, and Stein (9)

^{(9).} Obtained from Abbott Laboratories, North Chicago, Ill.

⁶ Performed by the Boston Medical Laboratory, Boston, Mass.

⁶ In the one subject in whom it was measured throughout the study, the urinary excretion of creatine increased from approximately 40 mg/g of creatinine during the control period to 120 mg/g of creatinine during the period from 48 to 72 hr after the T₄ load.

20 min after the T₄ load, $16.0 \mu g/100 \text{ ml}$ (range, 14.8–17.4) at 24 hr, and $13.7 \mu g/100 \text{ ml}$ (range, 12.2–15.0) at 72 hr.

Table I presents the values for the volumes of distribution of 135 I-labeled T_8 at 20 and 50 min after injection and the effects thereon of T_4 loading. The mean control value for the volume of distribution of T_8 at 20 min was 9.0 ± 0.7 liters (mean $\pm s_E$), and at 50 min, 12.0 ± 1.0 liters. T_4 loading was consistently followed by major increases in the volumes of distribution of T_8 at both times; and for the group as a whole, these increases were significant statistically. The fractional rate of disappearance of T_8 from 20 to 50 min, as judged from the ratio of the concentrations of TCA-precipitable 136 I in serum at the two times, did not change after the T_4 load.

The volume of distribution and fractional rate of turnover of T3 after attainment of distribution equilibrium and the effects thereon of T4 loading were calculated from the data-obtained from 24 to 72 hr after administration of the 181 labeled Ts. Verification that distribution equilibrium of the labeled Ts had been attained by 24 hr was obtained by the method described in the companion report (8). In the control study, the values for the pooled 24-hr fractional rates of disappearance were 54 $\pm 2\%$ (mean $\pm sE$) during the period from 24 to 48 hr and 55 $\pm 1\%$ during the period from 24 to 72 hr. After the T₄ load, the corresponding values were both 44 $\pm 1\%$. The excellent agreement of the 24-48 and 24-72 hr values indicated a single exponential rate of disappearance during this time and, therefore, that distribution equilibrium of the residual labeled Ta had been attained. Values for the volume of distribution and fractional rate of turnover of T3 derived from the data

obtained in each subject from 24 to 72 hr after each injection of T₈ are presented in Table II. T₄ loading was consistently followed by a major increase in the volume of T₈ distribution and by a decrease in the fractional rate of T₈ turnover. For the group as a whole, both these changes were significant statistically. The calculated rate of T₈ clearance did not change significantly after the T₄ load. T₄ loading was followed by a slight but consistent increase in the calculated value for the proportion of the injected ¹⁸¹I ultimately appearing in the urine (urinary maximum), suggesting that the proportion of ¹⁸¹I ultimately appearing in the feces (fecal maximum) might have decreased. These changes, however, were not significant statistically.

Values for both the proportion of T_3 bound by TBG and the per cent of free T_3 in serum are depicted in Fig. 1. T_4 loading was consistently followed by a decrease in the proportion of T_3 bound by TBG and by an increase in the per cent of free T_3 in serum; for the group as a whole, both these changes were significant statistically.

DISCUSSION

It has generally been accepted that phenomena related to the binding of thyroid hormones in vitro provide a qualitatively accurate reflection of the thyroid hormone-protein binding interactions that pertain in vivo. Within the framework of the concept that the extracellular binding of hormone limits the access of hormone to the tissues, the many circumstances in which alterations in T₄ binding, as assessed in vitro, are associated with predictable reciprocal alterations in the rate of clearance of T₄ in vivo have tended to support the applicability of in vitro binding phenomena. A large body of data

obtained in vitro suggests that TBG is the major binding protein for T₃ (2, 3). Nevertheless, several recent observations indicate that changes in the binding activity of TBG do not produce alterations in the in vivo metabolism of T₃ similar to those which occur in the case of T₄ (4–7). Consequently, it has been suggested that T₃ is not bound to TBG in vivo to a significant extent. This conclusion challenges the relevance of in vitro binding phenomena to the in vivo situation not only in the case of T₃ but also with respect to T₄.

Two lines of evidence derived from kinetic data have been taken to indicate that T₈ is not bound to a significant extent by TBG in vivo. First, Zaninovich, Farach, Ezrin, and Volpé have reported that alterations in the binding activity of TBG do not influence the rate of disappearance of 131 I-labeled T₃ from serum during the period from 20 to 50 min after its intravenous administration (4). On the other hand, similarly induced alterations in the binding activity of TBG did produce the expected alterations in the rate of disappearance of T₄ during the same period. In order to examine this interesting observation further, we have attempted to disrupt the extracellular T₈-TBG binding interaction by saturating the binding sites on TBG through the administration of a large T. load. In common with the findings cited above, the rate of disappearance of T₃ from serum during the period from 20 to 50 min was unaltered. On the other hand, calculated volumes of distribution were greatly increased by the T₄ load. The interpretation of such findings is exceedingly complex.

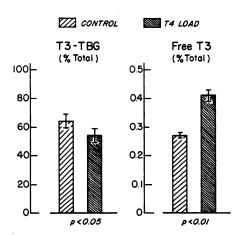

FIGURE 1 The effects of an intravenous load of L-thyroxine (T₄) on the in vitro binding of 3,3',5-triiodo-L-thyronine (T₃) in serum. T₃-TBG refers to the per cent of labeled T₈ bound by T₄-binding globulin (TBG), as assessed by conventional filter paper electrophoresis of serum obtained after an intravenous tracer dose of ¹³¹I-labeled T₃. In vitro enrichment with a very small quantity of ¹³¹I-labeled T₈ was required in only one instance before electrophoresis. The mean ±se of the values obtained in the five subjects are shown.

Before the attainment of distribution equilibrium, the conceptual differentiation between volume of distribution and fractional rate of disappearance is probably spurious. It is apparent that if T4 loading increased the volume of distribution of T_s at 20 min, then it must also have increased the rate of disappearance of T₈ from serum before that time. It is clear that the degradation of T3 during this early period is negligible. Hence, the disappearance of T₈ from serum is totally a reflection of distribution. Whether viewed as an increase in the volume of distribution at 20 min or as an increased rate of disappearance before 20 min, the present data indicate a greater early distributive loss of T₈ from serum after the T. load. This is consistent with the classical binding concept since the T. load would be expected to increase the proportion of free T₈ (as was actually observed in vitro), and it is generally held that the free hormone is more readily accessible to the tissues. Thus, the present data suggest that T₈ is significantly bound in vivo and that such binding can be disrupted by an increase in the concentration of T4; they do not, however, bear upon the question as to whether T₃ is significantly bound by TBG per se. Evidence bearing upon this question is discussed below.

The second line of evidence from which it has been concluded that To is not significantly bound by TBG in vivo derives from studies of the effects of alterations in the binding activity of TBG on the kinetics of peripheral T₃ metabolism after distribution equilibrium has been attained (5-7). Thus, several studies have demonstrated that when the binding activity of TBG is increased the fractional rate of T3 turnover is enhanced and that when the binding activity of TBG is decreased the fractional rate of T₃ turnover is diminished. These alterations are the converse of those observed in the case of T₄ (see review, reference 12). In the present study, T. loading was associated with an increase in the ultimate volume of distribution of T₈, a change again consistent with that to be expected from a disruption of the extracellular binding of T₃. However, the fractional rate of turnover of T3 was decreased after the T4 load. This observation is concordant with the previously observed effects on T₃ turnover produced by primary alterations in the binding activity of TBG cited immediately above. Although these alterations in the fractional rate of T₃ turnover appear superficially inconsistent with the expected effects of a Ts-TBG binding interaction, they do not constitute evidence that T_s is not significantly bound by TBG in vivo. If T3 were indeed not bound by TBG, one would expect that alterations in the binding activity of TBG would have no effect on the metabolism of T₈; such is obviously not the case. Hence, it must be concluded that regardless of whether T₈ is bound by TBG, alterations in the binding activity of TBG lead to some other change which in turn is reflected in the observed alterations in T₈ metabolism.

The most likely possibility is that the changes in T₃ metabolism are owing to a redistribution of T4, probably into the liver. The few data available would suggest that when there is a primary decrease in the binding activity of TBG T4 is shifted to cellular sites, particularly in liver, so that the cellular pool of hormone comprises a greater than normal fraction of the total extrathyroidal pool (13-15). Furthermore, in experiments comparable to those presented here, acute intravenous loads of T. have been shown to produce acute displacement of labeled (and hence stable) T. into extravascular sites, at least partly in the liver (16). Increased localization of T4 within the liver resulting from either primary decreases in TBG or from T4 loading could produce the observed alterations in T₈ metabolism in one of two ways. First, it could inhibit hepatic uptake of T₈, while permitting enhanced uptake at other sites where T₃ degradation might occur more slowly. Alternatively, enhanced hepatic uptake of T₈ owing to decreased extracellular binding may occur, but accumulated T4 may compete with accumulated T₈ for degradative or excretory pathways. Either explanation would be consistent with the slight decrease in the calculated fecal maximum that might have occurred after the T₄ load since this is a reflection of T₃ metabolism by the liver.

In conclusion, if it is granted that the data demonstrate that alterations in the binding activity of TBG do influence the peripheral metabolism of T₃, but that their effects on T₃ metabolism are secondary to some other change consequent to the alteration in the binding activity of TBG, then it is no longer necessary to postulate that T₃ is not significantly bound by TBG in vivo. One need only postulate that the secondary effects on T₃ metabolism preponderate over the primary effects of alterations in the T₃-TBG binding interaction. The latter conclusion would tend to preserve intellectual order and would be in accord with the great likelihood that in vitro binding interactions of T₃ do qualitatively reflect those that occur in vivo.
