ABSTRACT

Purpose

We examined the impact of hypofractionated radiation therapy and androgen suppression therapy (AST) on quality of life (QOL) in high-risk prostate cancer patients.

Methods

Between March 2005 and March 2007, 60 patients with high-risk prostate cancer were enrolled in a prospective phase II study. All patients received 68 Gy (2.72 Gy per fraction) to the prostate gland and 45 Gy (1.8 Gy per fraction) to the pelvic lymph nodes in 25 fractions over 5 weeks. Of the 60 patients, 58 received AST. The University of California–Los Angeles Prostate Cancer Index questionnaire was used to prospectively measure QOL at baseline (month 0) and at 1, 6, 12, 18, 24, 30, and 36 months after radiation treatment. The generalized estimating equation approach was used to compare the QOL scores at 1, 6, 12, 18, 24, 30, and 36 months with those at baseline.

Results

We observed a significant decrease in QOL items related to bowel and sexual function. Several QOL items related to bowel function were significantly adversely affected at both 1 and 6 months, with improvement toward 6 months. Although decreased QOL scores persisted beyond the 6-month mark, they began to re-approach baseline at the 18- to 24-month mark. Most sexual function items were significantly adversely affected at both 1 and 6 months, but the effects were not considered to be a problem by most patients. A complete return to baseline was not observed for either bowel or sexual function. Urinary function items remained largely unaffected, with overall urinary function being the only item

adversely affected at 6 months, but not at 1 month. Urinary function returned to baseline and remained unimpaired from 18 months onwards.

Conclusions

In our study population, who received hypofractionated radiation delivered using dynamic intensitymodulated radiotherapy with inclusion of the pelvic lymph nodes, and 2–3 years of AST prescription, QOL with respect to bowel and sexual function was significantly affected; QOL with respect to urinary function was largely unaffected. Our results are comparable to those in other published studies.

Prostate cancer, quality of life, hypofractionation, IMRT, toxicity, AST

1. INTRODUCTION

Prostate cancer is the leading cancer diagnosis in Canadian men, with 24,600 new cases diagnosed in 2010^{1} . It is also the third leading cancer-related cause of death, with an estimated 4300 cases in 2010^{1} . Although mortality has declined significantly in recent years, arguably because of earlier detection and improved treatment alike, prostate cancer remains the most prevalent cancer in men¹. By implication, then, an increasing number of survivors are living with the effects of cancer and its treatment, highlighting the importance of analyzing quality of life (QOL) for new treatment regimens. Several studies have explored the relevance of treatment choice and QOL to men being treated for prostate cancer ^{2–8}.

Current treatment for high-risk prostate cancer usually consists of external-beam radiation therapy and long-term androgen suppression therapy (AST)^{9,10}. Studies using dose-escalated radiation ^{11–15} for prostate cancer have shown that higher radiation doses improve tumour control.

The linear quadratic model of exponential radiation cell killing has proved to be a robust theory that can be readily applied to clinical data. The linear quadratic cell survival equation includes the coefficients α and β (and their ratio α/β), which, according to the model, are mechanistically related to DNA damage. Recent data suggest that the α/β ratio for prostate cancer is lower than had previously been assumed ^{16–19}. That observation has encouraged the use of hypofractionated radiation schedules for the treatment of prostate cancer²⁰ to increase the biologic effect of delivered radiotherapy, while maintaining toxicity at an acceptable level. Published comparisons of conventional and hypofractionated radiation schedules for the treatment of prostate cancer indicate that recurrence-free survival is equal or improved with hypofractionation $^{21-23}$. Those studies also showed that the QOL of prostate cancer patients is either similar or better with the hypofractionated schedules 24-30.

At our institution, we completed a phase II prospective study for high-risk prostate cancer patients. All patients received a hypofractionated schedule to the prostate gland and a conventionally fractionated schedule to the pelvic lymph nodes using a dynamic intensity-modulated radiotherapy (IMRT) technique with simultaneous integrated boost on a helical TomoTherapy Hi-Art system (Accuray, Sunnyvale, CA, U.S.A.). Most patients received variable-duration neoadjuvant, concomitant, and adjuvant AST. One of the study's endpoints was to assess QOL in those patients, and here, we report QOL outcomes in patients treated using that protocol.

2. METHODS

2.1 Patient Selection

Between March 2005 and March 2007, the study enrolled 60 patients with a histologic diagnosis of prostate cancer involving localized disease with high-risk features [clinical stage T3a or higher, or initial prostate-specific antigen 20 ng/mL or higher, or Gleason score 8–10, or a combination of prostatespecific antigen greater than 15 ng/mL and Gleason score 7]. Staging was based on computed tomography (CT) imaging of the pelvis, a bone scan, and a standard clinical examination, including digital rectal examination.

2.2 Radiation Therapy Planning

The clinical target volumes (CTVS) and organs at risk were delineated on co-registered planning CT and 3-T magnetic resonance imaging images. The prostate gland and the proximal 1 cm of seminal vesicle were contoured to generate a volume designated as CTV68. The planning target volume, PTV68, was grown from the CTV68 by adding a 1-cm margin radially and a 5-mm margin posteriorly. The internal iliac, upper external iliac, and lower common iliac vessels were delineated on each slice up to the lower border of L5 and were encompassed within at least a 5-mm margin (avoiding bone, bladder, muscle, and mesorectum). The external iliac vessel contouring was stopped at the top of the femoral head. The obturator lymph node contouring was stopped at the beginning of the obturator foramen. The upper external iliac vessel delineation also included the lateral presacral nodal area. However, the medial portion of the presacral nodal area was not included in the lymph node delineation ³¹. These lymph node delineations are similar to those of the pelvic lymph nodes shown at the Radiation Therapy Oncology Group Web site ³², except for the exclusion of the medial portion of the presacral area. The pelvic lymph nodes and the distal seminal vesicles (beyond the proximal 1 cm) were included in the CTV45. The volume PTV45 was grown from the CTV45 by adding uniform 1-cm margins all around. Organs at risk, including the rectum from the anal canal to the rectosigmoid junction, the full volume of the bladder, the femora from head to the ischial tuberosities and peritoneal cavity, including all potential areas of small bowel and large bowel, were also drawn using CT images.

A single-phase inverse treatment plan was generated using helical tomotherapy. A dose of 68 Gy in 25 fractions (2.72 Gy per fraction) was prescribed to 95% of the PTV68, and a dose of 45 Gy in 25 fractions (1.8 Gy per fraction) to the PTV45 using a simultaneous integrated boost technique. Dose constraints of 55 Gy or less and 60 Gy or less to 50% and 30% respectively of the volume of rectum, and 60 Gy or less and 65 Gy or less to 50% and 30% respectively of the volume of bladder were used. Maximum dose to the peritoneal cavity was limited to 54 Gy or less. All patients underwent daily megavoltage CT image-guided verification before each treatment.

2.3 Study Design

Patients completed QOL questionnaires before commencing radiation treatment (baseline) and at 1, 6, 12, 18, 24, 30, and 36 months after completion of radiation treatment. The questionnaires were selfadministered by the patients on their own time with no assistance from clinical staff.

2.4 QOL Assessment

The QOL assessments were obtained based on the University of California–Los Angeles Prostate Cancer Index questionnaire ²⁷. The questionnaire consists of 18 items in 3 sections: urinary function (5 items), bowel function (5 items), and sexual function (8 items). Patient completion of the QOL forms was optional at all time points.

2.5 Statistical Analysis

Each of the items on the QOL questionnaire was assigned a nominal score of 1–6, depending on the number of possible responses available for that item. These nominal scores were converted to continuous scores to obtain a composite of all the scores. A poor nominal score was assigned a low continuous score and vice versa. The higher the continuous score, the better the QOL, and vice versa. Table I explains the assignment of the continuous scores to the corresponding nominal scores of the Prostate Cancer Index (smaller numbers represent a poorer QOL and higher numbers represent a better QOL).

Means and standard errors were calculated for all 18 items of the Prostate Cancer Index at baseline and at 1 and 6 months after radiation therapy (Table II). The 1- and 6-month follow-up was based on the scoring system described (Table 1). The QOL scores for each of the 18 items for each follow-up point (1, 6, 12, 18, 24, 30, and 36 months) were compared with the baseline scores using the generalized estimating equation approach ³³. That approach accounts for the within-subject correlations arising because of repeated measurements of the same individual. It provides robust parameter estimates. Standard errors were then obtained (statistical analysis for repeated measurements). All statistical analyses were conducted using SAS (version 9.1.3: SAS Institute, Cary, NC, U.S.A.). Values of p < 0.05 were considered to be statistically significant.

3. RESULTS

The mean age at enrollment was 68 years (range: 55– 88 years), and all 60 patients completed the 36-month follow-up. In the analyses, 3 patients are excluded because, for administrative reasons, they were not approached to complete the QOL questionnaire at baseline. Of the 60 patients, 58 received AST (leuprolide 22.5 mg subcutaneously every 3 months), prescribed for a total duration of 2–3 years. The baseline QOL questionnaire was completed by 50 patients after they started AST (median time on therapy: 48 days) and by 7 patients before they started AST. Completion of

TABLE I Continuous scores assigned to the corresponding nominal scores ¹⁻⁶ of the Prostrate Cancer Index, depending on the number of available responses per question^a

As a problem overall	57±4.8	58±5.1	52±5.1

the sexual function portion of the questionnaire was refused by 9 patients. On surveys completed by other patients, some questions went unanswered, mainly in the sexual function section, for unknown personal reasons. The missing responses were excluded from the statistical analysis for the applicable time points.

Table II shows the means and standard errors for each questionnaire item score at baseline, 1 month, and 6 months. The QOL scores for 1, 6, 12, 18, 24, 30, and 36 months were compared with the baseline score, and the results are summarized in Table III. Significant and highly significant differences are noted. The differences between time points were deemed statistically significant if the *p* value was less than 0.05 and highly significant if the *p* value was less than 0.001.

TABLE III Parameter estimates and standard errors obtained from the quality-of-life (QOL) scores using the generalized estimating equation approach (statistical analysis for repeated

As shown in Figures 1 and 2, statistically significant trends toward a worse QOL were observed for bowel and sexual function. Urinary function remained largely unaffected except for "urinary function as a problem overall" (Figure 3). That item in the questionnaire showed an initial improvement in QOL at 1 month, with a subsequent decline at 6 months, and then a return to baseline leading up to 36 months. Figure 4 shows the percentage of patients choosing each available response on the QOL questionnaire at 1 and 6 months.

Statistically significant differences in the scores were observed at 1, 6, 12, and 18 months for items concerning rectal urgency, loose bowel movements, and distress caused by bowel movements. Distress secondary to bowel movements remained significantly

FIGURE 2 Statistically significant scores obtained in the sexual function portion of the quality-of-life questionnaire at baseline (0 months) and at 1, 6, 12, 18, 24, 30, and 36 months after completion of radiation treatment.

FIGURE 3 Statistically significant scores obtained in the urinary function portion of the quality-of-life questionnaire at baseline (0 months) and at 1, 6, 12, 18, 24, 30, and 36 months after completion of radiation treatment.

affected for the remainder of the follow-up period, as did bowel function as a problem overall.

In terms of sexual function, significant differences were observed for most items and for overall ability to function sexually, but not for the perception of sexual function as a problem overall. The adverse effect on QOL for most items persisted for the remainder of the follow-up period.

4. DISCUSSION

To our knowledge, no published reports describe QOL in high-risk prostate cancer patients when all patients received treatment to the pelvic lymph nodes using IMRT delivery with a hypofractionated schedule and AST (hormonal treatment).

In our study, use of a hypofractionated schedule resulted in a significant decline in early post-treatment QOL, largely in terms of bowel and sexual function. Urinary function was mostly unaffected, although QOL increased in terms of urinary function at 1 month, and subsequently declined at 6 months. That decline recovered by 12 months and remained close to baseline thereafter (Figure 3). The general trend for most bowel and sexual function QOL items (Figures 1 and 2) showed a lower score at 1 month, with bowel function improving somewhat toward baseline during subsequent follow-up, but with sexual function remaining lower in terms of quality and frequency of erections. These lower scores did not affect the patients' perceptions of their ability to function sexually, which remain constant up to the 36-month follow-up.

No significant difference was observed in terms of urine leakage, urinary control, or the number of pads or adult diapers used. The calculated scores reveal

FIGURE 4 The percentage of patients giving the indicated responses for (A) overall urinary function, (B) overall bowel function, and (C) overall sexual function at baseline (0 months) and at 1, 6, 12, 18, 24, 30, and 36 months after completion of radiation treatment.

that dripping urine, wetting pants, or urine leakage interfering with sexual activity did not affect QOL (Figure 3). Overall statistical comparisons of scores at baseline with those at 1 month and 6 months show that more patients experienced decreased urinary function overall at 6 months (Table II). The improvement in QOL at 1 month was not statistically significant, but the decline at 6 months was. That finding likely represents not only the subjective nature of QOL questionnaires, but also the changing attitudes of patients towards their QOL with time. Patients might adjust to their new level of functioning after the 6-month mark and thus might be less likely to rate their overall function as poorly as before. The usual adverse effects of radiation treatment (increased frequency, nocturia, burning sensation, urgency, and slow urinary streams) are not separately listed in the questionnaire, which might be the reason for worsening urinary function overall without individual functions being affected. The urinary function questions were later included in a modified and newly validated expanded Prostate Cancer Index Composite questionnaire. The percentage of respondents who maintained that they had no difficulties with urinary function at baseline (49%) declined to 30% at 1 month, with patients distributing more into the "small problem" category. Still, fewer than 2% reported a "big problem" with urinary function at 6 months [Figure 4(A)]. Our data therefore show some urinary function impairment, but without necessarily affecting the patient's QOL.

A significant decline in QOL was observed in terms of bowel function as it related to rectal urgency, loose bowel movements, distress with bowel movements, and bowel function as an overall problem. Worsening QOL scores were observed at both 1 and 6 months compared with baseline (Table II). The decrease in QOL was less at 6 months than at 1 month. These bowel function QOL items were still potentially below baseline at 6 months (Figure 1). Crampy pain showed a lower score (worse QOL) at 1 month, with some improvement at 6 months (Figure 1). The results at 6 months were, however, not statistically significant (Table II). Although lower QOL scores persisted beyond the 6-month mark, especially for items such as distress caused by bowel movements, other items such as "stools loose or liquid," crampy pain, and overall bowel function begin to approach baseline toward the 18- to 24-month mark. Whether that finding can be attributed to the patient's ability to accommodate to a new level of function or to a true improvement in OOL is difficult to ascertain.

Hanlon *et al.* ³⁴ compared QOL in patients receiving pelvic lymph node treatment with QOL in those receiving prostate-only treatment. The results show a decrease in QOL related to bowel function in patients with treated nodes. Our results, in patients who also received treatments to the pelvic lymph nodes, are similar. We delivered hypofractionated schedules using an IMRT technique; Hanlon and colleagues delivered a conventional schedule using a 3-dimensional conformal radiotherapy technique.

Significantly decreased QOL scores were observed for QOL items dealing with ability, quality, frequency, and occurrence of morning erections, and also with the ability to function sexually. That finding is not surprising in a cohort of patients receiving continuous AST. Many patients (n = 50) had already received AST for a median duration of 48 days before they completed the baseline QOL questionnaire, which may account for low scores at baseline. Of the 57 patients who were analyzed, 49 completed all items on the sexual function section of the questionnaire. That

number declined to 36 by 36 months of follow-up and is reflected in the large standard deviations observed (Figure 2). The problem of obtaining responses to sexual function questions is reflected in a number of studies that analyzed sexual function ^{24,25,28}. That problem is compounded by the fact that the QOL questionnaire was optional.

Overall sexual function declined at 1 month and remained at the same level at 6 months. As an overall problem, sexual function was not significantly affected at either time point; however, the ability to function sexually was significantly decreased at 1 month and remained so at 6 months (Table II) with no improvement toward baseline (Figure 2). There was no significant difference in the patient's perception of lower sexual function being a problem. That observation is reflected in the fact that, although 73% of patients rated their ability to function sexually at baseline as "very poor" or "poor," only 26% perceived that score as a big problem [Figure 4(C)]. At 36 months after treatment, the statistics remained about the same. Scores with respect to quality, frequency, and ability to achieve morning erections remained significantly lower at 36 months. The same trend is reflected in data from Namiki et al. 27 and Junius et al.²⁵. Thus, a large number of our patients did not perceive sexual function to be a problem despite significant impairment as discussed by Katz et al.³⁵.

The sexual function results may reflect the mean age of the patients included in the study (68 years). Men in that age group are both less likely to feel comfortable answering the questions and also more likely to experience sexual dysfunction secondary to age and comorbid medical conditions. According to Smith et al. ³⁶ and Lindau et al. ³⁷, only 37%–41% of men around the age of 70 are sexually active. Patients in our study may have felt confused at having to answer sexual function questions and may have perceived answering such questions as irrelevant to them. Most patients (79%) were not using any assistance (injection, vacuum pump, or phosphodiesterase type 5 inhibitor) to facilitate intercourse at baseline; that situation did not change over the course of treatment. Nearly all the patients in our study (58 of 60) were receiving AST; in a number of other studies, only some of the patients received AST 24,25,27. As previously documented, AST represents an independent risk factor for erectile dysfunction^{2,38}. In view of the use of AST and the hypofractionated radiation therapy schedule, the rates of erectile dysfunction over time will be interesting to observe and compare with those from existing studies ^{39,40}.

Other studies have contemplated comparing IMRT with either conformal radiation therapy or externalbeam radiation therapy ^{24,26,27} (Table IV). The patient characteristics, the use of concurrent AST, and the dose to the prostate may vary, but overall, the studies show an equally decreased QOL after both types of treatment, with improvement in some QOL areas if the patient had undergone IMRT. Lips *et al.*²⁴ showed better QOL in a few domains (urinary symptoms and pain). Kupelian *et al.*²⁶ showed no difference in QOL between IMRT (78 Gy) and external-beam radiation therapy (69.6 Gy). Namiki *et al.*²⁷ showed no difference in urinary function, but worse bowel and sexual function with conventional external-beam radiation therapy. Junius *et al.*²⁵ did not compare methods, but using IMRT (66 Gy to the prostate), they showed increased urinary symptoms at 1 month, with subsequent resolution at 6 months.

Although our questionnaire does not include the psychosocial categories present in other questionnaires, the responses from patients largely reflect the trends seen in other published data on the subject^{24–29}.

One limitation of the present study is the questionnaire, which was chosen at a time before recently validated questionnaires such as the Prostate Cancer Index Composite were available. It therefore fails to cover some of the psychosocial domains and irritable urinary symptoms included in other studies. But we have some concerns about increasingly long comprehensive questionnaires, in that patients might be less likely to complete them unless they are made mandatory. Another limitation is that many patients started AST before baseline QOL was obtained, which may be why sexual function was scored low at baseline.

5. CONCLUSIONS

In our study population, in whom hypofractionated radiation was delivered using dynamic IMRT (helical tomotherapy) with inclusion of the pelvic lymph nodes and with prescription of 2-3 years of AST, QOL was significantly affected in terms of bowel and sexual function. Individual urinary functions were unaffected, but urinary function as a problem overall declined. Bowel function QOL improved toward baseline with time, but sexual function did not improve. Those results are comparable to results from published studies in which hypofractionated schedules were used to treat the prostate only (no pelvic radiation) and in which conventional schedules were used to deliver treatment both to the pelvic lymph nodes and to the prostate. Further studies looking at the long-term effects on QOL of treatment with hypofractionated schedules are needed and are in progress.

6. ACKNOWLEDGMENTS

The authors thank the Alberta Cancer Board for bridge and pilot funding, and Juliette Jordan and Michelle Encarnacao for data collection. All physician and physicist authors participated in study. Nadeem Pervez designed the study with assistance from Robert Pearcey. Sunita Ghosh analyzed the data. All authors helped to interpret the findings. Andrea Oprea and Nadeem Pervez wrote the manuscript, which was modified and approved by all authors.
