Abstract

This open-label randomized trial compared isoniazid (9 months) to rifampin (4 months) on toxicity and completion in a jailed population with latent tuberculosis infection. Rifampin resulted in fewer elevated liver function tests (risk ratio [RR] 0.39, 95% confidence interval [CI] [0.18, 0.86]) and less toxicity requiring medication withdrawal (RR 0.51, 95% CI [0.13, 2.01]), although one participant receiving rifampin experienced an allergic reaction. Completion was achieved for 33% receiving rifampin compared to 26% receiving isoniazid ($p = .10$). With careful monitoring rifampin is a safe and less toxic regimen and appears to be a reasonable alternative because of its shorter duration, allowing more people to complete treatment behind bars. Therapy completion in released inmates is unacceptably low and ensuring follow-up after discharge must be part of a decision to treat.

Keywords

tuberculosis; preventive therapy; isoniazid; rifampin; correctional health care

Treatment of latent tuberculosis infection (LTBI) is a critical strategy for TB control in the United States (American Thoracic Society, 2000). Incarcerated persons have risk factors for LTBI and progression to disease (White, Tulskey, Menendez, Goldenson, & Kawamura,

2005), coming from racial/ethnic minority groups (Minton & Sabol, 2009; Sabol & Minton, 2008) and low-income, homeless, and mentally ill populations (American Thoracic Society, 2000; Barnes et al., 1996; Greenberg & Rosenheck, 2008) and having high rates of injection drug use associated with HIV infection (Maruschak, 2004) and limited health care access (Wilper et al., 2009). But treatment has not been successful in jails because inmates often are released before completion, and characteristics associated with incarceration are also associated with low rates of follow-up in the community (White et al., 2002). Success in this strategy has been an elusive goal and remains an important public health issue (Glaser & Greifinger, 1993; White et al., 2005).

Isoniazid (INH) has been the mainstay of treatment for LTBI, but the recommended 9-month regimen has been limited by poor adherence, even among nonincarcerated individuals (Horsburgh et al., 2010; Shieh et al., 2006; Sterling, 2008), and concerns about hepatotoxicity (Fountain, Tolley, Chrisman, & Self, 2005; Nolan, Goldberg, & Buskin, 1999). An alternative, rifampin (RIF) for 4 months (American Thoracic Society, 2000), has shown promising results (Fountain, Tolley, Jacobs, & Self, 2009; Lardizabal, Passannante, Kojakali, Hayden, & Reichman, 2006; Menzies et al., 2004, 2008; Page et al., 2006; Young, Wessolossky, Ellis, Kaminski, & Daly, 2009; Ziakas & Mylonakis, 2009). But to date there have been no studies in a jailed population. We report here the results of a randomized trial to test the toxicity and treatment outcomes of INH compared to RIF in a jailed population.

Method

Design, Setting, and Sample

This open-label, randomized trial compared two medications for LTBI (American Thoracic Society, 2000): INH, which is widely accepted, and RIF, which has less evidence of efficacy and although acceptable, is not currently the preferred treatment (Centers for Disease Control and Prevention, 2006). The sample included inmates in the San Francisco City and County Jail diagnosed with LTBI at jail entry. Excluded were inmates with history of treatment-limiting reaction to INH or rifamycins, pregnancy or breast-feeding, aspartate aminotransferase (AST) or alanine aminotransferase (ALT) > 3 times the upper limit of normal (ULN), bilirubin > 2 times ULN, platelets < 150 K/mm³, or taking protease inhibitors or nonnucleoside reverse transcriptase inhibitors. Also excluded were those not speaking English or Spanish, not in the routine level of jail security, or unable or unwilling to consent, some because of known transfer or imminent deportation. Sample size was determined to be 360 based on the toxicity rates for INH and RIF (Menzies et al., 2004) while accounting for loss from deportation or transfer to prison (White et al., 2002). Figure 1 shows participants consented and enrolled between November 30, 2004, and September 24, 2007, and followed through withdrawal, completion, or loss to follow-up.

Study Treatment Groups

INH (900 mg) was administered twice weekly in a 9-month regimen for a total of 76 doses that could be given over 12 months. Any participant off treatment < 1 month in the first 3 months had the regimen extended by the number of missed doses. If off treatment for 1 month in the first 3 months, the regimen was restarted. RIF (600 mg) was administered once per day in a 4-month regimen for a total of 120 doses that could be given over 6 months. If a participant missed a dose, medication was extended by the doses missed. Up to 2 weeks of missed doses could be added to the regimen; if a participant missed > 2 weeks, medication was restarted.

Treatment began in jail, by directly observed therapy (DOT). After release, field workers at the San Francisco County TB clinic gave medication by DOT using clinic protocols,

including incentives (lunch, restaurant coupon, and bus token) and a case management team throughout the course. If a released participant failed to come to clinic within 1 week, field workers attempted contact by visits to places or person/persons identified at baseline. Reincarcerated participants were continued on treatment, but if lost to follow-up restarted twice, allowing a maximum of three regimen attempts, per jail protocol.

Study Procedures

All participants had symptom reviews every 2 weeks for the first 6 weeks for possible drug toxicity including hepatitis, peripheral neuropathy, arthralgia, rash, memory loss, and other clinical symptoms. Subsequent reviews were 3- and 6-month reviews (INH) and 2-week reviews (RIF), resulting in the same number for each. Liver function tests (LFTs) were drawn at 4, 8, 12, 16, and 32 weeks (INH) and 2, 4, 8, 12, and 16 weeks (RIF).

Measures

Baseline interviews included sociodemographic and health information. Previous treatment and incarcerations came from jail records. Baseline laboratory data included hepatitis BsAg and hepatitis C antibody testing.

Adverse events were recorded from LFTs and symptom reviews. In jail, many participants went to “sick call” for many reasons; all were collected and evaluated by study personnel for their relatedness to the study medication.

Data Analysis

Baseline data were compared to evaluate equivalence of study groups, using chi-square or Fisher’s exact tests for categorical data and *t* tests for continuous data. Analyses of toxicity and adherence were by chi-square with risk ratios (RRs) and 95% confidence intervals (CI).

Toxicity was measured by counting adverse laboratory or clinical events related to study medication and the timing of the first event in relation to doses received. Because participants could begin medication with LFTs up to 3 times ULN (Grade 1), new adverse events were a change from normal to 1.25 to 3.0 times ULN, or a change from up to 3 times ULN to > 3 times ULN (Grade 2 or higher). Although we measured any changes in LFTs, we examined and presented separately those whose LFTs represented clinically significant hepatotoxicity (> 3 times ULN). Adverse events also included new clinical symptoms possibly, probably, or certainly related to the medication. Each occurrence of a new symptom and change in lab result counted independently as one event. Toxicity was also measured as the decision to withhold the medication, defined as LFT > 5.0 times ULN (Grade 3 or higher) or clinical judgment of jail or TB clinic physicians. The last regimen was used for the analysis if participants were restarted.

Adherence was measured by number of doses, from the last regimen, with completion as 76 doses in 12 months (INH) and 120 doses in 6 months (RIF). Therapy length was days between first and last dose in the final regimen. We believed adherence was dependent on participants remaining in jail, and because RIF therapy was shorter, dependent on study medication; remaining in jail virtually guaranteed completion. To evaluate adherence among those released and thus allowed to fail, participants were further divided into remained in jail (Jail), released (Community), and deported or sent to prison (Deported/Transferred). A survival analysis compared adherence by study group, stratified by these subgroups to allow for direct comparisons among released inmates, with time to non-adherence (withdrawal) as the outcome and observations censored after completion.

Analyses were performed using SAS 9.1 (SAS Institute, Cary, North Carolina) with $\alpha = .05$ for determining statistical significance. The protocol was approved by the Institutional Review Board of the University of California, San Francisco, California.

Results

Analysis of those who were consented and interviewed but then released, refused, or had elevated LFTs before randomization showed no differences in any sociodemographic or medical variables compared to those randomized to study group. Baseline characteristics (Table 1) and laboratory values did not differ by study group. Overall, 30 (8%) were positive for hepatitis C and 4 (1%) were positive for chronic hepatitis B.

Toxicity

Among INH participants, 34% experienced ≥ 1 adverse events compared to 27% taking RIF (ns). The proportion experiencing > 1 event was higher among INH participants than RIF participants (12% vs. 7%). A total of 161 adverse events were recorded for the 111 participants experiencing > 1 event.

Twenty-nine (11.4%, 21 INH participants and 4.4%, 8 RIF participants) had ≥ 1 elevated LFTs ($p = .18$) when considering all LFT elevations. None with elevated LFTs was positive for hepatitis B; 2 each from the 21 INH participants and the 8 RIF participants were positive for hepatitis C. Of the 21 INH participants with elevated LFTs, two had two separate events and three had three separate events; none of the 8 RIF participants had > 1 LFT elevation.

Of those with elevated LFTs, 10 participants on INH and 2 on RIF had elevations > 3 times ULN. As this population has high rates of substance abuse, we examined whether testing in jail or the community accounted for differences seen. But it appears that location of testing, and the influence of community access to alcohol, did not account for differences between groups (Table 2).

Clinical symptoms are presented in Table 3. For INH, 2 participants (1%) experienced elevated LFTs combined with gastrointestinal (GI) symptoms, 19 (10%) experienced elevated LFTs without GI symptoms, and 163 (89%) had no elevated LFTs. By contrast, for RIF, 1 participant (0.6%) had elevated LFT with GI symptoms, 7 (4%) had elevated LFTs alone, and 172 (96%) had no elevated LFTs. RIF participants had a lower risk of elevated LFTs (RR 0.39, 95% CI [0.18, 0.86] $p < .05$) as compared to INH participants. Use of RIF also resulted in lower risk of elevated LFTs combined with GI symptoms (RR 0.51), but this was not statistically significant ($p > .6$).

Nine participants experienced 10 adverse events of Grade 3 or higher or clinically were found to need their medication withheld (Table 4). Six (3.3%) INH participants experienced seven such events, while three (1.7%) RIF participants each experienced one event. Of the 7 who experienced elevated LFTs, only one had AST of 92 at study start; the remainder had LFTs within normal limits at baseline. Use of RIF resulted in half the likelihood of toxicity requiring medication withdrawal (RR 0.51, 95% CI [0.13, 2.01]), but true rates of toxicity resulting in permanent medication stoppage are unknown because of loss to follow-up in four of the nine participants. One RIF participant experienced an allergic reaction, characterized by shortness of breath, oxygen saturation of 85, and pruritic diffuse rash that resolved after administration of oxygen, antihistamine, and epinephrine.

Adherence

Overall, 107 of 364 completed therapy, 26% (47 of 184) of INH participants and 33% (60 of 180) of RIF participants ($p = .10$). Survival analysis evaluating time to nonadherence is

shown in Figure 2, stratified by disposition: The top two curves represent those remaining in jail for the duration of therapy (79% completed in INH group, 83% in RIF group); the bottom two curves represent those deported or transferred to another facility, none of whom by definition completed therapy; and the middle two curves represent those released while still taking medication (44% completed in INH group, 51% in RIF group). As expected because of its shorter duration, a higher proportion of RIF participants completed treatment both inside and outside of jail compared to INH participants, although neither was statistically different ($p = .72$ and $p = .49$, respectively). Treatment completion excluding deported/transferred participants produced results in the same direction as results for the total sample, as the proportion deported/transferred was similar for both groups.

Discussion

This is the first study to compare INH and RIF in a jail setting. Jail medical providers are often not linked to community providers, and therapy is complicated by inmate characteristics, recidivism, and fragmented care. The high rate of refusal among this population may be an indication of another difficulty in treating these patients, mistrust of health care in the jail setting (Maruschak, 2006; Wang, Tulsy, & White, 2007; White, Tulsy, Estes, Jamison, & Long, 2008). Although the study is limited by its open label, our purpose was to examine these medications in the usual care of an urban jail. Therefore, the study demonstrates low completion rates not because of the regimens themselves but because of the difficulties in coordinating care for patients who are transferred among institutions and at risk of deportation.

Overall adverse event rates were not statistically different by study drug, but participants taking INH were 2.57 times as likely to experience elevated LFTs (95% CI [1.17, 5.65], $p < .05$). Elevated LFTs combined with GI symptoms occurred slightly more often but still infrequently in the INH group (1%) as compared to the RIF group (0.6%; $p > .6$). INH is mostly well tolerated but up to 5% report side effects, most commonly hepatitis, rash, and GI upset. Hepatotoxicity, the most serious side effect, is associated with fatal and near-fatal liver failure, although transient asymptomatic AST elevations occur in 10% to 20% and represent hepatic adaptation (Centers for Disease Control and Prevention, 1993; Saukkonen et al., 2006). AST elevations in treatment studies have ranged from 0.1% to 0.6% in large reviews to 1% to 4% in smaller studies (Saukkonen et al., 2006).

In one study of RIF for 3 months, none developed hepatitis and none had ALT elevations compared with INH (Hong Kong Chest Service, 1992). Three chart reviews found similar results comparing INH with RIF among nonincarcerated patients. One concluded that RIF was no different from INH in symptomatic adverse events, but INH patients were more likely to experience neuropathy (4.5% vs. 0%) and symptomatic ALT elevations (Young et al., 2009). In another, adverse reactions resulting in permanent medication discontinuation occurred in 4.6% of INH patients compared to 1.9% of RIF patients (Page et al., 2006). And in the third, more reactions were observed for INH (5.8%) than for RIF (3.1%), but findings were not statistically significant (Lardizabal et al., 2006). In a randomized trial, Menzies and colleagues (2008) described adverse events resulting in permanent discontinuation in 14% of INH patients, compared to 3% of RIF patients, and drug-induced hepatitis only among INH patients. Our findings for elevated LFTs combined with GI symptoms were considerably lower, which may be explained by the young age of the sample or the high loss to follow-up. A recent meta-analysis demonstrated a reduced risk of hepatotoxicity leading to drug discontinuation for RIF (range 0% to 0.7%) compared to INH (range 1.4% to 5.2%; Ziakas & Mylonakis, 2009). Our findings for all events leading to drug discontinuation are in the same direction and point to the same conclusion. The notable exception is the allergic

reaction observed in one RIF participant, an event that is rare (Martinez, Collazos, & Mayo, 1999) but of concern.

Therapy completion was better for RIF than INH, but not statistically significant. Of concern is the fact that nearly half the participants started on either INH or RIF were lost to follow-up by transfer to another facility or deportation. We had no way to obtain data for these participants and assumed none in either group continued or completed, but acknowledge that their inclusion may have changed our findings. In studies of free populations, 80% versus 53% (Lardizabal et al., 2006), 91% versus 77% (Young et al., 2009), and 91% versus 76% (Menzies et al., 2008) completed RIF and INH therapy, respectively, more than twice the completion of either drug in our study. Our findings among those who remained in jail (83% for RIF and 79% for INH) were closer to the findings of these other researchers. Horsburgh's analysis demonstrated 45% INH and 69% RIF completion including public clinics with high-risk populations (Horsburgh et al., 2010); these rates are closer to our 44% and 51% rates, respectively, among the released. DOT for high-risk groups, including released inmates, is usual care at the San Francisco TB clinic, and has improved completion compared to self-administered therapy (White, Gournis, Kawamura, Menendez, & Tulsy, 2003). But this may not be common practice elsewhere, and completion rates for either drug would be expected to be lower when self-administration is employed.

Conclusions

With careful monitoring, RIF is a safe and less toxic regimen, requiring fewer clinical visits because of fewer side effects. RIF's shorter duration allows more to complete inside jail and fewer DOT visits after release. RIF has been suggested as a better alternative because of increasing levels of INH resistance among new immigrants (Reichman, Lardizabal, & Hayden, 2004), an important issue for urban jails with a high proportion of foreign-born inmates. Further work should demonstrate rates of progression to active TB, which was high in jail inmates (White et al., 2005); this study lacks efficacy data. It remains premature to recommend RIF until the relative efficacy and effectiveness compared to INH are known, but it is a suitable alternative, in particular when the patient is likely to be in the facility for the duration of therapy.

Completion with either regimen after jail release is unacceptably low, despite dedicated outreach and state-of-the-art case management. We suggest that starting LTBI treatment in a correctional setting should be discouraged unless the confinement term is known and treatment can be achieved, or there are other compelling individual or public health reasons, such as TB exposure during incarceration, severely compromised immune status, or multiple risk factors for disease progression. Ensuring follow-up after release should be part of a decision to treat, and research is crucial to identify discharge planning methods that are effective. Those about to be deported should be given information about how to obtain proper treatment in their home country. The shorter course of RIF combined with close monitoring and the 24-hour availability of care inside the correctional facility can both assure detection of side effects and improve completion rates in this high-risk population.

Notes: INH = isoniazid; RIF = rifampin.

Table 2

Percentage of Elevated LFTs (> 3 times ULN) by Time^a and by Location of Testing in Each Study Group at Follow-Up

Study Group and Test Location	2 Weeks % (N Tested)	4 Weeks % (N Tested)	8 Weeks % (N Tested)	12 Weeks % (N Tested)	16 Weeks % (N Tested)	32 Weeks % (N Tested)
INH in jail	–	1 (107)	1 (82)	3 (73)	4 (50)	9 (22)
INH in community	–	5 (20)	5 (20)	0 (19)	0 (25)	4 (27)
RIF in jail	1 (131)	0 (82)	0 (60)	3 (40)	0 (33)	–
RIF in community	0 (14)	0 (22)	0 (23)	0 (26)	0 (25)	–

Notes. INH = isoniazid; RIF = rifampin; LFT = liver function test; ULN = upper limit of normal.

^aTesting was done for the INH group at 4, 8, 12, 16, and 32 weeks and for the RIF group at 2, 4, 8, 12, and 16 weeks (before medication was completed). Elevations were defined as a change from any baseline to > 3 times ULN.

Table 3

Number of Adverse Events (Clinical Symptoms and LFTs) by Study Group

Adverse Event ^a	INH		RIF		Total	
	N	(% of 184)	N	(% of 180)	N	(% of 364)
LFTs	21	(11)	8	(4)	29	(8)
Gastrointestinal	19	(10)	16	(9)	35	(10)
Rash/pruritis	12	(6)	16	(9)	29	(8)
Central nervous system	20	(7)	6	(3)	26	(7)
Allergic reaction	0	(0)	1	(1)	1	(0)
Other ^b	14	(8)	13	(7)	27	(7)

Notes. INH = isoniazid; RIF = rifampin; LFT = liver function test.

^aCategories are not mutually exclusive; participants could experience symptoms in more than one body system category. Therefore, the number and percentage represent the number of participants and the percentage of the study group or total that had an adverse event in the category.

^bOther category includes symptoms such as appetite loss, muscle/body pain, fatigue, weight loss, malaise, cold symptoms, change of urine color, fever, and eye redness.

Table 4

Line Listing of 9 Participants Experiencing 10 Events Requiring Medication to Be Held or Stopped by Study Group

Study Group	Event Description	Grade ^a	Time Since Start of Regimen	Final Study Status
INH	LFT elevation	3	8 weeks	Participant withdrew soon after elevation
INH	LFT elevation	3	32 weeks	Medication resumed and completed
INH	LFT elevation	3	4 weeks	Medication resumed and completed
INH	LFT elevation	3	16 weeks	Medication resumed but participant transferred to another jail, not completed
INH	LFT elevation	3	8 weeks	Medication resumed but participant transferred to another jail after second elevation, not completed
	LFT elevation	3	16 weeks	
INH	Allergic reaction	3	8 weeks	Medication resumed but participant withdrew from study, not completed
RIF	LFT elevation	4	4 weeks	Medication stopped
RIF	LFT elevation	3	12 weeks	Medication resumed and completed
RIF	Nausea and vomiting	2	3 weeks	Medication stopped

Note. INH = isoniazid; RIF = rifampin; LFT = liver function test; AST = aspartate aminotransferase; ALT = alanine aminotransferase.

^aGrade 3 for LFTs was AST or ALT >5.0–10.0 times ULN.
