Parallel β-Sheet Secondary Structure is Stabilized and Terminated by Inter-Strand Disulfide Crosslinking

Aaron M. Almeida, Rebecca Li, and Samuel H. Gellman*

Abstract

Disulfide bonds between Cys residues in adjacent strands of parallel β -sheet are rare among proteins, which suggests that parallel β -sheet structure is not stabilized by such disulfide crosslinks. We report experimental results that show, surprisingly, that an inter-strand disulfide bond can stabilize parallel β -sheet formed by an autonomously folding peptide in aqueous solution. NMR analysis reveals that parallel β -sheet structure is terminated beyond the disulfide bond, which causes deviation from the extended backbone conformation at one of the Cys residues.

Keywords

Disulfide Bonds; Parallel Beta-sheet; Secondary Structure; Covalent Cross-links; Protein Design

Helices and sheets are dominant structural motifs within proteins, but these secondary structures are generally not very stable in isolation, particularly for linear peptides of ≤ 20 residues. Helical conformations (α , 3_{10} and π) and β -sheets can be stabilized via crosslinking, i.e., macrocycle formation, involving side chains and/or the backbone.^{1,2} This structural fortification strategy is observed among biological proteins and peptides, with cyclization most commonly achieved via disulfide formation between cysteine side chains.³ Other crosslinking modes are found among natural polypeptides as well, and an even wider variety has been explored in synthetic systems.⁴ Polypeptides generated via ribosomal biosynthesis and not modified post-translationally, however, are limited to disulfide crosslinks, which can form spontaneously under mildly oxidizing conditions.

Bioinformatics analysis of antiparallel β -sheets reveals that pairs of disulfide-linked Cys residues often occur at non-hydrogen bonded positions that are aligned on adjacent strands⁵ (Figure 1). This observation and geometric considerations suggest that such inter-strand crosslinks can stabilize antiparallel β -sheet secondary structure, a hypothesis that has been supported by numerous studies with designed β -hairpins that fold in aqueous solution.⁶ In contrast, disulfide crosslinks between adjacent strands are very rare within parallel β -sheets, ^{5f-h,7} which suggests that disulfide-based macrocyclization should destabilize

autonomously folding parallel β -sheets. We report the first test of this hypothesis. Our experiments lead to the surprising discovery that an interstrand disulfide can *stabilize* parallel β -sheet secondary structure to one side along the strand direction; however, the parallel sheet cannot propagate beyond the disulfide position.

Our experimental design builds upon guidelines we have previously developed for creating short peptides that can form two-stranded parallel β -sheets in aqueous solution.⁸ Use of an autonomously folding β -sheet rather than a full-fledged protein is intended to avoid the influence of a specific tertiary context; therefore, our findings should reflect the intrinsic conformational behavior of parallel β -sheet secondary structure. The diamine segment Dprolyl-1,1-dimethyl-1,2-diaminoethane (D-Pro-DADME) promotes but does not enforce β sheet interactions between peptide segments linked in parallel. Peptide 1-SH (Figure 2) is related to a molecule previously used to assess the thermodynamics of parallel β-sheet formation in aqueous solution.^{8c} The two Cys residues, near the N-terminus of each strand, enable oxidative cyclization to generate 1-SS. 2D NMR analysis reveals multiple NOEs between protons on residues that are not adjacent in sequence for both forms of 1, and in each case all NOEs are consistent with the expected parallel β -sheet folding pattern.⁹ NOErestrained molecular dynamics calculations for 1-SS (based only on NOEs and the CNS force field; no coupling-constant or H-bond constraintswere used) suggest canonical parallel β-sheet interactions between the segments bounded by the D-Pro-DADME unit and the Cys residues, i.e., between DFIQV on the upper strand (as drawn) and VLYRR on the lower strand (Figure 3). The β -sheet structure appears to be present throughout the hairpin, up to the location of the disulfide. Only the Cys residue of the lower strand, however, is part of the β -sheet; a kink is observed at the other Cys, which indicates that β -sheet secondary structure is terminated at this point.

Fraying at the open ends of autonomously folding hairpins has previously been noted,^{8a,10} but the NMR data suggest that the deviation from local β -sheet structure we observe at the disulfide position in **1-SS** is not attributable to fraying. Comparisons among the 10 lowest-energy structures from the NOE-restrained dynamics calculations for **1-SS** indicate an overall RMSD of 1.1 ± 0.4 Å. Similar RMSD values are obtained for comparisons focused on just a single Cys residue in either strand (1.0 ± 0.3 and 1.1 ± 0.5 Å, respectively, for the top and bottom Cys residues as drawn in Figure 2). If these Cys residues were frayed relative to the core of the β -sheet, then the Cys RMSD values should be larger than the overall RMSD.

For a residue that participates in β -sheet secondary structure, the α -proton chemical shift ($\delta C_{\alpha}H$) is generally downfield of the position expected for that residue in an unfolded ("random coil") state.¹¹ We have shown that $\delta C_{\alpha}H$ data can be used to assess parallel β -sheet population for molecules such as **1-SH**,^{8c-e} which are anticipated to equilibrate rapidly between folded and unfolded states on the NMR time scale. This analysis requires two reference compounds, one to provide $\delta C_{\alpha}H$ values for the fully unfolded state and another to provide $\delta C_{\alpha}H$ values for the fully folded state. The former goal is achieved by replacing D-Pro in the diamine linker with L-Pro,^{8a} and the latter goal is achieved by backbone cyclization with a diacid linking segment.^{8c,d,9}

We used this approach to estimate the extent of parallel β -sheet folding in **1-SH** and **1-SS** by focusing on four 'indicator residues', Ile and Gln in the upper strand and Tyr and the more N-terminal Arg in the lower strand (Figure 2). These residues provide four independent measurements of parallel β -sheet population, and each is sufficiently isolated from the variable C-terminal portion of its strand to be free of chemical shift influences induced by covalent changes. For **1-SH**, $\delta C_{\alpha}H$ values for all four indicator residues are significantly down-field of the $\delta C_{\alpha}H$ values in the unfolded reference peptide (Figure 4), which is

JAm Chem Soc. Author manuscript; available in PMC 2013 January 11.

consistent with the NOE data in indicating substantial parallel β -sheet formation. However, the indicator $\delta C_{\alpha}H$ values for **1-SH** do not differ significantly from the corresponding values for **1-SS** or the fully folded reference peptide, which makes it impossible to determine whether interstrand disulfide formation enhances parallel β -sheet stability.

We examined a second design that was intended to manifest a lower folding propensity in order to assess the thermodynamic impact of an inter-strand disulfide on parallel β -sheet stability. The sequence of **2-SH/2-SS** (Figure 5) differs at several points from that of **1-SH/ 1-SS**. Two changes are particularly noteworthy: (1) the Cys residues occur at the N-termini of the strands in **2**, rather than adjacent to the N-termini in **1**, and (2) a cross-strand Ile-Tyr pairing that was intended to provide a hydrophobic driving force for folding of **1** has been replaced by a Ser-Tyr pairing, which should be less conducive to parallel β -sheet formation. 2D NMR analysis suggests qualitatively that **2-SH** and **2-SS** display smaller extents of parallel β -sheet folding relative to **1-SH** and **1-SS**, because the number of inter-strand NOEs is smaller for both forms of **2** than for either form of **1**.⁹ Nevertheless, the 2D NMR data for **2-SH** and **2-SS** indicate adoption of the expected parallel β -sheet conformation, in the population of molecules that is folded, because all NOEs involving protons from sequentially non-adjacent protons are consistent with this conformation.⁹

The extent of parallel β -sheet folding for **2-SH** and **2-SS** in aqueous solution was estimated based on $\delta C_{\alpha}H$ data, via comparisons with appropriate fully-folded and fully-unfolded reference peptides.^{8e,9} Following the approach used for series 1, we focused on $\delta C_{\alpha}H$ data from four indicator residues, Ser and Gln in the upper strand and Tyr and the more Nterminal Arg in the lower strand. At each position, $\delta C_{\alpha} H$ values show a steady downfield movement in the order: unfolded reference, 2-SH, 2-SS, folded reference (Figure 6a). This consistent trend qualitatively suggests that neither version of 2 is fully folded, and, more important, that disulfide formation causes an increase in the extent of parallel β-sheet formation. δC_{α} H-based population analysis⁹ provides a reasonably consistent conclusion across the four indicator positions, suggesting that 2-SH is ~20% folded and that 2-SS is ~70% folded in 9:1 H₂O:D₂O, pH 3.8, 100 mM sodium deuterioacetate buffer (buffer pH was not corrected for isotope effects) at 4° C (Figure 6b). These folded state population values can be converted to Gibbs free energy of folding (ΔG_F) based on a two-state conformational model, random coil vs. parallel β-sheet conformation.^{8c-e} Data from the four indicator residues indicate a $\Delta\Delta G_F$ value of -1.1 ± 0.1 kcal/mol, which shows that the interstrand disulfide in 2-SS provides significant stabilization to the parallel β -sheet conformation.

Previous bioinformatics analysis suggested that interstrand disulfide crosslinks are not well accommodated in parallel β -sheet secondary structure,^{5f-h,7} and this conclusion is supported by our experimental findings with autonomously folding peptides, since the backbone kinks at the disulfide. However, our studies reveal an unexpected insight: an interstrand disulfide can stabilize parallel β -sheet secondary structure that forms in the C-terminal direction relative to the Cys residues. Covalent bonding between Cys side chains appears to require that the backbone deviate from the extended conformation, at least in one strand, which prevents the sheet from propagating through the disulfide position in our peptides. Overall these results suggest that interstrand cystine crosslinks can both stabilize and define the extent of parallel β -sheet secondary structure in designed peptides and proteins.
